PREFACE

MODAL LOGIC

This Handbook documents the current state of modal logic, a lively area of logical research which was born in philosophy, but which has since made its way into mathematics, linguistics, computer science, AI, and even economic game theory. As with other thriving scientific endeavours, it is not easy, and perhaps not even fruitful, to give an official definition of the subject. From the earliest days of modern modal logic, about a century ago now, there were many different interpretations, formalisms, and applications, and new developments have only added to this diversity. On the other hand, modal logic is also a remarkably coherent field in many ways, and its practitioners have no difficulty recognising research — and colleagues! — as being 'modal' in spirit. As editors, we see two broad perspectives that help give rise to this coherence. Writing with very broad strokes of the pen, we might say that the following two conceptions of the field have been particularly influential among modal logicians:

- *Modal logics as formalisations of modalities.* Many natural notions in language and science have a 'modal' character, in that they talk about possibility and necessity in some space of relevant situations. This was true for the original philosophical study of metaphysical modality, but it is equally true of modal logics of time, space, obligation, conditionality, knowledge, computation, and action, which have permeated other fields. Under this view, modal logics model natural reasoning concerning ubiquitous notions, and in doing so, they expand the descriptive scope of 'standard' logic. Technically, then, modal logics are obtained from standard logical systems (like classical propositional or predicate logic, intuitionistic logic, and so on) by adding new, *non-truth-functional operators* (that is, *modalities*). The non-truth-functional nature of the operators, reflecting the larger space of relevant situations, typically leads to systems richer than the underlying logic.

- *Modal logics as fragments of standard logics.* But surprisingly, another viewpoint on modal logic has become equally prominent among its practitioners. Under this view, modal logics inherit their semantics from the standard semantics of classical first or even higher-order predicate logic, but they restrict expressive power by using *operators instead of explicit quantification*. The term "fragment" carries no negative connotation of poverty here: curbing expressive power leads to systems with logical properties rather different from those of standard logic; the decidability of many modal logics is a striking example. The mathematical study of modal logics in this vein has brought to light a delicate balance between the expressive power and computational complexity of logical systems in general. That is, from this perspective modal logic is better viewed as a methodology for tapping into a core theme in standard logic. It is this second, more technical perspective, which provides much of the mathematical coherence of the field today.

The first perspective emphasises the *descriptive range* of modal logic as the study of key concepts and the reasoning patterns they give rise to. The second perspective emphasises the methodological aspect of *fine-structure*: modal languages bring to light the inner structure of classical systems. But these views are not in conflict. As the Handbook makes abundantly clear, most active research directions in modal logic take something from both. Indeed, the most widespread semantics of modal logic in terms of relational models (used in virtually every chapter of the Handbook) provides a setting in which these perspectives coexist fruitfully. Moreover, the two views help us better understand historical contributions made in the field. For example, the modal system **S4** was introduced in the 1920s as an analysis of the concept of necessary implication. But the limited expressive power of the formalism as an account of implicative structure turned out to be the key to **S4**'s wide range of other applications, and its attractive mathematical behaviour. In short, both perspectives on modal logic are widely applicable, and both have proved historically robust. Let's take a closer look at them, and see how they are related.

Modal logic as the study of old and new modalities Modal logic, conceived of as the *formal* study of modalities was invented in philosophy almost a century ago — though the *informal* study of modalities can be traced back much earlier: through the work of the medieval logicians, and back to the ancient Greeks. The first modal operators were introduced in order to solve the paradoxes of material implication and to obtain logics of necessity and possibility; the key figure here is C. I. Lewis, who published his pioneering work in 1918. Putting his idea in modern notation, we take some logical formula φ, and by prefixing it with a $\Box$ or a $\Diamond$ symbol we obtain the expressions $\Box\varphi$ ("the proposition φ is necessary") and $\Diamond\varphi$ ("the proposition φ is possible"). That is, the box and diamond notation enables us to assert fundamentally new modes of truth concerning the information expressed by φ, namely that it is necessary or possible.

In 1933, Kurt Gödel, driven by concerns in the foundations of mathematics, used modal operators to formalise the notion of mathematical provability. In particular, his work enabled intuitionistic logic to be reduced to classical logic extended with a provability operator, and the resulting logic turned out to be Lewis's system **S4**. A striking result indeed, but the general point is this: once again, modalities are being used to express fundamentally new modes of truth concerning a piece of information. In particular, now $\Box\varphi$ means that φ is provable, and $\Diamond\varphi$ means that it is consistent.

These early examples of applying modalities to logical formulas to make assertions concerning a novel mode of truth are only the tip of the iceberg. In the decades following the work of Lewis and Gödel, many modal operators were introduced and investigated, all dealing with truth in some space of possible situations. Tense logic (or temporal logic) arises with the addition of modalities like "eventually" or "earlier". Deontic logic adds modalities "it is permitted, or obligatory, that". In epistemic logic we make use of modalities like "it is known that", either for single agents or for groups. And conditional logics analyse further species of conditional reasoning far beyond Lewis's original account. This way of thinking about modal logic and modalities underlies the work of some of the field's most prominent pioneers, including G. H. von Wright, Arthur Prior, Jaakko Hintikka, Hans Kamp, and David Lewis.

Then the torch passed to other disciplines. In particular, temporal, dynamic and epistemic logics found their way into computer science, AI, and economic game theory. Temporal logics, of both branching and linear time, are now used in industry for automated verification of hardware and software. Epistemic, temporal and conditional operators are the main ingredient of knowledge-based programming. And modal logics of active agents with knowledge, beliefs, and desires form a theoretical backbone of modern accounts of intelligent dis-

tributed computing. Pioneers of modal methods in computer science include Edmund Clarke, Joe Halpern, Zohar Manna, Robin Milner, Rohit Parikh, Amir Pnueli, Vaughan Pratt, and many others — including quite a few of the authors and commentators in this Handbook. But again, diversity reigns, and creation of new modal formalisms for novel reasoning purposes continues unabated.

Summing up: it is entirely reasonable to say that modal logics are formalisms used to represent and reason about the plethora of modal notions that underlie, among other things, distributed computations and intelligent actions, and their corresponding modes of truth. They achieve this by making use of new operators, called modalities, whose truth-conditions involve access to some larger space of relevant situations, such as worlds, times, theories, or computational states. If you view modal logic in this descriptive way, you will be in excellent company.

Modal logic and the fine-structure of classical logics The invention of graph-based relational semantics (by Jaakko Hintikka, Stig Kanger, and Saul Kripke) in the late 1950s and early 1960s showed that standard modal logics could be regarded as fragments of first or second-order predicate logics. The underlying idea is straightforward. Suppose we read $\Box\varphi$ as "necessarily φ" and $\Diamond\varphi$ as "possibly φ". Drawing on an idea that dates back to the work of Leibniz, we could view "necessarily φ" as a claim that φ is true in all possible worlds, and "possibly φ" as a claim that φ is true in some possible world. Thus, modal operators perform quantification without making use of explicit variables and binding.

This idea, when expressed mathematically, has turned out to be the most significant milestone in the history of modal logic. For present purposes, the crucial idea in the above is just this. Because necessity means truth at *all* worlds, $\Box$ becomes linked to the universal quantifier $\forall$, and because possibility means truth at *some* world, $\Diamond$ becomes linked to the existential quantifier $\exists$. That is, necessity and possibility have been analysed in terms of classical quantification. The idea that modal operators are essentially concealed forms of classical quantification is fully general: for example, we can think of "eventually φ" as meaning "there is *some* future time at which φ holds", and we can think of "after performing a certain action, φ" as meaning "at *every* state which is accessible by performing a certain kind of action, φ holds".

But this is not all there is to the analogy. Viewed in this way, modal logics might just be different notation for classical ones! The creative difference is that the quantification in modal languages tends to be bounded in some way to 'relevant' or 'accessible' situations lying beyond the current one. In other words, we are working on structured universes of worlds, computational states, or what have you — and access is *mediated*. Together with the quantifier analogy, this bounded access explains two things. First, a number of properties of modal logics follow at once from those of their classical quantificational counterparts. Second, as the fragments of classical logic that modal operators correspond to typically have *less* expressive power than full first-order predicate logic, this results in many *new* properties. For example, the semantic invariances between models appropriate for modal expressive power are not those of classical logic, but rather turn out to be various forms of *bisimulation*, which preserve local properties of worlds and their transition patterns. Moreover, the study of fragments of classical systems and translations from modal to predicate logic (and sometimes back) has yielded satisfying explanations of why so many modal logics are decidable (unlike classical predicate logic), and why their computational complexity is often relatively low — and in a more activist way, modal analysis has led to the discovery of many new decidable fragments of classical logics. Indeed, the systematic design of modal languages stronger than the formalisms bequeathed to us by the founding fathers has been a major theme in recent research.

First-order languages have been the most traditional companions of modal ones, but the same points apply to modal fragments of higher-order languages, and — a significant development in recent years — to modal fragments of classical languages with fixed-point operators expressing iterative or recursive structures in action, computation, and knowledge representation.

Summing up: it is also entirely reasonable to say that modal logics are fragments of classical logics, which somehow strike an optimal balance between expressive power and computational simplicity. And if you view modal logic in this way (that is, as a laboratory for fine-structure) you will also be in excellent company.

Nowadays, few modal logicians would feel compelled to choose between the two perspectives just outlined. Their respective virtues are clear, and most researchers have assimilated both. Given the current explosion of practical applications and fundamental ideas in the field (amply documented in this Handbook), dogmatism concerning the nature of modal logic is becoming increasingly unsustainable. Let us emphasise this point a bit more.

Contemporary modal logic Modal logic today is a vast family of studies of modal notions, with the original philosophical and mathematical motivations still alive, but with an increasing symbiosis with other fields, and in particular, with computer science. Indeed, its interface with computer science (and more generally, informatics) is extremely broad, ranging from hardware and software verification, to ontologies in medical and bio-informatics, and the analysis of query languages for XML documents. Moreover, it also takes in commonsense reasoning in AI, covering issues ranging from representing and reasoning about space and time to modelling complex interactive multi-agent information systems. Nowadays, modal structures seem to occur everywhere, just as they did in the creative explosion of modality in the philosophical logic of the 1950s and 1960s. This independent (re-)discovery of modal operators in different settings is one of the strongest arguments for the stability and naturalness of the modal stance. Here are three striking illustrations of contemporary rediscoveries.

The first example is *description logic*, a branch of knowledge representation and reasoning in AI; nowadays it supplies many of the formalisms used to fix terminologies in medical and bio-informatics, and has been proposed as the language for annotating web pages to develop a semantic web. Since the late 1970s, the description logic community has articulated its fundamental research goal with great clarity: to obtain fragments of predicate logics which are computationally well-behaved but still have the expressive power required in knowledge representation applications. Intriguingly, around 1990 it became apparent that many of the logics obtained by pursuing this goal were in fact modal logics in a different notational guise. Bounded quantification turns out to be as fundamental for description logics as it is for standard modal logics. In this case, of course, the accessible objects are not worlds or situations but individual objects from some application domain (for example, the biological function of a DNA sequence). But many of the underlying ideas are the same, and this observation has opened the doors to joint work with the modal logic community, with benefits to both fields.

Another area where modal structure is currently surfacing is in the abstract study of *processes* in the emerging field of *coalgebra*. Though modally inspired process theories like dynamic logic, temporal logic, and process algebra have a long history in computer science, coalgebra adds a new twist. Starting from the work by Peter Aczel, Jon Barwise, and others on generalised set theory, coalgebra has now become a theory of finite and infinite processes, with deep connections with universal algebra and other parts of mathematics and theoretical computer science. The crucial feature here is that processes need not be bottom-up inductive, but can instead be top-down co-inductive streams of events. One gets to know a process through observation of events, chewing off the head of the event stream. The surprising discovery has been that such processes

and their observational analysis again shows clear modal patterns, leading to rapidly developing interfaces between coalgebra, modal logic, and universal algebra.

Finally, a third independent rediscovery of modal notions occurred in economic game theory. In the 1970s, Robert Aumann and others introduced formal models of *interactive knowledge* of agents in order to account for the reasoning underpinning the Nash equilibrium solutions that would be found by rational players of a game. Disregarding some differences in notation and style, the resulting formalisms turned out to be epistemic logics from the philosophical tradition, with operators for various forms of collective knowledge of groups. Over the past three decades, logical analysis of games has become another flourishing interface, with studies of beliefs and preferences in modal languages, and the development of dynamic logics of actions that can change modal attitudes as a game proceeds. Moreover, this modal study of games has now largely merged with that of computational processes, as games are naturally viewed as goal-driven multi-agent forms of computation. Traditional game theory was the mathematics of equilibrium, using methods from analysis and dynamical systems. The modal stance that is now emerging provides a natural level of fine-structure to go with this.

Despite this diversity of modal structures, there are also strong unifying tendencies, especially in the *mathematical metatheory* of the field, which got into its stride in the 1970s with work by Wim Blok, Kit Fine, Dov Gabbay, Rob Goldblatt, Larisa Maksimova, Steve Thomason, and others. Model theory of bisimulation and related frame constructions is one important strand here; among other things, it yielded broad definability techniques for matching modal languages with classical ones, and enabled the interpolation properties of modal languages to be charted. A second major strand is algebraic semantics and the duality between modal algebras and relational structures, which built on seminal work by Bjarni Jónsson and Alfred Tarski from the 1950s; since the rediscovery of their work in the 1970s, as universal algebra has grown in sophistication, so have its ties with modal logic. Another unifying force was the development of genuinely 'modal' techniques with wide applicability for proving completeness, axiomatizability and decidability results. And since the 1980s, further unifying mathematical themes have emerged: these include the study of the computational complexity of reasoning and its relation to succinctness; the exploration of the relation between various forms of tree automata, logical games, and the expressivity of modal languages; and the study of logic combinations and related model constructions, which has lead to a theory, still under active development, of various types of products of modal logics.

Another unifying tendency is the undeniable fact that the members of this growing modal family keep influencing each other. The word "applications" has a uni-directional ring to it, but it is a fact of life that every road can be walked both ways. For example, the action-oriented modal perspectives that are so prominent at the computer science interface have now crossed back into philosophy, giving rise to theories of information update and belief revision, which describe how agents come to acquire knowledge or change problematic beliefs. Moreover, setting up such systems also brings in conditional logics from the philosophical tradition; these are now seen as underlying belief revision and non-monotonic reasoning in deep and surprising ways.

This interdisciplinary and interactive setting is the stage where the drama of contemporary modal logic is played out. Modal structures are being studied in a growing number of areas, and often they seem to arise almost like naturally occurring phenomena; no premeditation by the modal logician is required. And at the same time, in response to this dramatic expansion, modal logicians have had to adopt a far wider range of technical ideas and tools than ever before, tools that lie beyond the placid waters of traditional textbook introductions to the field. It was against this exciting and challenging background that this Handbook was conceived.

THE HANDBOOK OF MODAL LOGIC

This Handbook presents a detailed overview of the main lines of research in contemporary modal logic. The editors have tried to present a fair picture of the modern scene, and one that (to the extent possible in a one-volume handbook) reflects the scene in its entirety. Moreover, the selection of authors has been made with a view toward representing the most active and creative research communities worldwide

The tricky question is: what is the best compromise between "detailed" and "overview"? We felt the field would be best served by a single volume handbook; that is, we opted for judicious selection and bounded access. Not that it would have been difficult to design a multi-volume handbook. On the contrary, the most frequent request we had from our authors was for more generous pages limits; the pull towards detail is strongly felt in a field such as modal logic, and quite rightly so. Many of the most treasured results and insights of the field are the results of years of painstaking work. In a sense, every student of the subject has to retrace these intellectual journeys; short cuts aren't possible.

But the evident need for an accessible overview of the whole, leaving deeper access to valleys and caves to a second stage, suggests that the one volume choice was correct. One of the points that emerged most strongly during the Handbook's preparation was just how unified modal logic still is. To be sure, some of its branches are now highly technical, whereas other branches are better thought of as conceptual investigations which use the language of modal logic as an aid to precision. Furthermore, some work emphasises generality and takes mathematical criteria as its primary guide, whereas other areas may be highly specific in their focus and take their cue from applications. But in spite of such differences, the field remains stubbornly coherent, and surprisingly comprehensible. It is not an exaggeration to claim that most researchers in modal logic have at least a nodding acquaintance with the majority of the topics discussed in this Handbook, feel that this sort of extensive knowledge is useful, and would like their students to have a map of the terrain at least as wide. This Handbook is an attempt to provide such a map. To put it another way, it tries to gather together the background assumptions, the working knowledge, the mathematical techniques, and the general world view that add up to that somewhat elusive entity "contemporary modal logic", and to bring it together in a digestible form. We hope it will provide exactly the sort of snapshot of the field that will serve as intellectual nourishment for the next generation of researchers in, and users of, modal logic.

We made no serious effort to impose notational or other kinds of uniformity on the authors. This was partly for pragmatic reasons: it was always evident that the attempt to impose a standard notation would please nobody — and who is to say that linguistic diversity is worse than linguistic, or even cultural, uniformity? But there are deeper reasons for our hands-off stance. Research in contemporary modal logic takes place in a shifting environment that jostles the borders of many fields. One modal logician's interests may lead to the frontiers of linguistics or automated reasoning, another to the foundations of computation and games, and another towards purely mathematical issues concerning topological spaces. Moreover, these interests keep converging, and diverging, in new and often unpredictable ways; we have given some telling examples already. Had this Handbook appeared five years earlier, the borders between various fields would have been drawn somewhat differently, and it is entirely possible that in another five years many will have to be drawn yet again. In the face of such flux, imposing uniformity would be an artificial exercise. Modal logic is a sea, and the point of this Handbook is to help the reader learn to swim in it; pretending it is a swimming pool distorts the truth, and what's worse, is unhelpful.

USING THE HANDBOOK

We suspect that most of our readers will be accustomed to navigating their way through weighty research tomes, and will require little in the way of advice. In particular, readers who already know something about modal logic should simply consult the Table of Contents and start where it looks most interesting; while there are cross-references between the chapters, each is, to a great extent, self contained, so this is a viable strategy. Moreover, the Handbook can be used as a reference to the field. In particular, the index gives detailed entries for most common logics, notions, and results.

But we have also attempted to make the Handbook accessible to less experienced readers. Now, we should say right away that by "less experienced" we mean less experienced in *modal* logic. This is a technical volume, and readers without technical background are going to find it difficult. Thus our less experienced reader is someone who already has some understanding of what modern logic is about, and why and where it is useful, and who wants to find out something about what modern modal logic has to offer.

The Handbook is structured to provide an answer to such readers. The book has 21 chapters, and is divided into four parts: Basic Theory, Advanced Theory, Variations and Extensions, and Applications. Although independent, together they tell a story, the story of contemporary modal logic. This story starts with the basic tools and techniques, takes the reader to the outer reaches of the underlying mathematical theory, surveys the key points where the modal approach is being adapted and extended, and finishes by examining the various applications which modal logic serves and from which it draws inspiration. Let's take a closer look at how all this unfolds over the course of the Handbook.

Part 1. Basic Theory The chapters in Part 1 lay the foundation for later ones. Together they present an overview of the most fundamental themes, techniques and results in contemporary modal logic. The growing impact of computer science is clearly reflected in the choice of topics: two chapters are wholly devoted to complexity, decision methods, and implementation.

Chapter 1. Modal Logic: A Semantic Perspective. Patrick Blackburn and Johan van Benthem.

This chapter discusses the semantic ideas underlying modern modal logic, and in particular, Kripke semantics — or relational semantics, as it now (more informatively and fairly) tends to be called. It introduces the basic model theoretic constructions in a modern way, explores links between modal logic and classical (predicate) logic, both on models and on frames, and examines the extent to which the key semantic ideas transfer to richer modal logics and languages while maintaining a relatively low computational complexity. It also introduces some alternative viewpoints: algebraic semantics, neighbourhood semantics, and topological semantics.

Chapter 2. Modal Proof Theory. Melvin Fitting.

Modal proof theory is the study of syntactic calculi, defined in terms of symbol manipulation, for performing modal logical reasoning. How can such systems be designed? Is there an interesting range of design choices? And how can the syntactic ideas underlying proof calculi be linked with the semantic ideas introduced in Chapter 1? This chapter answers these questions by introducing a wide range of proof styles, and discussing modal completeness theory, the fundamental bridge between proof-theoretical and semantic investigations.

Chapter 3. Complexity of Modal Logic. Maarten Marx.

The basic modal language, when interpreted over relational models, can be regarded as a decidable fragment of classical logic. But this observation immediately leads to a host of further questions. Given that it is decidable, how difficult is it to compute with? That is, what is the computational complexity of determining validity, or of performing more modest tasks like model checking? And what are the parameters that affect modal complexity results, and what happens when we play with their settings? This chapter, an introduction to the computational complexity of modal logic, provides some fundamental answers.

Chapter 4. Computational Modal Logic. Ian Horrocks, Ullrich Hustadt, Ulrike Sattler, and Renate Schmidt.

Although Chapter 2 introduced modal proof theory, and Chapter 3 studied the computational complexity of modal logic, only with this chapter do we reach the heartland of computational modal logic: how to build modal inference systems that are efficient in practice. Although it surveys a number of topics, this chapter concentrates on two fundamental issues: how resolution and tableaux methods can be adapted to modal logic, and how these methods are related.

Part 2. Advanced theory The chapters in Part 2 provide a deep and wide ranging theoretical analysis of modal logic that is broad enough to apply to many application areas. In some cases they provide deeper perspectives on topics already introduced in Part 1, but often they introduce ideas barely hinted at in earlier chapters. Taken together, they present the central core of contemporary insight into the mathematical structure of modal logic.

Chapter 5. Model Theory of Modal Logic. Valentin Goranko and Martin Otto.

At the heart of relational semantics is the idea of interpreting modal languages over relational structures by viewing them as fragments of first-order predicate logic or some stronger formalism. This perspective is not only intuitively attractive, it also makes available to modal logic the results and tools developed in such areas as classical model theory and finite model theory. This chapter shows, in great detail, how such tools can be put to work to gain a deep mathematical understanding of modal model theory, and what makes it *sui generis*.

Chapter 6. Algebras and Coalgebras. Yde Venema.

This chapter develops in detail the algebraic semantics of modal logic and introduces an alternative coalgebraic approach. Algebraic semantics, which has thrived as a research area since the early 1970s, is important because it makes it possible to apply general techniques from universal algebra to the study of modal logic. The approach has given rise to some of the most penetrating analyses of the mathematics of modality. The more recent coalgebraic approach, which also links up with category theory, is valuable because it offers a uniform mathematical setting in which to analyse dynamic systems in terms of modal logic.

Chapter 7. Modal Decision Problems. Frank Wolter and Michael Zakharyaschev.

Modal logic is decidable — or at least it is when interpreted on the class of all models. But change the interpreting class of models, and you change the logical validities, and decidability is typically lost when the structural conditions come too close to ‘danger zones’ such as tiling patterns, arithmetic, or other structures allowing for Turing machine computation. This chapter is a detailed examination of how such properties as decidability, the finite model property, and finite axiomatisability are distributed across the lattice of normal modal logics. The emphasis is on providing general results, and drawing attention to important open questions.

Chapter 8. Modal Consequence Relations. Marcus Kracht.

The notion of consequence, which tells us when a conclusion follows from given premises, is a fundamental logical concept, and in the setting of modal logic it can be defined in a number of different ways. This chapter surveys some of the most important ideas, covering in detail such topics as local versus global consequence, reducing multimodal consequence to monomodal consequence, interpolation theorems, and the admissibility of rules. As with Chapter 7, the emphasis is on providing general results which apply across a wide range of logics.

Part 3. Variations and Extensions The main focus of the chapters in Parts 1 and 2 was on relatively simple propositional modal systems based on (collections of) $\Diamond$ and $\Box$ modalities. Such systems are historically central but they don't exhaust the kinds of logic that now go under the name "modal logic". The chapters in Part 3 introduce some of the extensions and variations of the basic modal technology that the reader is likely to encounter.

Chapter 9. First-order Modal Logic. Torben Braüner and Silvio Ghilardi.

First-order modal logics are modal logics in which the underlying propositional logic has been replaced by a first-order predicate logic. These are one of the oldest forms of modal logic, and arguably the most philosophically important. They also pose some of the most difficult mathematical challenges. This chapter first surveys basic first-order modal logics, and then examines recent attempts to find a general mathematical setting in which to analyse them.

Chapter 10. Higher-order Modal Logic. Reinhard Muskens.

The basic ideas of modal logic have also been extended to higher-order settings, and indeed, extended in a number of different ways. This chapter motivates such extensions, some of them from linguistic semantics in the tradition of Richard Montague, examines some of the more historically influential ones, indicates some of the difficulties that can arise in the transition to higher-order logic, and finally shows how these difficulties can be overcome.

Chapter 11. Temporal Logic. Ian Hodkinson and Mark Reynolds.

Temporal logic is one of the classic branches of modal logic and is currently one of the most active. It has been remarkably fruitful in the issues it has raised (what kinds of temporal structure should we work with?), the results it has given rise to (it is the source of some of the most interesting expressivity results in modal logic), and as an applied tool (contemporary model checking technology is based on temporal logic). This chapter will introduce the reader to the key issues of this important and diverse area.

Chapter 12. Modal μ-Calculi. Julian Bradfield and Colin Stirling.

In the late 1960s, pioneers in reasoning about programs adopted some key ideas of modal logic. They repaid the debt handsomely. Among other things, they developed dynamic logic (used in several chapters of this Handbook), and the modal μ-calculus, one of the most interesting modal formalisms to have emerged in the last two decades. This provides second-order expressive power sufficient to generalise the most common temporal logics, but is still decidable and has the finite model property. It raises many intriguing issues about the interface between modal logic, complexity theory, and automata theory.

Chapter 13. Description Logic. Franz Baader and Carsten Lutz.

Modal logic is sometimes thought of as an intrinsically intensional logic, suitable only for applications such as reasoning about necessity, possibility, and knowledge. But description logics (which developed from pioneering work in the AI community) are undeniably modal logics and, as the description logic community has shown in impressive detail, are extremely well suited for

reasoning about ordinary individuals and the relations between them. This chapter is a detailed introduction to one of modal logic's closest neighbours.

Chapter 14. Hybrid Logics. Carlos Areces and Balder ten Cate.

Standard modal logics use modalities for talking about the relations in relational structures, but don't contain mechanisms for talking about particular worlds. Hybrid logic arises when mechanisms for naming and asserting identity of worlds are added; to give an analogy, they are to standard modal systems what first-order languages with equality are to equality-free languages. This chapter surveys the proof theory, expressivity, and complexity of a number of the better known hybrid logics, thereby giving a snapshot of the logical territory lying between the basic modal languages and their classical companions.

Chapter 15. Combining Modal Logics. Agi Kurucz.

The idea of combining modal logics (for example, a modal logic of time with a modal logic of knowledge) is natural for many applications. But how can modal logics be combined, and what happens when you combine them? This chapter surveys two key combination methods (fusions and products) in detail, shows how various properties do (or do not) transfer from the individual logics to the combination, and briefly examines a number of other combination methods. The properties of combined logics turn out to depend in subtle ways on those of their components plus the particular method of combination.

Part 4. Applications Historically, modal logic has been profoundly influenced by its applications, which have been extremely diverse in nature. The chapters in Part 4 survey the key application domains, thereby showing where modal logic comes from, where it has visited along the way, and also indicating areas to which it is likely to return.

Chapter 16. Modal Logic in Mathematics. Sergei Artemov.

Mathematics is one of modal logic's oldest application areas. In particular, the pioneering work of Gödel in the 1930s showed that modal logic offered an important perspective on the notion of mathematical provability, and (more recently) modal logics of proof have been developed. But modal logic also gives rise to natural logics of space and dynamic systems, and even turns out to be a tool with applications in set theory. This chapter surveys these themes. In doing so, it emphasises an intriguing duality in interpreting the modal box: either as the universal quantifier "in all worlds", or as the existential "there exists a proof". Just when and how such accounts converge is a deep metamathematical issue.

Chapter 17. Automata-Theoretic Techniques for Temporal Reasoning. Moshe Y. Vardi.

Many modal and temporal logics can be viewed as fragments of monadic second-order logic over trees in a suitable signature, so there is a clear theoretical link (via Rabin's celebrated decidability theorem) between modal logic and automata theory. But this link turns out to have practical repercussions for computational applications. In particular, by viewing temporal formulas as giving rise to what are known as "alternating automata", we gain a theoretically transparent but also practical perspective on both validity and model checking, one of the most significant applications of contemporary modal logic.

Chapter 18. Intelligent Agents and Common-Sense Reasoning. John-Jules Meyer and Frank Veltman.

Modal logics have been used in AI in a number of different ways. This chapter discusses two of its more important roles there. The first is as a logic of agents, and here the chapter takes the reader from basic epistemic and deontic logic to multi-agent logics of beliefs, desires, and

intentions. The second is as a model of common sense reasoning, and here the chapter covers modal treatments of counterfactual conditionals and non-monotonic reasoning in a variety of guises, including default reasoning.

Chapter 19. Applications of Modal Logic in Linguistics. Lawrence S. Moss and Hans Jörg Tiede.

Modal logic is best known in linguistics for the light it throws on semantics; indeed Richard Montague's use of higher-order modal logic for this purposes is widely considered to be the starting point of modern natural language semantics. Recently, however, modal logic has also been used to analyse syntactic structure, and interesting links with formal language theory have thereby emerged. This chapter discusses both topics, providing a sophisticated view of modern interfaces between logic and natural language.

Chapter 20. Modal Logic for Games and Information. Wiebe van der Hoek and Marc Pauly.

Game-theoretic ideas have long played an influential rule in analysing various branches of logic, but the focus of this chapter is on using modal logics to describe and reason about games. After introducing the basic ideas of game theory, it systematically investigates how modal logic can be used to do this. Three main topics are discussed: modeling imperfect information and multi-agent information update via dynamic epistemic logics; reasoning about game structure through operations for combining games; and logics of collective action and the power of coalitions of agents over time.

Chapter 21. Modal Logic and Philosophy. Sten Lindström and Krister Segerberg.

Modal logic was born in philosophy, and though it has since travelled widely, it still retains important links with the discipline. This chapter first discusses the historical heartland of philosophical modal logic: namely, the scope and limitations of modal logic as an account of necessity and possibility. It then examines two more recent topics: modal logic and the logic of belief change, and modal logic as a logic of action.

Together, these chapters present a broad picture of modal logic today. Of course, some choices had to be made, and some bias may remain. In particular, the emphasis throughout has been on relational graph-style models. The editors fully acknowledge that there are other important traditions, such as modal logics based on non-classical logics, proof-theoretic semantics, as well as the more general neighbourhood semantics. Some of these have a historical pedigree reaching back to the 1930s, and they are still very much alive. These approaches do occur at various places in the book, but we have not made them fundamental to the Handbook's architecture. We think this is a fair reflection of the bulk of current research, but times may change.

Some readers may also think that this Handbook has a bias toward propositional model systems, leaving predicate-logical versions underrepresented. This may be true to some extent — however, the chapters on modal predicate logic, modal logic in philosophy, and also temporal logic give a clear account not only of the basic theory of modal predicate logic, but also of recent developments of its mathematics and its relevance to computer science. But there is also a more defiant stance. Predicate logic itself can be profitably viewed as a modal logic of variable assignment and assignment change. And in that light, modal predicate logic is not some privileged enrichment of modal logic. It is really about combining a propositional modal logic of worlds and one of variable assignment. And the reader can learn a lot about both, and about combination methods, from the pages of this Handbook!

Once these chapters are seen together, many questions may at once be formulated concerning further relationships between them. The editors considered adding some remarks on this topic,

as diversity tempered by the resulting need for system comparison are a major driving force for innovation in the field. But in the end, we have decided to let the chapters, and their juxtaposition, speak for themselves.

Finally, we would like to remark that modal logic is as much a community of living people as a family of systems. The results and insights in this Handbook exist only because of a long line of distinguished researchers who have shaped modal logic and its interfaces with computer science and other fields. The Hall of Fame of our field certainly extends beyond the grand old names of the classical period; just read this Handbook, and you will come to know the grand new names by their fruits.

COMMENTATORS

Following an idea of Dov Gabbay's used in many publications, we made use of the designated commentator system in this Handbook. That is, in addition to editorial feedback, we attempted to find, for each chapter, a reader who could provide the kind of feedback that would inspire the authors during the writing process. In some cases we chose commentators with special expertise in the topic of the chapter. In other cases, we felt that the comments offered by someone working in a somewhat different area might be more appropriate and helpful. Moreover, whenever possible, we chose authors of other chapters as commentators, as we felt this would improve the Handbook's coherence.

We are extremely grateful to everyone who agreed to undertake this task; in many cases the input of a commentator acted as precisely the catalyst needed to help the full potential of a chapter to emerge. Our commentators were (Chapter 19 had no commentator):

Chapter 1: Aleksander Chagrov.	*Chapter 2: Heinrich Wansing.*
Chapter 3: Martin Otto.	*Chapter 4: Carlos Areces.*
Chapter 5: Maarten de Rijke.	*Chapter 6: Aleksander Kurz.*
Chapter 7: Rosalie Iemhoff.	*Chapter 8: Ian Hodkinson.*
Chapter 9: Melvin Fitting.	*Chapter 10: Grigori Mints.*
Chapter 11: Valentin Goranko.	*Chapter 12: Yde Venema.*
Chapter 13: Silvio Ghilardi.	*Chapter 14: Ulrike Sattler.*
Chapter 15: Carsten Lutz.	*Chapter 16: Rineke Verbrugge.*
Chapter 17: Julian Bradfield.	*Chapter 18: Reinhard Muskens.*
Chapter 20: Giacomo Bonanno.	*Chapter 21: Vincent Hendricks.*

FURTHER INFORMATION

We have set up a home page for the Handbook at:

`http://www.csc.liv.ac.uk/~frank/MLHandbook`

We will make available there any corrections that may need to be made, and news concerning future Handbook-related developments. We welcome feedback from our readers.

It would not be useful to attempt to list all the workshops, conferences, and journals where work on modal logic is published; given what we have said about its wide range of applications and techniques, it will come as no surprise that such work may be made public in a wide variety of forums. However it is worthwhile taking this opportunity to mention two workshops specifically

devoted to modal logic. The first is *Advances in Modal Logic* (AiML), modal logic's main event, which is held every two years. You can find out more about this event, and the associated book series at:

`http://www.aiml.net`

Here we'll simply say that AiML attempts to bring together scholars working in all areas of modal logic and its applications. The second workshop is *Methods for Modalities* (M4M), see

`http://m4m.loria.fr`

M4M is also held every two years. It is more practically oriented than AiML, focusing on the development of computational tools and results for modal logic.

ACKNOWLEDGEMENTS

Editing a handbook is a lengthy task, and sometimes, very modally, it seems as if all the things that could go wrong take the opportunity to actually do so. Fortunately, we had the benefit of a great deal of support, which generally enabled us to dissolve problems before they became too pressing. Indeed, in retrospect, it's clear we had a relatively easy time of it, and we would like to thank all the people who made this possible.

First, and foremost, we would like to thank the authors of the Handbook's chapters. They showed enormous enthusiasm for the project, many of them going out of their way to attend a meeting to set the Handbook in motion (in March 2004, Amsterdam; the meeting was kindly sponsored by NWO, KNAW and other Dutch scientific organisations). We received a great deal of valuable feedback from them, and they showed good-humoured patience when faced by style file changes, demands for quick attention to page proofs, and requests for additions or alterations to their chapters. It is a privilege to work with such a lively and cooperative community. The resulting Handbook is a testimony to their efforts. Our deepest thanks to them all.

We were also extremely lucky with the support we received on the production side. First, our thanks to Arjen Sevenster, of Elsevier, for his enthusiastic support in making this Handbook happen right from the start, including judicious alternations of leaving us be and prodding, and to Andy Deelen, our contact at Elsevier, for her prompt responses to our questions. We are also extremely grateful to Carlos Areces, Christian Günsel, Eric Kow, Oliver Kutz and Dirk Walther for the technical help they gave us with the website, the style files, and the indexing. Special thanks are due to Balder ten Cate for organising the meeting in Amsterdam, and to Guido Governatori, who wrote the LaTeX style file used to produce the final version of the Handbook, and who responded quickly and generously to our urgent requests.

And, finally, we come to Jane Spurr. Without her, it is hard to imagine how we could have put the Handbook together. It was Jane who grafted the 21 chapters into one big LaTeX file overcoming many evil obstacles, who dealt with final corrections, and who found ways of making our numerous formatting requests work. Thanks to her unflagging good humour and patience, the final production stage became a positive pleasure.

1 INTRODUCTION

This chapter introduces modal logic from a semantic perspective. That is, it presents modal logic as a tool for talking about *structures* or *models*. But what kind of structures can modal logic talk about?

There is no single answer. For example, modal logic can be given an *algebraic semantics*, and under this interpretation modal logic is a tool for talking about what are known as boolean algebras with operators. And modal logic can be given a *topological semantics*, so it can also be viewed as a tool for talking about topologies. But although we briefly discuss algebraic and topological semantics, for the most part this chapter focuses on modal logic as a tool for talking about *graphs*. To put it another way, this chapter is devoted to what is known as the *relational* or *Kripke* semantics for modal logic. This is the best known and (with the possible exception of algebraic semantics) the best explored style of modal semantics. It is also, arguably, the most intuitive. Over the years modal logic has been applied in many different ways. It has been used as a tool for reasoning about time, beliefs, computational systems, necessity and possibility, and much else besides. These applications, though diverse, have something important in common: the key ideas they employ (flows of time, relations between epistemic alternatives, transitions between computational states, networks of possible worlds) can all be represented as simple graph-like structures. And as we shall see, modal logic is an interesting tool for talking about such structures: it provides an internal perspective on the information they contain.

But modal logic is not the only tool for talking about graphs, and this brings us to one of the major themes of the chapter: the relationship between modal logic and other forms of logic. As we shall see, under the graph-based perspective discussed here, modal logic is closely linked to both first- and second-order classical logic. This immediately raises interesting questions. How does modal logic compare with these logics as a tool for talking about graphs? Can modal expressivity over graphs be characterised in terms of classical logic? We shall ask (and answer) such questions in the course of the chapter.

Games (in various guises) are another recurring motif. The simple way that modal formulas are interpreted on graphs naturally gives rise to games and game-like concepts. The most important of these is the notion of *bisimulation*. This is a relation between two models, weaker than isomorphism, which can be thought of as giving rise to a transition-matching game between two players. As we shall see, this concept holds the key to modal model theory and characterises the link with first-order logic.

This chapter has two pedagogical goals. The first is to provide a bread-and-butter introduction to relational semantics for modal logic that can be used as a basis for tackling the more advanced chapters in this handbook. Thus the reader will find here definitions and discussions of all the basic tools needed in modal model theory (such as the standard translation, generated submodels, bounded morphisms, and so on). Basic results about these concepts are stated and some simple proofs are given. But we have a second, more ambitious, goal: to help the reader start thinking semantically. We want to give the reader a sense of how modal logicians view structure, and what they look for when exploring new logics. To this end we have tried to isolate the intuitions that guide working modal logicians, and to present them vividly. We also make numerous asides, some of which touch on advanced logical topics. Their purpose is to situate the key ideas in a wider context, and even beginners should try to follow them.

Here is our plan. In Section 2, we introduce basic modal languages and the graphs over which they are interpreted. We give the satisfaction definition (which tells us how to interpret modal formulas in graphs) and the standard translation (which links modal logic with classical logic).

With these preliminaries out of the way, we are ready to go deeper. What can (and cannot) modal languages say about graphs? In Section 3 we introduce the notion of bisimulation and use it to develop some answers; among other things, we characterise modal logic as a fragment of first-order logic. In Section 4 we examine the computability and computational complexity of modal logic. A shift of topic? Not at all. In essence, this section examines modal logic as a tool for talking about *finite* graphs. In Section 5 we move to the level of frames and re-examine the link between modal and classical logic. As we shall see, at this level the fundamental correspondence is between modal logic and (monadic) second-order logic. In Section 6 we move beyond the basic modal language and discuss a number of richer languages that offer more expressivity. But what makes them all modal? As we shall see, many of the themes explored in earlier sections re-emerge, and point towards an idea that seems to lie at the heart of modal logic: guarding. Moreover, in some cases it is possible to prove Lindström-style characterisation results. In Section 7 we discuss three alternatives to relational semantics, namely algebraic, neighbourhood, and topological semantics. We conclude in Section 8.

Two final remarks. First, although we introduce modal logic from scratch, we assume that the reader has at least a basic understanding of classical first-order logic (especially its model-theoretic semantics) and some grasp of the notion of computability. Any standard introduction to mathematical logic (Enderton [37] is a good choice) supplies more than enough material to follow the main line of the chapter. Second, we *don't* discuss modal proof-theory or related notions such as completeness in any detail (these topics are the focus of Chapter 2 of this handbook). Although we haven't banished all mention of normal modal logics and completeness from the chapter, in our view traditional introductions to modal logic tend to overemphasise these topics. We want this chapter to act as a counterbalance. As we hope to convince the reader, simply asking the question "But what can I *say* with these languages?" swiftly leads to interesting territory.

2 BASIC MODAL LOGIC

In this section we introduce the basic modal language and its relational semantics. We define basic modal syntax, introduce models and frames, and give the satisfaction definition. We then draw the reader's attention to the internal perspective that modal languages offer on relational structure, and explain why models and frames should be thought of as graphs. Following this we give the standard translation. This enables us to convert any basic modal formula into a first-order formula with one free variable. The standard translation is a bridge between the modal and classical worlds, a bridge that underlies much of the work of this chapter.

2.1 First steps in relational semantics

Suppose we have a set of proposition symbols (whose elements we typically write as p, q, r and so on) and a set of modality symbols (whose elements we typically write as m, m', m'', and so on). The choice of PROP and MOD is called the *signature* (or *similarity type*) of the language; in what follows we'll tacitly assume that PROP is denumerably infinite, and we'll often work with signatures in which MOD contains only a single element. Given a signature, we define the *basic modal language* (over the signature) as follows:

$$\varphi \quad ::= \quad p \mid \top \mid \bot \mid \neg\varphi \mid \varphi \wedge \psi \mid \varphi \vee \psi \mid \varphi \rightarrow \psi \mid \varphi \leftrightarrow \psi \mid \langle m \rangle \varphi \mid [m]\varphi.$$

That is, a basic modal formula is either a proposition symbol, a boolean constant, a boolean combination of basic modal formulas, or (most interesting of all) a formula prefixed by a diamond

or a box. There is redundancy in the way we have defined basic modal languages: we don't need all these boolean connectives as primitives, and it will follow from the satisfaction definition given below that, for all $m \in \text{MOD}$, $[m]\varphi$ is equivalent to $\neg\langle m\rangle\neg\varphi$ and $\langle m\rangle\varphi$ is equivalent to $\neg[m]\neg\varphi$ (so boxes and diamonds are what are known as *dual connectives*, just as $\exists$ and $\forall$ are in first-order logic). But we won't bother picking out a preferred set of primitives, as this is not relevant to our discussion. If there is only one modality in our language (that is, if MOD has only one element) we simply write $\Diamond$ and $\Box$ for its diamond and box forms. We often tacitly assume that some signature has been fixed, and say things like "the basic modal language", or "the basic modal language with one diamond". We won't need many syntactic concepts in this chapter, but the following ones will be useful. First, the *subformulas* of a basic modal formula φ are φ itself together with all the formulas used to build φ. Second, we say that a subformula ψ of φ occurs *positively* if it is under the scope of an even number of negations, otherwise we say it occurs *negatively* (when this definition is applied, subformulas of the form $\psi \to \theta$ should be read as $\neg\psi \vee \theta$, and subformulas of the form $\bot$ should be read as $\neg\top$). Finally, the *modal operator depth* of a basic modal formula φ is the maximum level of nesting of modalities in φ, and we write *md*(φ) to denote this number.

A *model* (or *Kripke model*) $\mathfrak{M}$ for the basic modal language (over some fixed signature) is a triple $\mathfrak{M} = (W, \{R^m\}_{m\in\text{MOD}}, V)$. Here W, the *domain*, is a non-empty set, whose elements we usually call *points*, but which, for reasons which will soon be clear, are sometimes called *states*, *times*, *situations*, *worlds* and other things besides. Each R^m in a model is a binary relation on W, and V is a function (the valuation) that assigns to each proposition symbol p in PROP a subset $V(p)$ of W; think of $V(p)$ as the set of points in $\mathfrak{M}$ where p is true. The first two components $(W, \{R^m\}_{m\in\text{MOD}})$ of $\mathfrak{M}$ are called the *frame* underlying the model. If there is only one relation in the model, we typically write (W, R) for its frame, and (W, R, V) for the model itself. We encourage the reader to think of Kripke models as graphs (or to be slightly more precise, *directed graphs*, that is, graphs whose points are linked by directed arrows) and will shortly give some examples which show why this is helpful.

Suppose w is a point in a model $\mathfrak{M} = (W, \{R^m\}_{m\in\text{MOD}}, V)$. Then we inductively define the notion of a formula φ being *satisfied* (or *true*) in $\mathfrak{M}$ at point w as follows (we omit some of the clauses for the booleans):

$$
\begin{array}{rll}
\mathfrak{M}, w \models p & \text{iff} & w \in V(p), \\
\mathfrak{M}, w \models \top & & \text{always}, \\
\mathfrak{M}, w \models \bot & & \text{never}, \\
\mathfrak{M}, w \models \neg\varphi & \text{iff} & \text{not } \mathfrak{M}, w \models \varphi \text{ (notation: } \mathfrak{M}, w \not\models \varphi), \\
\mathfrak{M}, w \models \varphi \wedge \psi & \text{iff} & \mathfrak{M}, w \models \varphi \text{ and } \mathfrak{M}, w \models \psi, \\
\mathfrak{M}, w \models \varphi \to \psi & \text{iff} & \mathfrak{M}, w \not\models \varphi \text{ or } \mathfrak{M}, w \models \psi, \\
\mathfrak{M}, w \models \langle m\rangle\varphi & \text{iff} & \text{for some } v \in W \text{ such that } R^m wv \text{ we have } \mathfrak{M}, v \models \varphi, \\
\mathfrak{M}, w \models [m]\varphi & \text{iff} & \text{for all } v \in W \text{ such that } R^m wv \text{ we have } \mathfrak{M}, v \models \varphi.
\end{array}
$$

A formula φ is *globally satisfied* (*globally true*) in a model $\mathfrak{M}$ if it is satisfied at all points in $\mathfrak{M}$, and if this is the case we write $\mathfrak{M} \models \varphi$. A formula φ is *valid* if it is globally satisfied in all models, and if this is the case we write $\models \varphi$. A formula φ is *satisfiable in a model* $\mathfrak{M}$ if there is some point in $\mathfrak{M}$ at which φ is satisfied, and φ is *satisfiable* if there is some point in some model at which it is satisfied. These definitions are lifted to sets of formulas in the obvious way. For

example, a set of basic modal formulas Σ is satisfiable if there is some point in some model at which all the formulas it contains are satisfied. A formula φ is a *semantic consequence* of a set of formulas Σ if for all models $\mathfrak{M}$ and all points w in $\mathfrak{M}$, if $\mathfrak{M}, w \models \Sigma$ then $\mathfrak{M}, w \models \varphi$, and in such a case we write $\Sigma \models \varphi$. Instead of writing $\{\varphi\} \models \psi$ we write $\varphi \models \psi$.

We now have all the concepts needed to begin exploring modal logic. But instead of moving on, let us reflect upon the ideas just introduced. First, note the *internal* character of the modal satisfaction definition: *modal formulas talk about Kripke models from the inside*. In first-order classical logic, when we talk about a model, we do so from the outside. A *sentence* of first-order logic does not depend on the contextual information contained in assignments of values to variables: sentences take a bird's-eye-view of structure, and, irrespective of the variable assignment we use, are simply true or false of a given model. Modal logic works differently: we evaluate formulas *inside* models *at some particular point*. A modal formula is like an automaton placed inside a structure at some point w, and forced to explore by making transitions to accessible points. This may seem a fanciful way of thinking about the satisfaction definition, but it turns out to be crucial. When we isolate the mathematical content of this intuition, we are led, fairly directly, to the notion of *bisimulation*, the key to modal model theory, which we will introduce in Section 3.

Second, note that basic modal languages are syntactically extremely simple: we are working with languages of propositional logic augmented with additional unary operators. And yet these languages clearly pack quantificational punch. Diamonds and boxes can be thought of as macros that encode quantification over R^m-accessible states in a perspicuous variable-free notation. We will shortly define the *standard translation*, which makes this macro analogy precise.

Third, note that Kripke models can (and in our opinion should) be thought of as (directed) graphs. As we have already mentioned, modal logic has been applied in many different areas. What these areas have in common is that they deal with applications in which the important ideas can be represented by relatively simple graph-like structures. Let's consider some examples,

A classic interpretation of Kripke models of the form (W, R, V) is to regard the elements of W as times, and the relation R as the relation of temporal precedence (that is, Rww' means that time w is earlier than time w'). Consider the (directed) graph in Figure 1. This shows a

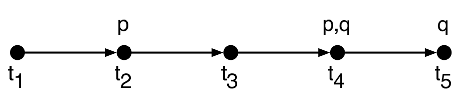

Figure 1. A simple temporal model.

simple flow of time consisting of five points. Here we will take the precedence relation to be the transitive closure of the next-time relation indicated by the arrows (after all, we think of the flow of time as transitive) thus every point t_i precedes all points to its right. Note that (as we would expect from the internal perspective provided by modal languages) whether or not a formula is satisfied depends on where (or in this example, *when*) it is evaluated. For example, the formula $\Diamond(p \wedge q)$ is satisfied at points t_1, t_2 and t_3 (because all these points are to the left of t_4 where both p and q are true together) but not at t_4 and t_5. On the other hand, because q is true at t_5, we have that $\Diamond q$ is true at t_1, t_2, t_3 and t_4. One special case is worth remarking on: note that for any basic formula φ whatsoever, $\Box\varphi$ is satisfied at t_5. Why? Because the clause in the satisfaction definition for boxes says that $\Box\varphi$ is satisfied if and only if φ is satisfied at *all* R-accessible points. As no points are R-accessible from t_5 (it has no points to its right) this condition is trivially met.

The idea of using modal logic as a tool for temporal reasoning is due to Arthur Prior [104, 105]. His work offers what is probably the clearest example of modal logic being appreciated for its internal perspective. In languages such as English and Dutch, the default way of locating information temporally is to use tenses, and tenses locate information *relative* to the point of speech. For example, if at some time t I say "Clarence will fly", then this will be true if at some future time t' Clarence does in fact fly. Prior viewed tensed talk as fundamental: we exist in time, and have to deal with temporal information from the inside. He believed that the internal perspective offered by modal languages made it an ideal tool for capturing the situated nature of our experience and the context-dependent way we talk about it. Prior called his system *tense logic*. He wrote F for the forward looking (or future) diamond, and had a second diamond, written P, for looking back into the past (so in Figure 1, $P(p \wedge q)$ is true at t_5, for this point is to the right of t_4, where p and q are true together). Prior needed backward looking operators to mimic the effect of natural language past tense constructions; for further discussion of Prior's work in this area, see Chapter 19 of this handbook.

Our next example brings us to one of the most influential ways of thinking about Kripke models: to give them a *process interpretation*, which means that we view models as collections of computational states, and the binary relations as computational actions that transform one state into another. This interpretation dates back to the classic work of Hoare [67] and Dijkstra [32]. Let's look at a simple example. Consider the graph shown in Figure 2. This shows a finite state

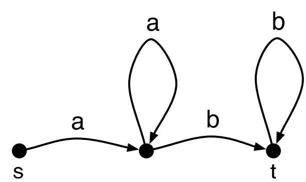

Figure 2. Finite state automaton for $a^n b^m (n, m > 0)$.

automaton for the formal language $a^n b^m$ $(n, m > 0)$, that is, for the set of all strings consisting of a non-empty block of as followed by a non-empty block of bs. But this is precisely the type of graph we can use to interpret a modal language. In this case it would be natural to work with a language with two diamonds $\langle a \rangle$ and $\langle b \rangle$. The $\langle a \rangle$ diamond will be used to explore the a-transitions in the automaton, while the $\langle b \rangle$ diamond explores the b-transitions. It follows that all formulas of the form

$$\langle a \rangle \cdots \langle a \rangle \langle b \rangle \cdots \langle b \rangle t$$

(that is, an unbroken block of $\langle a \rangle$ diamonds preceding an unbroken block of $\langle b \rangle$ diamonds in front of a proposition symbol t which is only true at the terminal node t) are satisfied at the start node s, for all modality sequences of this form correspond to the strings accepted by the automaton. Although simple, this example shows the key feature of many computational interpretations of modal logic: the relations are thought of as processes (here our processes are "read the symbol a" and "read the symbol b"). Note that in this case we are thinking in terms of deterministic processes (each relation is a partial function) but we could just as well work with arbitrary relations, which amounts to working with a non-deterministic model of processes. The process interpretation, in various forms, underlies much of the discussion of this chapter, and it underlies Chapters 12 and 17 of this handbook.

Another important application of modal languages is to model the logic of knowledge and

belief; this line of work was pioneered by Jaakko Hintikka [66], and as the more recent treatise by Fagin, Halpern, Moses, and Vardi [39] makes clear, the study of *epistemic logic* continues to flourish. Again, simple graph-based intuitions underly this application. Consider, for example, the graph shown in Figure 3. Here we see the epistemic state of a very simple agent. One

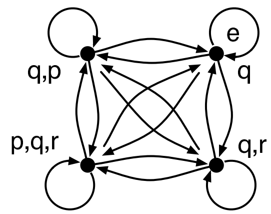

Figure 3. Epistemic state of a simple agent.

of the epistemic situations making up this state is marked e; this represents the agent's current knowledge (the agent knows that q is the case). The other situations represent the way the world might be. For example, although neither p nor r are true in the current situation, the agent views situations in which p and q are true together, and situations in which r and q are true together, and even situations in which p and q and r are all true together, as epistemically acceptable alternatives to the current situation e. So $\Diamond(p \wedge q)$ ("$p \wedge q$ is consistent with what the agent knows"), and $\Diamond(r \wedge q)$, and $\Diamond(p \wedge q \wedge r)$ are all satisfied at e. Moreover $\Box q$ ("the agent knows that q") is satisfied at e, as at every alternative epistemic situation the information q holds. Hintikka introduced the symbol K for this usage of box (that is, he wrote Kq for "the agent knows that q") and his notation is still standard in contemporary epistemic logic. Epistemic logic is discussed in Chapters 18 and 20 of this handbook.

The next example is important for another reason. Modal logic is often viewed as an intrinsically *intensional* logic, interpreted using *possible world semantics*. This view comes from what is probably the most historically influential interpretation of modal logic, namely as the logic of necessity and possibility. In this interpretation, $\Diamond$ is read as "possibly", $\Box$ is read as "necessarily", and the points of Kripke models are regarded as possible worlds. Unfortunately, this interpretation has tended to overshadow the others, at least in certain research communities (some philosophers view modal logic, intensionality, and possible worlds as inextricably intermingled). To ensure that this illusion is dispelled, our last example will be completely *extensional*. Consider the graph in Figure 4.

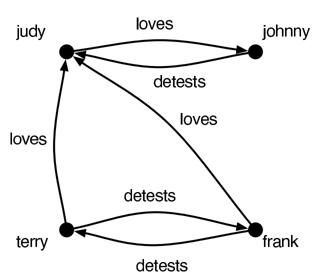

Figure 4. Ordinary individuals.

This is the sort of extensional information that classical logics (such as first-order logic) are

often used for. But modal logic is at home here too. We can say lots of interesting things about such situations. For example

$$\langle \text{LOVES} \rangle \top \wedge \langle \text{DETESTS} \rangle \langle \text{LOVES} \rangle \top$$

is true when evaluated at Terry: he loves someone and he detests someone who loves someone. Nowadays, modal logic is widely used for reasoning about such extensional situations. In particular, the concept languages which lie at the heart of the *description logics* used in knowledge representation are often notational variants of (various kinds of) modal languages. Description logics are used in a wide range of applications for representing and reasoning about extensional information. They are treated in depth in Chapter 13 of this handbook.

We're almost ready to define the standard translation, but before doing so let's deal with three other matters. First, in most branches of logic and mathematics, there is a notion of two structures being *isomorphic*, which can be glossed as "mathematically indistinguishable". Let's take this opportunity to be precise about what isomorphism means in basic modal logic (we give the definition for models and frames with one relation; it generalises straightforwardly to structures with multiple relations).

DEFINITION 1 (Isomorphism). Let $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$ be models, and $f : W \mapsto W'$ a bijection. If for all $w, v \in W$ we have that Rwv if and only if $Rf(w)f(v)$ then we say that f is an isomorphism between the frames (W, R) and (W', R') and that these frames are isomorphic. If in addition we have, for all proposition symbols p, that $w \in V(p)$ if and only if $f(w) \in V'(p)$ then we say that f is an isomorphism between the models $\mathfrak{M}$ and $\mathfrak{M}'$ and that these models are isomorphic.

As this definition makes clear, if models $\mathfrak{M}$ and $\mathfrak{M}'$ are isomorphic, each replicates perfectly the information in the other. Hence the following result is unsurprising:

PROPOSITION 2. *Let f be an isomorphism between models $\mathfrak{M}$ and $\mathfrak{M}'$. Then for all basic modal formulas φ, and all points w in $\mathfrak{M}$, we have that $\mathfrak{M}, w \models \varphi$ if and only if $\mathfrak{M}, f(w) \models \varphi$.*

Proof. Immediate by induction on the construction of φ (see Lemma 9 for an example of such a proof.) ❑

Second, we want to point out that it is possible to take a more dynamic perspective on the satisfaction definition. In particular, we can think of it as a game. Let's start with a concrete example. Consider the model in Figure 5.

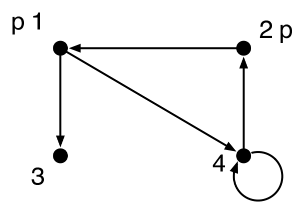

Figure 5. The formula $\Diamond\Box\Diamond p$ is true at 1 and 4, but false at 2 and 3.

As the reader should check, $\Diamond\Box\Diamond p$ is true at points 1 and 4, but false at points 2 and 3. Now suppose we play the following *evaluation game*. This game has two players, a Verifier (V) and a

Falsifier (F), who disagree about the satisfiability of a formula in some model. The two players react differently to the connectives in the formula: for example, occurrences of disjunction allow V to make a choice as to which disjunct to verify, and play continues with the formula chosen; negation switches the roles of the two players; and diamonds make V pick a successor of the current point, while boxes do the same for F. Moreover, for any proposition symbol p, V wins the p-game if p is true at the current state, otherwise F wins. A player also wins the game if the other player must make a move for a modality but cannot.

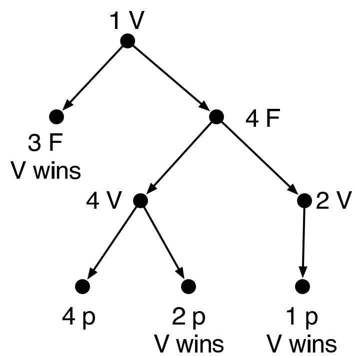

Figure 6. Initial segment of a game tree.

So let's play the game for $\Diamond\Box\Diamond p$ at 1. Figure 6 shows (an initial segment of) the resulting game tree. Note that V can always win. Her most obvious option is to play 3 in response to the outermost diamond; this leaves F with no possible response when faced with the task of falsifying $\Box\Diamond p$. But V can also safely play 4 on her first move. As the tree shows, irrespective of F's response, V can always reach a winning position. What this example suggests is completely general: for any model $\mathfrak{M}$, point w, and basic formula φ, we have that $\mathfrak{M}, w \models \varphi$ if and only if V has a winning strategy when the φ-game is played in $\mathfrak{M}$ starting at w. Moreover, as we see in this example, different strategies correspond to different ways of showing that the given formula is true.

Finally, some historical remarks. Where does the relational interpretation of modal logic come from? The three authors usually cited as pioneers are Saul Kripke, Jaakko Hintikka, and Stig Kanger. Kripke's contributions are the best known (indeed relational semantics is often called Kripke semantics) and Kripke [83, 84] are regarded as landmarks in the development of modal semantics. But Hintikka independently developed the idea in his work on logics of knowledge and belief (see, for example, his classic monograph "Knowledge and Belief" [66]). Furthermore, although his work was not well known at the time, Kanger, in a series of papers and monographs published in 1957, introduced relational semantics for modal logic (see, for example, Kanger [77, 78]). Indeed, the idea of relational semantics seems to have been in the air at around this time, and a number of other logicians (for example Arthur Prior and Richard Montague) discussed similar ideas. For a detailed discussion of who did what and when, the reader should consult Goldblatt [59].

2.2 The standard translation

We now understand what modal languages are, how they can be interpreted in graphs, and why this can be an interesting thing to do. What next? Well, if we were following a traditional path, we would probably remark that as modal languages are to be used for reasoning, some sort of proof system is called for. For example, if we were working in a language with one modality (and in which we had chosen to define $\Diamond$ in terms of $\Box$) we might point out that the set of all modal validities (that is, the *minimal modal logic*) in the language could be axiomatised by a Hilbert-style proof system called **K**. This proof system can be defined in a number ways; we might, for example, stipulate that the axioms of **K** consist of all formulas in the language which have the form of a propositional tautology (by which we mean not merely tautologies such as $p \to p$ which contain no modalities, but also formulas such as $\Box\Diamond p \to \Box\Diamond p$, which contain modalities but are truth-functionally tautologous too) and all instances of the following axiom schema:

$$\Box(\varphi \to \psi) \to (\Box\varphi \to \Box\psi).$$

There are two rules of proof: *modus ponens* (if $\vdash \varphi$ and $\vdash \varphi \to \psi$ then $\vdash \psi$) and *modal generalisation* (if $\vdash \varphi$ then $\vdash \Box\varphi$); in the definitions of these rules, $\vdash \theta$ is standard notation that means "the formula θ is provable". Now, this looks like a standard axiomatisation of first-order logic with $\Box$ behaving like $\forall$. But **K** has no analogs of the first-order axioms with tricky side conditions on freedom and bondage of variables, such as $\forall x\varphi \to [\tau/x]\varphi$, where τ is a first-order term. This is no coincidence. As the standard translation given below will make clear, modal logic is essentially a perspicuous variable-free notation for a fragment of first-order logic.

But proof systems are not our goal. This chapter is concerned with semantic issues, so quite different aspects of modal logic call for our attention. To get the ball rolling, let's return to our basic semantic entities (Kripke models) and ask what they actually are. This will provide a point of entry to one of the main themes of the chapter: the relationship between modal and classical logic.

So, what is a Kripke model? No mystery here. A Kripke model $(W, \{R^m\}_{m \in \text{MOD}}, V)$ is what model theorists call a *relational structure*. That is, we have a domain of quantification W, a collection of binary relations over this domain, and a collection of unary relations as well (after all, $V(p)$ is a unary relation for each $p \in$ PROP). But this means that we are not forced to talk about Kripke models using modal languages: they provide us with everything needed to interpret classical languages too. For example, to talk about a model $(W, \{R^m\}_{m \in \text{MOD}}, V)$ using first-order logic we would simply make use of a first-order language with a binary relation symbol R^m for every $m \in$ MOD, and a unary relation symbol P for every $p \in$ PROP. Modal logicians have a name for this language: they call it the *first-order correspondence language* (for the basic modal language over PROP and MOD).

Why "correspondence language"? Because every basic modal formula (in the language over PROP and MOD) corresponds to a first-order formula from this language via the *standard translation*:

$$\begin{array}{rcl}
\text{ST}_x(p) & = & Px \\
\text{ST}_x(\bot) & = & \bot \\
\text{ST}_x(\neg\varphi) & = & \neg\, \text{ST}_x(\varphi) \\
\text{ST}_x(\varphi \wedge \psi) & = & \text{ST}_x(\varphi) \wedge \text{ST}_x(\psi) \\
\text{ST}_x(\langle m \rangle\varphi) & = & \exists y(R^m xy \wedge \text{ST}_y(\varphi)) \\
\text{ST}_x([m]\varphi) & = & \forall y(R^m xy \to \text{ST}_y(\varphi)).
\end{array}$$

That is, the standard translation maps proposition symbols to unary predicates, commutes with booleans, and handles boxes and diamonds by explicit first-order quantification over R^m-accessible points. The variable y used in the clauses for diamonds and boxes is chosen to be any new variable (that is, one that has not been used so far in the translation). We remarked earlier that diamonds and boxes were essentially a simple macro notation encoding quantification over accessible states; the standard translation expands these macros. Note that $\mathrm{ST}_x(\varphi)$ always contains exactly one free variable (namely x). This free variable is what allows the internal perspective, typical of modal logic, to be mirrored in a classical language: assigning a value to this variable is analogous to evaluating a modal formula inside a model at a certain point.

Here's an example of the translation at work:

$$\begin{array}{rcl} \mathrm{ST}_x(p \to \Diamond p) & = & \mathrm{ST}_x(p) \to \mathrm{ST}_x(\Diamond p) \\ & = & Px \to \mathrm{ST}_x(\Diamond p) \\ & = & Px \to \exists y(Rxy \wedge \mathrm{ST}_y(p)) \\ & = & Px \to \exists y(Rxy \wedge Py). \end{array}$$

As the reader can easily check, $p \to \Diamond p$ and its standard translation $Px \to \exists y(Rxy \wedge Py)$ are equisatisfiable in the following sense: for any model $\mathfrak{M}$, and any point w in $\mathfrak{M}$, we have that $\mathfrak{M}, w \models p \to \Diamond p$ if and only if $\mathfrak{M} \models Px \to \exists y(Rxy \wedge Py)[x \leftarrow w]$, where the notation $[x \leftarrow w]$ means assign w to the free variable x. Unsurprisingly, this relationship is completely general:

PROPOSITION 3. *For any basic modal formula φ, any model $\mathfrak{M}$, and any point w in $\mathfrak{M}$, we have that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M} \models \mathrm{ST}_x(\varphi)[x \leftarrow w]$.*

Proof. There is practically nothing to prove. The clauses of the standard translation mirror the clauses of the satisfaction definition. Hence the result is immediate by induction on the structure of modal formulas. ❑

Thus the standard translation gives us a bridge between modal logic and classical logic. And we can immediately use this bridge to transfer meta-theoretic results for first-order logic to modal logic.

PROPOSITION 4. *Basic modal logic has the compactness property. That is, if Σ is a set of basic modal formulas, and every finite subset of Σ is satisfiable, then Σ itself is satisfiable. Moreover, basic model logic has the Löwenheim-Skolem property. That is, if a set of basic modal formulas Σ is satisfiable in at least one infinite model, then it is satisfiable in models of every infinite cardinality.*

Proof. We show that basic modal logic has the Löwenheim-Skolem property. Suppose that Σ is a set of basic modal formulas that has at least one infinite model. Let $\mathrm{ST}_x(\Sigma)$ be the set of (first-order) formulas obtained by standardly translating all the formulas in Σ. Now, as Σ has an infinite model, by Proposition 3 so does $\mathrm{ST}_x(\Sigma)$. But first-order logic has the Löwenheim-Skolem property, hence $\mathrm{ST}_x(\Sigma)$ has a model of every infinite cardinality. But, again by appeal to Proposition 3, each of these models satisfies Σ, so basic modal logic has the Löwenheim-Skolem property too. The argument showing it has the compactness property is similar. ❑

Another easy consequence of the standard translation is that the set of validities (in basic modal languages) is recursively enumerable. For a basic modal formula φ is valid iff $\mathrm{ST}_x(\varphi)$ is a first-order validity, and the set of first-order validities is recursively enumerable.

Let's sum up what we have learned so far. Propositional modal languages are syntactically simple languages that offer a neat (variable-free) notation for talking about relational structures. They talk about relational structures from the inside, using the modal operators to look for information at accessible states. This internal perspective on models, coupled with the simplicity of modal syntax, means that propositional modal logic is an attractive tool for certain applications. Moreover, viewed as a tool for talking about models, any basic modal language can be regarded as a fragment of its corresponding first-order language: the standard translation systematically maps modal formulas to first-order formulas (in one free variable) and makes the quantification over accessible states explicit. This allows us to quickly establish some basic modal meta-theory by appeal to known results for first-order logic.

3 BISIMULATION AND DEFINABILITY

With the basics behind us it is time to look deeper. In particular, it is time to start mapping the expressive strengths and weaknesses of the basic modal language. Now, the expressive power of a language is usually measured in terms of the distinctions it can draw. A language with just the two expressions "like" and "dislike" would provide only the roughest possible classification of the world, whereas a richer language of assent and dissent would make it possible to draw finer distinctions inside the accepted and rejected situations. So what distinctions can modal languages draw? In this section we discuss this question at the level of models, and in Section 5 we shall reconsider it at the level of frames. In what follows it will often be useful to think in terms of *pointed models*. That is, we shall often present models together with an explicit distinguished point to indicate where we are trying to find a difference.

3.1 Drawing distinctions

A modal language (and indeed any logical language whose formulas form a set) can distinguish between some models $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$, but not between all such pairs. For example, our basic modal language can distinguish the pair of models shown in Figure 7.

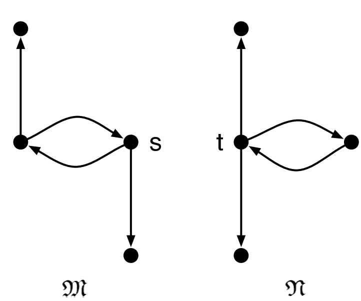

Figure 7. $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ are modally distinguishable.

Here $\Box(\Box\bot \vee \Diamond\Box\bot)$ is a modal formula that distinguishes these models: it is true in $\mathfrak{M}$ at s, but false in $\mathfrak{N}$ at t. But now consider the pair of models shown in Figure 8. Is it possible to *modally* distinguish $(\mathfrak{M}, s)$ from $(\mathfrak{K}, u)$? That is, is it possible to find a (basic) modal formula that is true in $\mathfrak{M}$ at s, but false in $\mathfrak{K}$ at u? Note that it is easy to distinguish them if we are

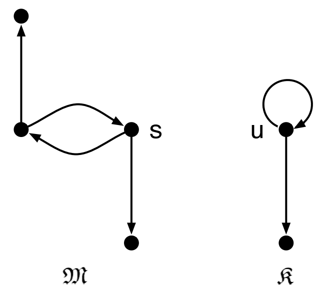

Figure 8. $(\mathfrak{M}, s)$ and $(\mathfrak{K}, u)$ are not modally distinguishable.

allowed to use first-order logic: all points in $\mathfrak{M}$ (including s) are irreflexive, while point u in $\mathfrak{K}$ is reflexive, hence the first-order formula Rxx is not satisfiable (under any variable assignment) in model $\mathfrak{M}$, but it is satisfied in $\mathfrak{K}$ when u is assigned to x. But no matter how ingenious you are, you will not find any formula in the basic modal language that distinguishes these models at their designated points. Why is this?

3.2 Bisimulation

A natural approach to this question is to consider its dual: when should two models be viewed as modally identical? For example, given a process interpretation, when would we view two transition diagrams as representations of the same process? The models $\mathfrak{M}$ and $\mathfrak{K}$ of Figure 8 provide an intuitive example: they seem to stand for the same process when we look at possible actions and deadlocks (note that at each state the process can enter a deadlock situation; that is, it can enter a state from which it cannot exit). By contrast, $\mathfrak{M}$ and $\mathfrak{N}$ in Figure 7 are different, as the right hand state in $\mathfrak{N}$ is not threatened with immediate dead-lock. Or consider the epistemic interpretation: when would we want to say that two graphs represent the same epistemic state? For example, we would probably want to identify the two epistemic models shown in Figure 9 at their distinguished points s and t.

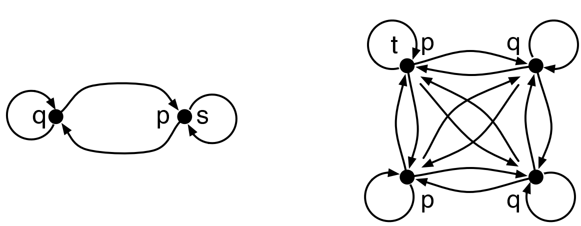

Figure 9. Two epistemically equivalent models.

After all, in essence both models present us with a two way choice: either we are in an epistemic situation where p holds and there is an accessible epistemic situation where q holds, or we are in an epistemic situation where q holds and there is an accessible epistemic situation where p holds. The intuition that both these graphs code the same epistemic state is captured by our

modal language: the reader will not find any modal formula that distinguishes them.

The modal logician's idea of asking when two distinct structures are modally identical (that is, make the same modal formulas true) lies within an older (and broader) tradition of looking for the structure preserving morphisms in a given mathematical domain, and letting the corresponding theory describe those notions that are invariant for such morphisms. This is the spirit of Klein's Program in geometry, proposed around 1870, and still influential in many fields. Of course, there is no unique answer to the question of when two structures are the same. This insight was stated forcefully in recent years by President Clinton during the Lewinsky hearings: *It all depends on what you mean by "is"*. Clinton's Principle for modal logic means that we should first try to stipulate some notion of structural equivalence for models that is appropriate for modal languages. This is the purpose of the following definition (first formulated in van Benthem [128, 131]). We state it here for models with one relation R, but the definition generalises straightforwardly to models with any number of relations.

DEFINITION 5 (Bisimulation). A bisimulation between models $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$ is a non-empty binary relation E between their domains (that is, $E \subseteq W \times W'$) such that whenever wEw' we have that:

Atomic harmony: w and w' satisfy the same proposition symbols,

Zig: if Rwv, then there exists a point v' (in $\mathfrak{M}'$) such that vEv' and $R'w'v'$, and

Zag: if $R'w'v'$, then there exists a point v (in $\mathfrak{M}$) such that vEv' and Rwv.

If there is a bisimulation between two models $\mathfrak{M}$ and $\mathfrak{N}$, then we say that $\mathfrak{M}$ and $\mathfrak{N}$ are bisimilar. Moreover, we say that two states are bisimilar if they are related by some bisimulation.

Putting this in words: two states are bisimilar if they make the same atomic information true and if, in addition, their transition possibilities match. That is, if a transition to a related state is possible in one model, then the bisimulation must deliver a matching transition possibility in the other. Atomic harmony, coupled with the matching transitions concept embodied in the zigzag clauses, make bisimulation a natural notion of process equivalence, and indeed bisimulations were independently discovered in computer science (see Park [100]).

Returning to the models $\mathfrak{M}$, $\mathfrak{K}$, and $\mathfrak{N}$ considered above (and disregarding proposition symbols) it is easy to see that $\mathfrak{M}$ and $\mathfrak{K}$ are bisimilar: the dotted lines in Figure 10 indicate the required bisimulation (note that the indicated bisimulation links the two designated points). Furthermore, it is easy to see that there is no bisimulation that links the designated points of $\mathfrak{N}$ and $\mathfrak{K}$. Why not? Because a move from t to the right-hand world in $\mathfrak{N}$ has no matching move in $\mathfrak{K}$: moving downwards from u is no option (end-points never bisimulate with points having successors) but neither is moving reflexively from u to itself (as one can move from u to a successor which is an endpoint, but this can't be done from the right-hand world in $\mathfrak{N}$).

Given any modal model $\mathfrak{M}$, bisimulations can be used in a number of ways. The so-called *bisimulation contraction* makes $\mathfrak{M}$ as small as possible. To define this, note that it follows from Definition 5 that any union of bisimulations between two models is itself a bisimulation. Therefore the union of all bisimulations between two models is a maximal bisimulation between them. Now form the maximal bisimulation of model $\mathfrak{M}$ with itself (incidentally, a bisimulation of a model with itself is called an *autobisimulation*). Define a quotient of $\mathfrak{M}$ whose points are the equivalence classes, and relate the equivalence class $|w|$ to the equivalence class $|v|$ iff $|w|$ and $|v|$ contain points w' and v' such that $Rw'v'$. The map from points to their equivalence classes is a bisimulation. For example, the bisimulation shown in Figure 10 between $\mathfrak{M}$ and $\mathfrak{K}$ is a bisimulation contraction. Bisimulation contractions are the most compact representation of processes,

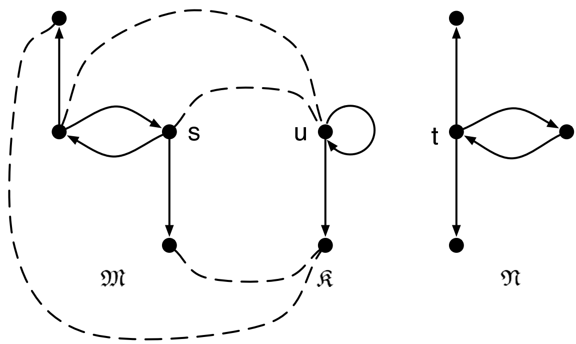

Figure 10. $(\mathfrak{M}, s)$ and $(\mathfrak{K}, u)$ are bisimilar, $(\mathfrak{K}, u)$ and $(\mathfrak{N}, t)$ are not.

at least from a modal standpoint. They remove all the redundancies in the representation — but also all aesthetic symmetries. (A butterfly is a redundant object, as one wing contains enough information under this perspective.)

Bisimulations can also be used to make bigger models: one important construction which does this is called *tree unraveling* (for a very early paper using this construction, see Dummett and Lemmon [34]; for an influential paper that made heavy use of it, see Sahlqvist [111]).

To unravel a model, take all finite R-sequences of points in $\mathfrak{M}$ that start at some point w. These sequences form a tree with one-step extensions of sequences as the tree-successor relation. Projection from a sequence to its last element is a bisimulation onto the original model $\mathfrak{M}$. As an example, consider the unraveling of the two element model $\mathfrak{K}$ around its distinguished point u to the infinite comb-like structure shown in Figure 11 (we use v as the name of the other point in this model). Reasoning about trees is often easier than reasoning about arbitrary graphs, and

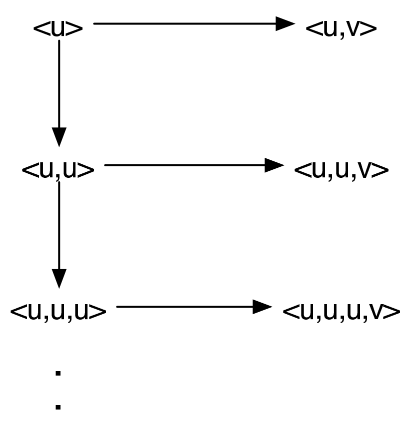

Figure 11. Unraveling $\mathfrak{K}$ around u.

so this method is of considerable theoretical utility. Moreover, as we shall see in the following

section, tree unraveling is relevant to the *decidability* of modal logic.

Three other model constructions used in modal logic, namely *disjoint unions*, *generated submodels*, and *bounded morphisms* (or *p-morphisms*) are also bisimulations. Historically, all three constructions were widely used in modal logic more than a decade before the unifying concept of bisimulation was introduced (the classic source for these constructions is Segerberg [113], where they are heavily used, often in combination, to prove completeness theorems). All three constructions are fundamental tools in many areas of modal logic (for example, when reformulated at the level of frames, they are key ingredients in the Goldblatt-Thomason Theorem which we discuss in Section 5) so we take this opportunity to define them for models with one accessibility relation. These definitions generalise straightforwardly to models of arbitrary signature.

The simplest construction is forming disjoint unions. If we have a pair of disjoint models (that is, a pair of models (W, R, V) and (W', R', V') such that W and W' are disjoint) then their disjoint union is the model $(W \cup W', R \cup R', V + V')$, where $V + V'$ is the valuation defined by $(V + V')(p) = V(p) \cup V'(p)$, for all proposition symbols p. That is, forming a disjoint union of two models means lumping together all the information in the two graphs. What if the graphs are not disjoint? Then we simply take disjoint isomorphic copies of the two models, and form the disjoint union of the copies. This lumping together process can be generalised to arbitrarily many models, which prompts the following definition.

DEFINITION 6 (Disjoint Unions). Given mutually disjoint models $\mathfrak{M}_i = (W_i, R_i, V_i)$, where i ranges over the elements of some index set I, we define the disjoint union of these models to be $\mathfrak{M} = (W, R, V)$, where $W = \bigcup_{i \in I} W_i$, $R = \bigcup_{i \in I} R_i$, and $V(p) = \bigcup_{i \in I} V_i(p)$ for all proposition symbols p. To form the disjoint union of a collection of models that are not mutually disjoint, we first take mutually disjoint isomorphic copies, and then form the disjoint union of the copies.

It is immediate from this definition that any component model $\mathfrak{M}_i$ of a disjoint union $\mathfrak{M}$ is bisimilar with $\mathfrak{M}$: for the bisimulation relation E we simply take the identity relation. Identity clearly satisfies the atomic harmony and zigzag conditions required of bisimulations.

Disjoint unions build bigger models from (collections of) smaller ones. Generated submodels do the reverse. They arise by restricting attention to subgraphs of a given graph that are closed under relational transitions. For example, consider the two graphs in Figure 12. It is clear that

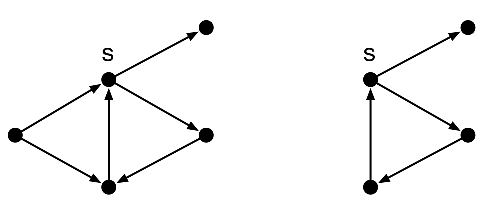

Figure 12. Generating a submodel from s.

the graph on the right arises by restricting attention to a certain transition-closed subgraph of the graph on the left, namely the set of point reachable by taking sequences of transitions from s. This motivates the following definition.

DEFINITION 7 (Generated Submodels). Let $\mathfrak{M} = (W, R, V)$ be a model and let $W' \subseteq W$. We say that a model $\mathfrak{M}' = (W', R', V')$ is the restriction of $\mathfrak{M}$ to W' if $R' = R \cap (W' \times W')$ and for all proposition symbols p we have that $V'(p) = V(p) \cap W'$. We say that W' is R-closed

if for all $u \in W'$, if Ruv then $v \in W'$. Finally, we say that $\mathfrak{M}'$ is a generated submodel of $\mathfrak{M}$ iff $\mathfrak{M}'$ is the restriction of $\mathfrak{M}$ to an R-closed subset of W.

If $\mathfrak{M}' = (W', R', V')$ is a generated submodel of $\mathfrak{M} = (W, R, V)$, and $S \subseteq W'$ has the property that every $w' \in W'$ is reachable via a finite sequence of R-transitions from some $s \in S$, then we say that $\mathfrak{M}'$ is the submodel of $\mathfrak{M}$ generated by S. If S is a singleton set $\{s\}$, then we say that $\mathfrak{M}'$ is the submodel of $\mathfrak{M}$ generated by the point s.

A generated submodel is bisimilar to the model that gave rise to it: as with disjoint unions, the identity relation relates the two models in the appropriate way. Incidentally, note that every component model of a disjoint union is a generated submodel of the disjoint union.

Finally we turn to bounded morphisms (or p-morphisms as they are often called).

DEFINITION 8 (Bounded Morphisms). A bounded morphism between models $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$ is a function f with domain W and range W' such that:

Atomic harmony: Points in W and their f-images satisfy the same proposition symbols (that is, $w \in V(p)$ iff $f(w) \in V'(p)$, for all proposition symbols p).

Morphism: if Rwv, then $R'f(w)f(v)$.

Zag: if $R'f(w)v'$, then there exists a v (in $\mathfrak{M}$) such that $f(v) = v'$ and Rwv.

If f is a bounded morphism from $\mathfrak{M}$ to $\mathfrak{M}'$ and f is surjective, then we say that $\mathfrak{M}'$ is a bounded morphic image of $\mathfrak{M}$.

Bounded morphisms are bisimulations: a bounded morphism is simply a bisimulation in which the bisimulation relation E is an R-preserving morphism f (note that the only essential difference between the two definitions is that the morphism clause replaces the zig clause, and clearly morphism implies zig). Historically, it was the definition of bounded morphisms that inspired the definition of bisimulations.

As an example of a bounded morphism between models, consider Figure 13 (again we ignore proposition symbols).

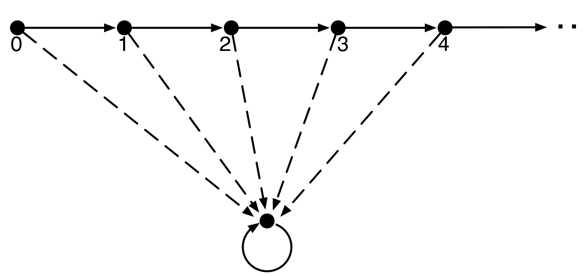

Figure 13. Bounded morphism collapsing the natural numbers to a reflexive point.

Here we have collapsed the natural numbers in their usual order to a single reflexive point. It is clear that this map satisfies both the morphism and zig clauses, so it is indeed a bounded morphism.

3.3 Invariance and definability in first-order logic

Structural invariances preserve certain patterns definable in appropriate languages. Before pursuing the match between bisimulation and modal logic, let us examine the situation in first-order logic. The archetypal structural invariance is *isomorphism* between models. As we saw earlier (recall Proposition 2) modal formulas are invariant for isomorphism. More generally, it is well known that if f is an isomorphism between $\mathfrak{M}$ and $\mathfrak{N}$, then for each first-order formula $\varphi(x_1, \ldots, x_k)$, and each matching tuple of objects $\langle d_1, \ldots, d_k \rangle$ in $\mathfrak{M}$, the following equivalence holds:

$$\mathfrak{M} \models \varphi[d_1, \ldots, d_k] \text{ iff } \mathfrak{N} \models \varphi[f(d_1), \ldots, f(d_k)],$$

or stated in words: first-order formulas are invariant for isomorphism.

On special models, the converse also holds. For example, it is a well-known fact that any two finite models with the same first-order theory are isomorphic. But no general converse holds, as there are many more isomorphism classes of models than complete first-order theories. Invariance for isomorphism is even a defining condition for any logic in abstract model theory. But no matter how strong the logic, the converse still fails whenever the formulas of a logic form a set, as opposed to the proper class of isomorphism types.

Thus it makes sense to look at invariance conditions for weaker notions of structural equivalence. For example, a *potential isomorphism* between two models $\mathfrak{M}$ and $\mathfrak{N}$ is a non-empty set I of finite partial isomorphisms satisfying the back-and-forth extension conditions that, whenever $f \in I$ and $d \in \mathfrak{M}$, then there is an $e \in \mathfrak{N}$ such that $f \cup \{(d, e)\} \in I$, and vice-versa. Note that isomorphisms induce potential isomorphisms: simply take I to be the family of all finite restrictions. The converse is not true. Matching up all finite sequences of rational numbers with equally long sequences of real numbers (in the same order) is a potential isomorphism between $\mathbb{Q}$ and $\mathbb{R}$, even though these two structures are not order-isomorphic for cardinality reasons.

It is easy to show that all first-order formulas are invariant for potential isomorphism, but the real match is with a stronger language: two models are potentially isomorphic iff they have the same complete theory in the *infinitary* first-order logic $\mathcal{L}_{\infty\omega}$. This formalism also gives rise to much stronger definability results. For example, for each model $\mathfrak{M}$ there is a sentence $\delta_{\mathfrak{M}}$ of $\mathcal{L}_{\infty\omega}$ which holds only in those models $\mathfrak{N}$ which have a potential isomorphism with $\mathfrak{M}$; that is, models can be defined up to potential isomorphism. Moreover, countable models can even be defined (modulo isomorphism) using only countable conjunctions and disjunctions. This is all very nice of course, but infinitary logic is a bit outlandish from a practical viewpoint.

Better matches between structural invariance and first-order definability arise in the more fine-grained setting of Ehrenfeucht-Fraïssé comparison games between models $\mathfrak{M}$ and $\mathfrak{N}$ played between a Spoiler (who looks for differences between the models) and a Duplicator (who looks for analogies between them). Models $\mathfrak{M}$ and $\mathfrak{N}$ have the same first-order theory up to quantifier depth k iff the Duplicator has a winning strategy in their comparison game over k rounds. We won't give details here, as we will define a modal comparison game of this sort at the end of the section.

3.4 Invariance and definability in modal logic

With these analogies in mind, let us now investigate the modal situation. For a start, modal formulas are *invariant for bisimulation*:

LEMMA 9 (Bisimulation Invariance Lemma). *If E is a bisimulation between $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$, and wEw', then w and w' satisfy the same basic modal formulas.*

Proof. By induction on the construction of modal formulas. The case for proposition symbols is immediate by atomic harmony. The inductive steps for the boolean connectives are straightforward. And the inductive step for $\Diamond$ formulas shows exactly what the zigzag clauses were designed for. For consider the left to right direction. Given $\mathfrak{M}, w \models \Diamond\varphi$ and wEw', we want to show that $\mathfrak{M}', w' \models \Diamond\varphi$. Now, $\mathfrak{M}, w \models \Diamond\varphi$ means that there is some v in $\mathfrak{M}$ such that Rwv and $\mathfrak{M}, v \models \varphi$. But then (by zig) there must be a point v' in $\mathfrak{N}'$ such that vEv' and $R'w'v'$. By the induction hypothesis, $\mathfrak{M}', v' \models \varphi$, hence $\mathfrak{M}', w' \models \Diamond\varphi$ as required. The argument for the right to left direction is essentially the same, using zag in place of zig. ❑

The result allows us to show failures of bisimulation easily. For example, we have already sketched an argument showing that the models $\mathfrak{N}$ and $\mathfrak{K}$ of Figure 10 have no bisimulation between their designated points, but a quicker proof is now possible: these points *cannot* be bisimilar because there are modal formulas (for example $\Box(\Box\bot \vee \Diamond\Box\bot)$) which are satisfied at one point but not the other. On the other hand, the dotted lines in Figure 10 show that $\mathfrak{M}$ and $\mathfrak{K}$ are bisimilar; it follows that all points linked by a dotted line in these graphs make exactly the same modal formulas true. Another typical application of this result is to show the undefinability of certain structural notions. For example, we can show that irreflexivity is modally undefinable: no modal formula holds in exactly those points w of models such that $\neg Rww$. To prove this, it suffices to find two bisimilar points in two models, one of which is reflexive, the other irreflexive. One such example is the bisimulation between the designated points of $\mathfrak{M}$ and $\mathfrak{K}$ shown in Figure 10. Another is the bounded morphism of Figure 13 which collapses the natural numbers to a single reflexive point.

Another consequence of this result is that the disjoint union, generated submodel, and bounded morphism constructions are all satisfaction preserving. More precisely:

LEMMA 10. *Modal satisfaction is invariant under the formation of disjoint unions, generated submodels, and bounded morphisms. That is:*

1. *If $\mathfrak{M} = (W, R, V)$ is the disjoint union of $\mathfrak{M}_i = (W_i, R_i, V_i)$, for i from some index set I, then for all $w \in W_i$ and all $i \in I$ we have that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}_i, w \models \varphi$.*

2. *If $\mathfrak{M}' = (W', R', V')$ is a generated submodel of $\mathfrak{M} = (W, R, V)$, then for all $w' \in W'$ we have that $\mathfrak{M}, w' \models \varphi$ iff $\mathfrak{M}', w' \models \varphi$.*

3. *If $\mathfrak{M}' = (W', R', V')$ is a bounded morphic image of $\mathfrak{M} = (W, R, V)$ under the bounded morphism f, then for all $w \in W$ we have that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}', f(w) \models \varphi$.*

Proof. All three results could be proved by induction on the structure on φ. But such proofs are unnecessary: we know that disjoint unions, generated submodels, and bounded morphisms are all examples of bisimulations, hence these results follow from Lemma 9. ❑

To sum up the discussion so far, bisimulation implies modal equivalence. But what about the converse? For finite models, we have the following.

PROPOSITION 11. *If points w and w' from two finite models $\mathfrak{M}$ and $\mathfrak{N}$ satisfy the same modal formulas, then there is a bisimulation E between $\mathfrak{M}$ and $\mathfrak{N}$ such that wEw'.*

Proof. Assume we are working with models containing only a single relation R. We will show that the relation of modal equivalence is itself a bisimulation. That is, we will define the

bisimulation relation E by wEw' iff w and w' make the same modal formulas true. We now verify that E so defined is indeed a bisimulation.

It is immediate that E satisfies atomic harmony. As for zig, assume that wEw' and Rwv. Assume for the sake of contradiction that there is no v' in $\mathfrak{M}'$ such that $R'w'v'$ and vEv'. Let $S' = \{u' \mid R'w'u'\}$. Now, as w has an R-successor v, we have $\mathfrak{M}, w \models \Diamond\top$. As wEw', we have $\mathfrak{M}', w' \models \Diamond\top$ too, hence S' is non-empty. Furthermore, as $\mathfrak{M}'$ is finite, S' must be finite too, so we can write it as $\{u'_1, \ldots, u'_n\}$. By assumption, for every $u'_i \in S'$ there exists a formula ψ_i such that $\mathfrak{M}, v \models \psi_i$ but $\mathfrak{M}', u'_i \not\models \psi_i$. It follows that

$$\mathfrak{M}, w \models \Diamond(\psi_1 \wedge \cdots \wedge \psi_n) \text{ and } \mathfrak{M}', w' \not\models \Diamond(\psi_1 \wedge \cdots \wedge \psi_n),$$

which contradicts our assumption that wEw'. Hence E satisfies zig. A symmetric argument shows that E satisfies zag too, hence it is a bisimulation. ❑

Thus, on finite models, the expressive power of modal languages matches up exactly with bisimulation invariance. This result can be extended to broader model classes, such as models with finite branching width for successors (note that the proof just given does not depend on the models involved being finite: it would also work for infinite models in which each point has only finitely many R-successors) and suitably saturated models in a model-theoretic sense. But no general converse can hold, for the set-theoretic reasons mentioned earlier. Indeed, the converse does not hold generally even for countable models: not all modally equivalent countable models are bisimilar. Consider the two models in Figure 14 (assume that all proposition symbols are true at all points in both models). Both models have infinitely many branches leading away from their root nodes, but whereas all the branches in the model on the left are of finite length, the model on the right has a branch of infinite length. Now, as the reader should check, both models satisfy the same modal formulas at their root nodes. However there is no bisimulation that links their root nodes; the infinite branch in the model on the right makes it impossible to define one.

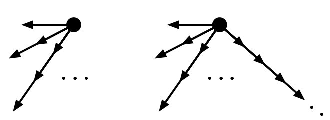

Figure 14. Modally equivalent but not bisimilar.

This counterexample could be repaired by passing to an *infinitary modal language* $\mathcal{L}^{\Diamond}_{\infty\omega}$ with arbitrary (countable) conjunctions and disjunctions. Infinitary modal equivalence occurs between countable models $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ whenever there is a bisimulation linking s to t. Furthermore, every countable model $(\mathfrak{M}, s)$ is defined up to bisimulation by some $\mathcal{L}^{\Diamond}_{\infty\omega}$ formula $\delta_{\mathfrak{M},s}$. Again, such infinitary languages are somewhat impractical, but there are some useful bisimulation invariant formalisms which lie between the basic modal language and its infinitary extension. Two examples are *propositional dynamic logic* and the *modal μ-calculus*, which are discussed in Section 6.

Lemma 9 and its partial converses do not exhaust what needs to be said about the role played by bisimulations in modal model theory. But to gain a deeper understanding, we need to bring in a third component: the first-order correspondence language that we met in Section 2.2 when we introduced the standard translation.

3.5 Modal logic and first-order logic compared

The basic modal language can be viewed as a sort of miniature version of full first-order logic over graph models. The standard translation defined in the previous section shows that each modal formula φ corresponds to a first-order formulas $\mathrm{ST}_x(\varphi)$ containing a free variable x. But the converse does not hold: some first-order formulas in the correspondence language are not modally definable. We have already see an example. As the bisimulation between models $\mathfrak{M}$ and $\mathfrak{K}$ shows (recall Figure 10) no modal formula defines $\neg Rxx$. Thus, viewed as a tool for talking about models, modal logic is strictly less expressive than the full first-order correspondence language. And this prompts a further question: given that a modal language is essentially a fragment of the corresponding first-order language, exactly which fragment is it? This question has an elegant answer. First, a preliminary definition.

DEFINITION 12. A first-order formula $\varphi(x)$ is invariant for bisimulation if for all models $\mathfrak{M}$ and $\mathfrak{M}'$, and all points w in $\mathfrak{M}$ and w' in $\mathfrak{M}'$, and all bisimulations E between $\mathfrak{M}$ and $\mathfrak{M}'$ such that wEw', we have that $\mathfrak{M} \models \varphi[x \leftarrow w]$ iff $\mathfrak{M}' \models \varphi[x \leftarrow w']$.

We can now state the main result: basic modal languages correspond to the fragment of their first-order correspondence language that is invariant for bisimulation. More precisely:

THEOREM 13 (Modal Characterisation Theorem). *The following are equivalent for all first-order formulas $\varphi(x)$ in one free variable x:*

1. *$\varphi(x)$ is invariant for bisimulation.*
2. *$\varphi(x)$ is equivalent to the standard translation of a basic modal formula.*

Proof. That clause 2 implies 1 is a more or less immediate consequence of Lemma 9. The hard direction is showing that clause 1 implies 2. The original proof can be found in van Benthem [128, 131]. Two other proofs are given in Chapter 5 of this handbook. One is quite close to van Benthem's original approach, the other is based on games. ❑

Nowadays many different proofs are known for this result, and for various extensions and variants. For example, Rosen [109] showed that the result holds over finite models; this is far from obvious, as the restriction to finite models means that many standard results of first-order model theory (such as the Compactness Theorem) cannot be applied. And Otto [99] showed that the modal equivalent guaranteed to exist by the previous theorem can be restricted to a formula of modal operator depth 2^k, where k is the quantifier depth of $\varphi(x)$.

Basic modal logic and first-order logic are analogous in many ways. As we mentioned in Section 2, via the standard translation modal logic immediately inherits basic meta-theoretic properties of its more powerful neighbour, such as the Compactness and Löwenheim-Skolem Theorems. But not all such transfer is automatic. Consider, for example, the *Craig Interpolation* property:

> *If $\varphi \models \psi$ then there exists a formula θ whose vocabulary is included in that of both φ and ψ such that $\varphi \models \theta$ and $\theta \models \psi$.*

Does the same result hold for basic modal formulas φ and ψ such that $\varphi \models \psi$? Appealing to the result for first-order logic gives us a first-order formula θ such that $\mathrm{ST}_x(\varphi) \models \theta$ and $\theta \models \mathrm{ST}_x(\psi)$. But what guarantees that this interpolant is modally definable? Interpolation does in fact hold for the basic modal language (for a detailed account, see Chapter 8 of this handbook),

but additional work is needed to prove this. Nonetheless, interpolation does mesh well with the above preservation results; here is an improvement on the Modal Characterisation Theorem. We say that a first-order formula φ *implies* ψ *along bisimulation* if the following implication holds: if E is a bisimulation between $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$, and $\mathfrak{M}, s \models \varphi$, then $\mathfrak{N}, t \models \psi$.

THEOREM 14 (Modal Characterisation-Interpolation Theorem). *The following are equivalent for all first-order formulas $\varphi(x)$:*

1. *$\varphi(x)$ implies $\psi(x)$ along bisimulation.*

2. *There is a modally definable θ in the common vocabulary of φ and ψ such that $\varphi \models \theta$ and $\theta \models \psi$.*

Proof. The proof can be found in Barwise and van Benthem [11]. Note that the Modal Characterisation Theorem follows by taking $\varphi(x)$ equal to $\psi(x)$. This result does not imply ordinary modal interpolation as it stands: additional work is again needed. ❑

Behind the above observations is the fact that the cheaply transferred properties are universal in some sense, whereas the universal-existential property of interpolation requires honest work. Even so, there is an intuition (based on decades of positive experience with transferring results) that modal logic and first-order logic share all general meta-properties except decidability. No proofs of significant formulations of this idea have been found so far, but we can point to some broad analogies regarding methods. Generally speaking, bisimulation plays the same role for modal logic that potential isomorphism does for first-order logic. This can even be made precise in the following sense. To each first-order model $\mathfrak{M}$ we can associate a modal model whose points are the variable assignments into $\mathfrak{M}$, and whose accessibility relations are changes from one assignment g to another $g(x := d)$ that resets the value for the variable x to the object $d \in \mathfrak{M}$. Then two models $\mathfrak{M}$ and $\mathfrak{N}$ have a potential isomorphism between them iff their associated modal models are bisimilar; see van Benthem [136] for details.

We conclude this discussion with two general results that allow us to switch between modal and first-order relations between models. In essence, both results have the form of a commutative diagram.

LEMMA 15 (First Lifting Lemma). *The following are equivalent for all models $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$:*

1. *$(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ are modally equivalent.*

2. *$(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ have elementary extensions to models $(\mathfrak{M}^+, s)$ and $(\mathfrak{N}^+, t)$ which are bisimilar.*

LEMMA 16 (Second Lifting Lemma). *The following are equivalent for all models $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$:*

1. *$(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ are modally equivalent.*

2. *$(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ are bisimilar to models $(\mathfrak{M}^+, s)$ and $(\mathfrak{N}^+, t)$ which are elementarily equivalent.*

Proof. The first lifting lemma was originally proved in van Benthem [128]. It is the key item in (some proofs of) the Characterisation Theorem (the $^+$-models are suitably saturated elementary extensions which allow the Characterisation Theorem to be proved rather straightforwardly). The second lifting lemma (see van Benthem [134] for the original result, and Andréka, van Benthem, and Németi [5] for full proof details) involves judicious tree unraveling of the two models, duplicating sub-trees to create uniformity, coupled with an Ehrenfeucht-Fraïssé argument to establish elementary equivalence. ❑

3.6 Bisimulation as a game

Bisimulation can naturally be thought of as a form of process equivalence, but a more dynamic perspective is also possible. We have already seen that the modal satisfaction definition can be recast in the form of a game (recall Figure 6) but the task of determining whether two models are bisimilar can also be viewed in this way. Consider a game between Spoiler (the difference player) and Duplicator (the similarity player) comparing successive pairs in two pointed models $(\mathfrak{M}, w)$ and $(\mathfrak{N}, w')$:

> *If w and w' do not agree on atomic information, Spoiler wins the game in zero rounds. In subsequent rounds, Spoiler chooses a state in one model which is a successor of the current w or w', and Duplicator responds with a matching successor in the other model. If the chosen points differ in their atomic properties, Spoiler wins. If one player cannot move, the other wins. Duplicator wins on infinite runs on which Spoiler does not win.*

This game captures the zigzag behaviour of bisimulations in an obvious sense. It is also *determined*: one of the two players has a winning strategy. (This is because it is an open Gale-Stewart game in the sense of game theory.) For example, returning yet again to the models $\mathfrak{M}$, $\mathfrak{N}$ and $\mathfrak{K}$ considered at the start of this section, we see that Duplicator has a winning strategy in the comparison game for the models $\mathfrak{M}$ and $\mathfrak{K}$ starting from their matched designated points, while Spoiler has one for $\mathfrak{M}$ and $\mathfrak{N}$. The following result clarifies the role of these games precisely:

LEMMA 17 (Adequacy of Modal Comparison Games).

1. *There is an explicit correspondence between Spoiler's winning strategies in a k-round comparison game between $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ and modal formulas of modal operator depth k on which s and t disagree.*

2. *There is an explicit correspondence between Duplicator's winning strategies over an infinite-round comparison game between $(\mathfrak{M}, s)$ and $(\mathfrak{N}, t)$ and the set of all bisimulations between $\mathfrak{M}$ and $\mathfrak{N}$ that link the points s and t.*

Proof. This result is essentially a fine-grained restatement of the Lemma 9 from a game-theoretic perspective. See Chapter 5 of this handbook for more on game-based approaches to bisimulation. ❑

For example, in the game between the models $\mathfrak{M}$ and $\mathfrak{K}$ given earlier, Duplicator wins by choosing responses that stick to the bisimulation links. And in the game between $\mathfrak{M}$ and $\mathfrak{N}$, Spoiler can win in at most three rounds by using the earlier modal difference formula $\Box(\Box\bot \vee \Diamond\Box\bot)$ of modal operator depth three. In each round he can make sure that some modal difference remains at the current match, with the modal operator depth descending each time.

4 COMPUTATION AND COMPLEXITY

We view modal logic as a tool for representing and reasoning about graphs. Our discussion of expressivity has given us some insight into the representational capabilities of modal logic (at least at the level of models) but what about reasoning?

In this section we discuss modal reasoning from a computational perspective. We concentrate on the *model checking task* and the *satisfiability and validity* problems, but also make some remarks about the *global satisfiability* and the *model comparison* tasks. As we shall see, the complexity of the modal version of these tasks is lower than that of their first-order counterparts.

Before going further, two general remarks. First, although we are about to study reasoning, we are not about to embark on the study of modal proof systems (apart from anything else, the standard proof systems are only relevant to satisfiability and validity checking, and there is more to modal reasoning than this). Secondly, although we are ostensibly moving on from expressivity issues to computational issues, the two topics are intertwined. In essence, the positive computational results reported here arise from negative expressivity results (for example, the inability of the basic modal language to force the existence of infinite models).

4.1 Model checking

The model checking task can be formulated locally:

> *Given a (finite) model $\mathfrak{M}$, a point w in $\mathfrak{M}$, and a basic modal formula φ, is φ satisfied in $\mathfrak{M}$ at w?*

Or globally:

> *Given a (finite) model $\mathfrak{M}$, and a basic modal formula φ, is φ satisfied at all points in $\mathfrak{M}$?*

Or in a form that subsumes both the local and global perspectives:

> *Given a (finite) model $\mathfrak{M}$, and a basic modal formula φ, return the set of points in $\mathfrak{M}$ that satisfy φ.*

In what follows we shall work with the last formulation, which is probably the most common way of thinking about model checking in practice.

Now, model checking is clearly a task with computational content — but is it really a *reasoning* task? In our view, yes. In essence, a model is a 'flat' store of information: it consists of a collection of entities, together with a specification of which entities have which properties, and which entities are related by which atomic relations. A modal formula, on the other hand, is a recursively constructed tree. The embedding of connectives and modalities within one another permits relatively short formulas to make interesting assertions, assertions that go way beyond the mere listing of atomic facts. If we add to these differences the practical observation that in typical applications the formula will be much smaller than the model, we see that model checking is about synchronising two very different forms of information: it tells us whether the abstract information embodied in the formula is implicitly present in the model, and gives us a set of points where this implicit information emerges. Viewed this way, model checking is a quintessential reasoning task.

Moreover, model checking has turned out to be of great practical importance — indeed, one of the more salutary lessons computer science has taught logic is just how important this modest looking form of reasoning actually is. Nowadays the practical importance of modal model

checking dwarfs that of determining modal satisfiability or validity (the tasks logicians have traditionally viewed as paramount) as a wide range of practical tasks can be modeled in a computationally natural manner, and efficiently solved, via model checking. A classic example is hardware verification. Even though a computer chip is a concrete object, it gives rise to a natural abstract model, namely the set of all states the chip can be in, and the transitions between them. If a chip is to work satisfactorily, its computational runs (that is, the sequences of states it can follow by making transitions from the initial state) should possess a number of high-level 'emergent' properties: for example, these runs should not enter deadlock situations. If we have a modal language that can express the desired properties (for example, absence of deadlock) then by checking the formula in the model representing the chip we can determine whether the design is satisfactory or not.

So how should we perform model checking? The standard approach is to use a bottom-up *labeling algorithm*. To model check a formula φ we label every point in the model with all the subformulas of φ that are true at that point. We start with the proposition symbols: the valuation tells us where these are true, so we label all the appropriate points. We then label with more complex formulas. The booleans are handled in the obvious way: for example, we label w with $\psi \wedge \theta$ if w is labeled with both ψ and θ. As for the modalities, we label w with $\Diamond\varphi$ if one of its R-successors is labeled with φ, and we label it with $\Box\varphi$ if all of its R-successors are labeled with φ. A precise definition of the algorithm for checking diamond formulas is given in the pseudo-code of Figure 15.

procedure $\mathit{Check}\Diamond(\psi)$
    $T := \{v \mid \psi \in \mathit{label}(v)\}$;
    while $T \neq \emptyset$ **do**
        choose $v \in T$;
        $T := T \setminus \{v\}$;
        for all w **such that** Rwv **do**
            if $\Diamond\psi \notin \mathit{label}(w)$ then
            $\mathit{label}(w) := \mathit{label}(w) \cup \{\Diamond\psi\}$;
            end if ;
        end for all ;
    end while ;
end procedure

Figure 15. Model checking $\Diamond\psi$.

The beauty of this algorithm is that we never need to duplicate work: once a point is labeled as making φ true, that's it. This makes the algorithm run in time polynomial in the size of the input formula and model: the algorithm takes time of the order of

$$\mathit{con}(\varphi) \times \mathit{nodes}(\mathfrak{M}) \times \mathit{nodes}(\mathfrak{M}),$$

where $\mathit{con}(\varphi)$ is the number of connectives in φ, and $\mathit{nodes}(\mathfrak{M})$ is the number of nodes in $\mathfrak{M}$. To see this, note that $\mathit{con}(\varphi)$ tells us how many rounds of labeling we need to perform, one of the $\mathit{nodes}(\mathfrak{M})$ factors is simply the upper bound on the nodes that need to be labeled, while the other is the upper bound on the number of successor nodes that need to be checked.

Thus modal model checking is a computationally tractable task, but this is not the case for first-order logic. In fact, model checking first-order formulas is a PSPACE-complete task (see

Chandra and Merlin [22]). That is, although it is possible to write an algorithm that solves the first-order model checking task using an amount of computer memory that is only polynomial in the size of the input model and formula, the algorithm may require running time that is exponential in the size of the input. The problem, of course, lies with the quantifiers. Assuming that the standard assumptions made in complexity theory are correct, there is no way of adapting the labeling algorithm (or indeed, any other algorithm) to perform first-order model checking in polynomial time.

However the labeling algorithm sketched above *does* adapt to more powerful modal languages, and this is important. As we said above, when model checking we want to state interesting high-level properties of the situation we are modeling, and often the ordinary $\Box$ and $\Diamond$ modalities simply aren't expressive enough. In model checking applications, it is usual to work with tree-like models, namely trees of computational runs. On such models $\Diamond$ is interpreted as "at some immediate successor state". This is natural, to be sure, but somewhat limited. However, by adding the binary Until modality, we gain access to entire *sequences* of successor states:

$$\begin{array}{lll} \mathfrak{M}, s \models U(\psi,\theta) & \text{iff} & \text{there is a } t \text{ such that } sR^*t \text{ and } \mathfrak{M}, t \models \psi, \\ & & \text{and for all } u \text{ such that } sR^*u \text{ and } uR^+t \text{ we have } \mathfrak{M}, u \models \theta. \end{array}$$

Here R^* is the reflexive transitive closure of the "immediate successor" transition relation R explored by $\Diamond$, and R^+ is its transitive closure. Thus Until gives us a direct handle on the computational runs that can be followed in the model, and this clearly places interesting expressive power at our disposal. Nowadays the Until modality is a fundamental component of some of the most important model checking formalisms — formalisms such as LTL (Linear Time Temporal Logic) and CTL (Computational Tree Logic). For an introduction to these logics, see Chapter 11 of this handbook, or Clarke, Grumberg and Peled [25].

We shall examine the Until operator and the extra expressivity it offers more closely in Section 6.3. Here we simply want to address the following question: how do we extend the labeling algorithm to handle formulas of the form $U(\psi,\theta)$? Here's the basic idea. First, if any point w is labeled with ψ, label w with $U(\psi,\theta)$. Second, if any point v is labeled with θ and at least one R-successor of v is labeled with $U(\psi,\theta)$, then label v with $U(\psi,\theta)$. It should be clear that these two steps reflect the semantics for Until just given; the pseudo-code given in Figure 16 shows how to make the basic idea precise.

Now for an important point. Throughout the previous discussion we have tacitly assumed that we have some way of representing formulas and finite models that is suitable for computational implementation. It is probably not worth sketching details of how this might be done: nowadays it seems safe to assume that most readers of a technical book on logic have at least a nodding acquaintance with programming (indeed, we suspect that most of our readers would find it straightforward to devise a computational syntax for models and modal languages, and to implement simple programs for working with them).

Nonetheless, such issues cannot be taken lightly. A major factor in the spectacular progress of model checking has been the development of *Binary Decision Diagrams* (BDDs) and *Ordered Binary Decision Diagrams* (OBDDs). BDDs (which are compact representations of boolean expressions) were introduced by Lee [88] and Akers [3], and OBDDs (a more sophisticated form of BDD with fewer representational redundancies) were introduced by Bryant [17]. BDDs were first proposed for model checking by Burch, Clarke, McMillan, Dill, and Hwang [18] and as the title of this paper indicates ("Symbolic model checking: 10^{20} states and beyond") this led to a dramatic increase in the size of the models that could be handled. It is important not to underestimate the gap between the labeling algorithm sketched above, and what it takes to make

```
procedure CheckU(ψ, θ)
    T := {v | ψ ∈ label(v)} ;
    for all v ∈ T do
        label(v) = label(v) ∪ {U(ψ, θ)} ;
    end for all ;
    while T ≠ ∅ do
        choose v ∈ T ;
        T := T \ {v} ;
        for all w such that Rwv do
            if U(ψ, θ) ∉ label(w) and θ ∈ label(w) then
                label(w) := label(w) ∪ {U(ψ, θ)} ;
                T := T ∪ {w} ;
            end if ;
        end for all ;
    end while ;
end procedure
```

Figure 16. Model checking $U(\varphi, \theta)$.

a working model checker handle a large model. Crossing this gap requires a combination of theoretical insight and computational expertise, and an entire research community is devoted to exploring the issues involved.

For a good textbook level introduction to model checking, see Huth and Ryan [72]. This book not only introduces the basic algorithms, it also shows how they can be implemented with the aid of OBDDs. Moreover, it discusses modal checking for the modal μ-calculus (which we introduce in Section 6.7). For a more advanced treatment, see Clarke, Grumberg and Peled [25]. Finally, for an account of model checking via automata-theoretic methods, see Chapter 17 of this handbook.

4.2 *Satisfiability and validity: decidability*

It is often said that modal logic is decidable. This can be read as shorthand for the following claim: the *validity problem* for the basic modal language (*given a basic modal formula φ, is φ valid?*) is decidable. That is, it is possible (ignoring constraints of time and space) to write a computer program which takes a basic modal formula as input, and halts after a finite number of steps and correctly tells us whether it is valid or not.

The decidability of modal logic can also be viewed as a claim that the *satisfiability problem* for the basic modal language (*given a basic modal formula φ, is φ satisfiable in some model?*) is decidable. That is, it is possible (again, ignoring constraints of time and space) to write a computer program which takes a basic modal formula as input, and halts after a finite number of steps and correctly tells us whether it is satisfiable in some model or not. The validity and satisfiability problems are *dual problems*: a modal formula φ is valid iff $\neg\varphi$ is not satisfiable, hence if we have a method for solving one problem, we have a method for solving the other. In what follows we show that both problems are decidable; we'll talk in terms of satisfiability.

A lot is known about the decidability of satisfiability problems for various logics, so it is not too difficult to establish modal decidability: we can do so by reducing the problem to known

results for other logics. Here's an easy example. The satisfiability problem for the *two variable fragment* of first-order logic (that is, the fragment of first-order logic in which every formula contains only two variables) is decidable. Now, every basic modal formula can be translated into a formula in the two-variable fragment. To see this we need simply make a small adjustment to the standard translation ST_x. Whenever we translate a $\Diamond$ or a $\Box$, instead of choosing a completely new variable to quantify over accessible points, we use a second fixed variable (say y). If we later encounter another $\Diamond$ or $\Box$, we flip back to the original variable x, and so on. More precisely, we redefine ST_x so it always uses y to quantify over accessible points, and define a twin translation ST_y which always quantifies using x. Here are the key clauses:

$$\begin{array}{ll} \mathrm{ST}_x(\Diamond\varphi) = \exists y\,(Rxy \wedge \mathrm{ST}_y(\varphi)) & \mathrm{ST}_y(\Diamond\varphi) = \exists x\,(Ryx \wedge \mathrm{ST}_x(\varphi)) \\ \mathrm{ST}_x(\Box\varphi) = \forall y\,(Rxy \rightarrow \mathrm{ST}_y(\varphi)) & \mathrm{ST}_y(\Box\varphi) = \forall x\,(Ryx \rightarrow \mathrm{ST}_x(\varphi)). \end{array}$$

The interleaving of ST_x and ST_y guarantees that for any basic modal formula φ, $\mathrm{ST}_x(\varphi)$ will contain only the two variables x and y, and it should be clear that the modified translation is equivalent to the original one. It follows that the satisfiability problem for the basic modal language must be decidable: to test a modal formula for satisfiability, simply translate it with this new version of the standard translation, and then apply the satisfiability algorithm for the two-variable fragment to the output.

It is pleasant that modal decidability can be established so easily, but the proof isn't particularly instructive. The following semantic argument is somewhat more revealing. We shall show that the basic modal language has the *finite model property*, or to put it another way, that it does not have the expressive strength required to force the existence of infinite models. Needless to say, this is in sharp contrast with first-order logic: even such a simple first-order formula as

$$\forall x \neg Rxx \wedge \forall xyz(Rxy \wedge Ryz \rightarrow Rxz) \wedge \forall x \exists y Rxy$$

has only infinite models. In fact, the basic modal language has a rather strong form of the finite model property. We shall show the following:

THEOREM 18 (Strong Finite Model Property). *Let φ be a basic modal formula. If φ is satisfiable, then it is satisfiable on a finite model containing at most $2^{s(\varphi)}$ points, where $s(\varphi)$ is the number of subformulas of φ.*

The decidability of the modal satisfiability problem follows immediately from this result. If a modal formula φ is satisfiable at all, it is satisfiable on a model containing at most $2^{s(\varphi)}$ points. As there are (up to isomorphism) only finitely many such models, exhaustive (and exhausting!) search through them all will settle the issue of φ's satisfiability.

Just as important as the result is the method we shall use to prove it: *filtrations*. These are a standard item in the modal logician's toolkit, and have been used to prove completeness and decidability results for many different modal systems. The basic idea underlying the method is simplicity itself: given a modal formula φ and a model $\mathfrak{M}$ that satisfies it, we make a finite model $\mathfrak{M}$ by collapsing to a single point all the points within $\mathfrak{M}$ that satisfy the same subformulas of φ. But there is a tricky issue: how should we define the relation on the collapsed points in such a way that φ remains true in the finite model? Let's work through the details and see.

We shall say that a set of basic modal formulas Σ is *subformula closed* if every subformula of every formula in Σ is a member of Σ (that is, if $\varphi \wedge \psi \in \Sigma$ then so are φ and ψ, and if $\neg\varphi \in \Sigma$ then so is φ; and if $\Box\varphi \in \Sigma$, then so is φ, and so on). We now define:

DEFINITION 19 (Filtrations). Let $\mathfrak{M} = (W, R, V)$ be a model, let Σ be a subformula closed set of formulas, and let $\leftrightsquigarrow_\Sigma$ be the equivalence relation on the states of $\mathfrak{M}$ defined as follows:

$$w \leftrightsquigarrow_\Sigma v \text{ iff for all } \varphi \text{ in } \Sigma\text{: } (\mathfrak{M}, w \models \varphi \text{ iff } \mathfrak{M}, v \models \varphi).$$

The official notation for the equivalence class of a point w of $\mathfrak{M}$ with respect to $\leftrightsquigarrow_\Sigma$ is $|w|_\Sigma$, but in what follows we'll usually assume that Σ is clear from context and simply write $|w|$.

Let $W_\Sigma = \{|w| \mid w \in W\}$. Suppose $\mathfrak{M}^f_\Sigma$ is any model (W^f, R^f, V^f) such that:

1. $W^f = W_\Sigma$.
2. If Rwv then $R^f|w||v|$.
3. If $R^f|w||v|$ then for all $\Diamond\varphi \in \Sigma$, if $\mathfrak{M}, v \models \varphi$ then $\mathfrak{M}, w \models \Diamond\varphi$.
4. $V^f(p) = \{|w| \mid \mathfrak{M}, w \models p\}$, for all proposition symbols p in Σ.

Then $\mathfrak{M}^f_\Sigma$ is called a filtration of $\mathfrak{M}$ through Σ. In what follows we'll drop the subscripts and write $\mathfrak{M}^f$ instead of $\mathfrak{M}^f_\Sigma$.

Two points should be made about this definition. First, observe $\mathfrak{M}^f$ is a filtration of $\mathfrak{M}$ through a subformula closed set of formulas Σ, then $\mathfrak{M}^f$ contains at most $2^{|\Sigma|}$ nodes, where $|\Sigma|$ is the cardinality of Σ. This should be clear: after all, the points of $\mathfrak{M}^f$ simply are the equivalence classes in W_Σ, and there cannot be more than $2^{|\Sigma|}$ of these. Second, the previous definition does *not* specify an accessibility relation on W_Σ — it only imposes constraints (namely clauses 2 and 3) on the properties a suitable accessibility relation R^f should have. That the constraints imposed are sensible is shown by the following result:

THEOREM 20 (Filtration Theorem). *Let $\mathfrak{M}^f$ $(= (W_\Sigma, R^f, V^f))$ be a filtration of $\mathfrak{M}$ through a subformula closed set of basic modal formulas Σ. Then for all formulas $\sigma \in \Sigma$, and all nodes w in $\mathfrak{M}$, we have $\mathfrak{M}, w \models \sigma$ iff $\mathfrak{M}^f, |w| \models \sigma$.*

Proof. By induction on the structure of formulas. The case for proposition symbols is immediate from the definition of V^f, and because Σ is closed under subformulas, the inductive step for the boolean connectives is clear.

So suppose $\Diamond\sigma \in \Sigma$ and $\mathfrak{M}, w \models \Diamond\sigma$. Then there is a v such that Rwv and $\mathfrak{M}, v \models \sigma$. As $\mathfrak{M}^f$ is a filtration, by the first constraint on R^f (clause 2 of the previous definition) we have that $R^f|w||v|$. As Σ is subformula closed, $\sigma \in \Sigma$, hence by the inductive hypothesis $\mathfrak{M}^f, |v| \models \sigma$. Hence $\mathfrak{M}^f, |w| \models \Diamond\sigma$.

Conversely, suppose $\Diamond\sigma \in \Sigma$ and $\mathfrak{M}^f, |w| \models \Diamond\sigma$. Then there is a state $|v|$ in $\mathfrak{M}^f$ such that $R^f|w||v|$ and $\mathfrak{M}^f, |v| \models \sigma$. As $\sigma \in \Sigma$, by the inductive hypothesis $\mathfrak{M}, v \models \sigma$. Making use of the second constraint on R^f (clause 3 of the previous definition) yields $\mathfrak{M}, w \models \Diamond\sigma$. ❑

It only remains to verify that relations satisfying the constraints demanded of R^f actually exist. They do. Define:

1. $R^s|w||v|$ iff $\exists w' \in |w|\ \exists v' \in |v|\ Rw'v'$.
2. $R^l|w||v|$ iff for all formulas $\Diamond\varphi$ in Σ: $\mathfrak{M}, v \models \varphi$ implies $\mathfrak{M}, w \models \Diamond\varphi$.

It is straightforward to show that both relations satisfy the required constraints. Actually, you can show a little more: if R^f is any relation satisfying the above constraints then $R^s \subseteq R^f \subseteq R^l$. For this reason, R^s and R^l are said to give rise to the smallest and largest filtrations respectively.

So we have proved Theorem 18: the basic modal language indeed has the strong finite model property. As we argued above, this in turn establishes the decidability of the basic modal satisfiability problem. Now, as is well known, the satisfiability problem for full first-order logic is undecidable. First-order logic is the classic example of a language where expressivity has been purchased at the expense of decidability. The basic modal language reverses this trade-off.

4.3 Satisfiability and validity: complexity

What do the decidability proofs just given tell us about the computational complexity of the modal satisfiability problem? Only that it can be solved in NEXPTIME (that is, non-deterministic exponential time). This is clear from the filtration proof: to see if φ is decidable, we can non-deterministically choose a model containing at most $2^{s(\varphi)}$ points, and then check whether or not it satisfies φ. As we have seen from our discussion of model checking, the checking takes time polynomial in the size of model; however as the model is exponential in the size of the input formula φ, this is a complex task. The reduction to the satisfiability problem for the two-variable fragment yields the same upper bound, as this problem is NEXPTIME-complete.

But the satisfiability problem for basic modal logic is PSPACE-complete. That is, given a modal formula φ, it is possible to write an algorithm to determine whether or not φ is satisfiable that uses an amount of computer memory that is only polynomial in the size of φ. Now, most complexity theorists believe that PSPACE-complete problems are harder than the satisfiability problem for classical propositional logic (the classic NP-complete problem) but easier than EXPTIME-complete problems, which in turn are believed to be easier than NEXPTIME-complete problems. So, given standard complexity-theoretic assumptions, the modal satisfiability problem is probably easier than our earlier decidability proofs suggest.

How do we design a PSPACE algorithm for modal satisfiability? We cannot give a detailed answer here, but we can point to an expressive weakness of modal logic which should make it plausible that PSPACE algorithms for modal satisfiability exist.

LEMMA 21. *Let $\mathfrak{M} = (W, R, V)$ be a model, let $w \in W$, let n be a natural number, let $S_{n,w}$ be the subset of W containing w and all points in W reachable from w by making at most n R-transitions, and let $\mathfrak{N}$ be the submodel $(S_{n,w}, R|_S, V|_S)$, where $R|_S$ and $V|_S$ are the restrictions of R and V respectively to $S_{n,w}$. Then, for all basic modal formulas φ such that md$(\varphi) \leq n$, we have that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{N}, w \models \varphi$.*

That is, if we take a model $\mathfrak{M}$, and extract a submodel $\mathfrak{N}$ from it by throwing away all points that are more than n steps away from w, then no formula with modal operator depth of at most n can distinguish the two models at w. Modal formulas have shallow vision. And if we combine this lemma with what we have already learned about finite models and bisimulations, we obtain the following:

THEOREM 22. *Every formula φ in the basic modal language is satisfiable in a model based on a finite tree of depth at most md(φ).*

Proof. As model logic has the finite model property, if a modal formula is satisfiable, it is satisfiable on a finite model $\mathfrak{M}$ at some point w. As we remarked in the previous section, it is always possible to unravel a model into an equivalent tree-based model. Now, if we unravel $\mathfrak{M}$ about w, we don't necessarily obtain a finite model, but (as $\mathfrak{M}$ is finite) we do obtain a model

based on a tree with a finite branch factor, and this model satisfies φ at its root. If we then chop off all points more than $md(\varphi)$ away from the root we obtain a finite model which (by the previous lemma) satisfies φ at its root. ❑

So every modal formula is satisfiable on a shallow tree, and we are now in a position to appreciate how PSPACE algorithms for modal satisfiability work. In essence, they construct shallow trees branch by branch. If a branch is successfully constructed (something which takes only space polynomial in the size of the input formula, as the length of the branch is bounded by $md(\varphi)$) the branch is discarded (thus freeing up the memory) and the next branch is then constructed. There may be many branches, so it may take exponential time to construct them all, but as all branches are discarded once they are constructed, such an algorithm uses only polynomial space. This sketch has neglected some important issues (such algorithms require space for recording book-keeping details, and we need to ensure that the space used for this is not excessive) but it does describe, in broad terms, how many modal satisfiability algorithms (notably those based on tableaux or games) work.

But we should issue a word of warning: it's not always so easy. Yes, matters are relatively straightforward here, but that is because we have been working with the *basic* modal language over the class of *all* models. If we impose restrictions on the class of models we are working with (as we shall do in Section 5) or work with richer modal languages (as we shall do in Section 6), or both, we can easily find ourselves faced with undecidable, or even highly undecidable, satisfiability and validity problems.

4.4 Other reasoning tasks

We have discussed the big three (model checking, and satisfiability and validity checking) but this by no means exhausts the reasoning tasks of interest. To conclude this section, let's briefly consider two others.

Although we have stressed the locality of modal logic, some problems demand a global perspective. In particular, if we view a modal formula as a general background *constraint*, we will typically want it to be globally satisfied: that is, we will be interested in models $\mathfrak{M}$ such that $\mathfrak{M} \models \varphi$. The importance of the global satisfiability problem has been strongly emphasised by the description logic community. Indeed, description logic builds into its architecture the idea of a *Terminological Box* (or *TBox*), a collection of formulas that encode background knowledge about some domain (for example, that all men are mortal, that all Martians own flying saucers, or that each employee has a social security number). Description logicians are interested in models in which the TBox is globally satisfied, for these are the models that reflect all the background assumptions.

Once the importance of background constraints is realised, it becomes clear that it is not the pure global satisfiability task itself that is of primary interest. Rather, it is the *local-global satisfiability task*: given formulas φ and ψ, is there a model which locally satisfies φ and globally satisfies ψ? That is, is it possible to satisfy φ subject to the global constraint ψ?

Here's an example. Suppose we're working in a zoological setting, and are interested in the interaction of maternal love and professional responsibility on the feeding of our furry ursine brethren. To put it another way, suppose we have the following TBox:

$$\begin{array}{rl} \mathit{bear} \vee \mathit{human} & \qquad \mathit{bear} \rightarrow \langle \text{MOTHER} \rangle \mathit{bear} \\ \mathit{bear} \rightarrow \neg \mathit{human} & \qquad \mathit{bear} \rightarrow [\text{FEDBY}](\mathit{zoo\text{-}keeper} \vee \mathit{mother}) \end{array}$$

Let's call this TBox BEAR-CARE. The sort of queries we might be interested in posing are: is it possible to globally satisfy BEAR-CARE and, simultaneously, to locally satisfy

$$\langle \text{MOTHER} \rangle (\textit{bear} \wedge \textit{human})?$$

(No, it's not.) And is it possible to globally satisfy BEAR-CARE and simultaneously to locally satisfy

$$\langle \text{FEDBY} \rangle (\neg \textit{human} \wedge \neg \textit{mother})?$$

(Yes, it is: BEAR-CARE doesn't rule out having bears as zoo-keepers. This may well be a bug in the TBox.)

Local-global satisfiability problems are also natural in the setting of parsing problems. It is possible to encode various kinds of grammars (such as regular grammars or context-free grammars) as modal formulas (see Chapter 19 of this handbook for a discussion of such approaches). Then, given a string of symbols, the parsing problem is to decide whether it is possible to find a model which embodies all the constraints encoded in the grammar, and which simultaneously satisfies the formula encoding the input string. That is, we would like to globally satisfy the modal formula GRAMMAR and simultaneously locally satisfy INPUT-STRING.

Unsurprisingly, both the global, and the local-global satisfiability tasks are tougher than the ordinary satisfiability problem:

THEOREM 23. *The global satisfiability and the local-global satisfiability tasks for basic modal languages are both EXPTIME-complete.*

Proof. The stated result is an immediate consequence of Hemaspaandra's [118, 65] complexity results for the universal modality (we introduce the universal modality in Section 6.1). But the result holds for even stronger languages; see De Giacomo and Lenzerini [28] for related results for more expressive description logics. ❑

EXPTIME-complete problems are decidable but provably intractable: they contain problem instances that will require time exponential in the size of the input to solve (which can mean that they require more time than the expected lifetime of the universe). This, however, is a worst-case scenario. One of the most important recent developments in computational logic has come from the description logic community, who have shown it is possible to specify and implement tableaux-based algorithms for such problems that are remarkably efficient in practice. Moreover, interesting work exists on performing modal theorem proving via (non-standard) translations into first-order logic, so that optimised first-order resolution provers can be applied to the task. For a detailed discussion and comparison of these methods, see Chapter 4 of this handbook, and for a deeper examination of the complexity of modal logic, see Chapter 3.

We conclude with a remark on the *model comparison* task. As bisimulation is the modally fundamental notion of graph equivalence, it is natural to wonder how difficult it is to determine when two models are bisimilar. The corresponding problems for first-order logic (namely, testing for graph isomorphism) is thought to be difficult: there is no known polynomial algorithm for testing for graph isomorphism, though the problem has not been shown to be NP-complete either. In fact, the problem of identifying isomorphic graphs is sometimes regarded as giving rise to a special complexity class of its own.

Testing for bisimulation, however, turns out to be computationally tractable, and there are elegant polynomial algorithms which work by discarding pairs of point that cannot make it into any bisimulation (see Dovier, Piazza and Policriti [33]). Again an expressivity result lies behind this result: the maximal bisimulation between two models $\mathfrak{M}$ and $\mathfrak{N}$ is explicitly definable

in a first-order fixed-point language over the disjoint union $\mathfrak{M} \uplus \mathfrak{N}$ of the two models. Such languages have been studied extensively in computer science, and they are known to have good computational behaviour.

Let us summarise our discussion. For a number of tasks, the basic modal language (interpreted over the class of all models) is computationally better behaved than the corresponding first-order language (interpreted over the same models). Figure 17 summarises the relevant facts (PTIME is short for Polynomial Time). Of course, this better computational behaviour comes about because

	Model Checking	Satisfiability	Model Comparison
FOL	PSPACE-complete	Undecidable	in NP
ML	PTIME	PSPACE-complete	PTIME

Figure 17. First-order logic and modal logic: computational properties summarised.

the basic modal language is not nearly as expressive as first-order logic. Thus the pressing questions are: what are the trade-offs? And can this better computational behaviour be lifted to more expressive modal logics, and (if so) how? We shall revisit these questions in the following two sections.

5 RICHER LOGICS

Until now, we have deliberately said rather little about modal *logics* and what they are. Instead we have acted as if there was only one modal logic of any interest, namely the set of valid formulas (that is, the set of formulas satisfied at all points in all models) or, to put it syntactically, the set of formulas generated by the minimal proof system **K** (which we defined at the start of Section 2.2). But traditional presentations of modal logic tend to emphasise the *multiplicity* of modal logics, and devote a great deal of attention to logics richer than **K**, logics with such names as **T**, **K4**, **S4**, **S5**, **GL**, and **Grz**. Where do richer modal logics come from?

As a first approximation (we'll shortly see why it's only an approximation) we might say that richer logics emerge at the level of *frames*, via the concept of *frame validity*. Let $\varphi(p_1, \ldots, p_n)$ be a basic modal formula built out of the proposition symbols $p_1, \ldots, p_n$. We say that $\varphi(p_1, \ldots, p_n)$ is *valid on a frame* $\mathfrak{F} = (W, R)$ *at a point* w if, for each valuation V for its proposition symbols $p_1,\ldots,p_n$, we have that φ is satisfied in the resulting model at w; in such a case we write $\mathfrak{F}, w \models \varphi$. We say φ is *valid on* $\mathfrak{F}$ if it is valid at each point in $\mathfrak{F}$, and we write this as $\mathfrak{F} \models \varphi$. Moreover, we say that a modal formula is *valid on a class of frames* F if it is valid on each frame $\mathfrak{F}$ in F. Note that a valid formula (as defined in Section 2.1) is simply a formula that is valid on the class of all frames.

The starting point for this section is the observation that different applications of modal logic typically validate different modal axioms, axioms over and above those to be found in the minimal system **K**. For example, if we view our models as flows of time, it is natural to assume that the accessibility relation is transitive, and (as the reader should check) any instance of the schema $\Box\varphi \to \Box\Box\varphi$ is valid on the class of transitive frames (for example, the formula $\Box p \to \Box\Box p$ is valid on such frames, and $\Box(p \vee q) \to \Box\Box(p \vee q)$ is too). However no instance of this schema (which for historical reasons is called 4) is provable in **K**, so if we want a logic for working with temporal flows we should add all its instances as extra axioms, and doing so yields the logic known as **K4**. Or suppose we are modeling situations where the frame relation has to be treated

as a partial function. As the reader should check, all instances of the schema $\Diamond\varphi \rightarrow \Box\varphi$ are valid on the class of such frames, and none of them can be proved in **K**, so once again we should add them as extra axioms. Doing so yields the logic called $\mathbf{KAlt}_1$.

We begin this section by briefly discussing such axiomatic extensions of **K** a little further. But our real interest is not the richer logics that arise by adding extra axioms (for an introduction to this topic, see Chapter 2 of this handbook) rather it centres on the following semantic questions: what can modal formulas say about frames, and how do they say it? As we shall see, there is a fundamental expressivity distinction between the level of models and the level of frames: whereas modal logic at the level of models is the bisimulation invariant fragment of first-order logic, at the level of frames it is a fragment of second-order logic.

5.1 Axioms and relational frame properties

One of the most attractive features of modal logic is the illumination provided by the fact that modal axioms reflect properties of accessibility relations. A typical modal completeness theorem reads like this:

THEOREM 24. *A formula is provable in* ***S4*** *iff it is true in all models based on frames whose accessibility relation is transitive and reflexive.*

Proof. See Chapter 2 of this handbook (or indeed, virtually any introduction to modal logic). ❑

That is, the theorems of **S4** are true in all graphs with a transitive and reflexive relation, while its non-theorems have some transitive and reflexive counter-model; the additional axioms reflect simple visualisable geometric conditions in the semantics. There are many techniques for proving such completeness results, ranging from simple inspection of the *canonical model* constructed from all complete theories in the logic (this fundamental technique is introduced in Chapter 2 of this handbook) to various types of model surgery (such as filtration, unraveling, and taking bounded morphic images). Moreover, the motivations for proving modal completeness theorems may differ. Sometimes we start with an independently interesting proof system and try to find a useful corresponding class of frames. The classic example of this is the proof system **GL**, that is **K** enriched with all instances of the Löb axiom schema $\Box(\Box\varphi \rightarrow \varphi) \rightarrow \Box\varphi$, which arose via the study of arithmetical provability (see Chapters 2 and 16 of this handbook for further discussion of **GL**) and was later proved complete with respect to the class of finite trees (where the binary relation interpreting the modalities is the transitive closure of the one-step daughter-of tree relation). Sometimes, however, we might start with a natural model class — say an interesting space-time structure — and try to axiomatise its modal validities. The literature is replete with both variants.

Nowadays a lot is known about axiomatic extensions of **K**. For a start, it turns out that there are uncountably many such *normal modal logics*, as they are often called. It is usual to identify a normal modal logic with the set of formulas it generates, and we say that a modal logic is consistent if it does not contain all formulas. This identification immediately induces a lattice structure on the set of all such logics. The cartography of this landscape is an object of study in its own right; here we shall only mention that, because of the following result, it contains two major highways.

THEOREM 25. *Let* ***Id*** *be the normal modal logic generated by* ***K*** *enriched with all instances of the axiom schema $\varphi \leftrightarrow \Box\varphi$, and let* ***Un*** *be the normal modal logic generated by* ***K*** *enriched with the axiom $\Box\bot$. Every consistent normal modal logic is either a subset* ***Id*** *or* ***Un****.*

Proof. See Makinson [92] for the original (algebraic) proof. After we have introduced generated submodels and bounded morphisms for frames we will be able to sketch the semantic ideas that underly this result, and we shall do this shortly. ❑

Now, as the reader should check, every instance of $\varphi \leftrightarrow \Box\varphi$ is valid on frames which consist of a collection of isolated reflexive points, and $\Box\bot$ is valid on frames consisting of a collection of isolated irreflexive points. Moreover, using standard techniques it is easy to show that **Un** is complete with respect to the first frame class, and **Id** with respect to the second. Thus the semantic content of Theorem 25 is that every normal modal logic is contained in the logic of one of these frame classes; for example, **S4** lies on the first road, and **GL** on the second.

But the most important fact to have emerged about normal modal logics is that *not* all of them have frame-based characterisations. In fact, frame completeness results (such as the result for **S4** noted above) are the exception rather than the rule. Thus our earlier remark that richer logics emerged at the level of frames via the concept of frame validity was very much a first approximation: the notion of frame validity simply does not provide an adequate semantic basis for studying all normal modal logics. Here is a concrete example of a *frame incompleteness* result:

THEOREM 26. *Let* ***TMEQ*** *be the normal modal logic obtained by enriching* ***K*** *with all instances of the following schemas:* $\varphi \to \Diamond\varphi$ *(**T**),* $\Box\Diamond\varphi \to \Diamond\Box\varphi$ *(**M**),* $\Diamond(\Diamond\varphi \wedge \Box\psi) \to \Box(\Diamond\varphi \vee \Box\varphi)$ *(**E**), and* $(\Diamond\varphi \wedge \Box(\varphi \to \Box\varphi)) \to \varphi$ *(**Q**). There is no class of frames that validates precisely the formulas in* ***TMEQ****.*

Proof. See van Benthem [129]. ❑

Such incompleteness results (which were first proved in the early 1970s by Thomason [125] and Fine [43]) were important in the development of modal logic. For a start, they forced modal logicians to examine alternative ways of semantically characterising normal modal logics, and this led to a renaissance in algebraic semantics of modal logic (see Chapter 6 of this handbook for more on this topic). But they also had another effect, one more relevant to the present chapter: they stimulated a wave of semantic research at the level of frames. This new wave of research was centred around the notion of frame definability, the topic to which we now turn.

5.2 Frame definability and undefinability

Before getting to work, a brief remark. There is another way of thinking about axiomatic extensions of **K**. Instead of viewing them as giving rise to brand new modal logics, we can simply view them as *theories* constructed over the minimal logic **K** in much the same way as a first-order theory (of say, linear orders) is constructed over the set of first-order validities. Nothing of substance hangs on this shift of perspective, but it fits more naturally with our focus on expressivity.

So, bearing this in mind, let's pose the first question: what can modal formulas say about frames? A natural way to approach this is to introduce the concept of *frame definability*. We shall say that a modal formula φ defines a class of frames F iff it is valid on precisely the frames in F. That is, not only must φ be valid on every frame in F, it must also be possible to falsify φ on any frame that is not in F. So, what classes of frames can modal languages define? Here are some simple examples:

PROPOSITION 27.

1. $\Box p \to \Box\Box p$ *defines the class of transitive frames; that is, frames such that* $\forall xyz(Rxy \wedge Ryz \to Rxz)$.

2. *$\Diamond p \to \Box p$ defines the class of frames where the frame relation R is a partial function; that is, frames such that $\forall xyz(Rxy \wedge Rxz \to y = z)$.*

3. *$p \leftrightarrow \Box p$ defines the class of frames which consist of isolated reflexive points; that is, frames such that $\forall xy(Rxy \leftrightarrow x = y)$.*

4. *$\Box \bot$ defines the class of frames which consist of isolated irreflexive points; that is, frames such that $\forall xy \neg Rxy$.*

Proof. We have already asked the reader to check that these formulas are valid on the class of frames in question. So to complete the proofs of these definability claims we need merely check that each formula can be falsified on any frame that does not belong to the relevant class.

Let's deal with the second example. Suppose (W, R) is a frame where R is not a partial function. This means that there is a point $w \in W$ that has two distinct R-successors, say u and v. It follows that we can falsify $\Diamond p \to \Box p$ on (W, R) at w. For let V be the valuation that makes p true at u and nowhere else. Then $(W, R, V), w \models \Diamond p$ but $(W, R, V), w \not\models \Box p$, since p is not true at v. So we have falsified $\Diamond p \to \Box p$ on (W, R) as required. ❑

A remark on terminology. Instead of saying, for example, that $\Box p \to \Box\Box p$ defines the class of transitive frames, we often simply say that $\Box p \to \Box\Box p$ defines transitivity. It is also usual to say that $\Box p \to \Box\Box p$ corresponds (at the level of frames) to $\forall xyz(Rxy \wedge Ryz \to Rxz)$, or that $\forall xyz(Rxy \wedge Ryz \to Rxz)$ is a frame correspondent for $\Box p \to \Box\Box p$.

Now for an important question: how do we go about showing that a class of frames *cannot* be modally defined? Answering such questions is typically more demanding than proving the type of result noted in Proposition 27, for instead of checking that a given formula defines a given frame class, we now have to prove that no modal formula is capable of this. How can we prove such general results? By finding ways of transforming frames that preserve frame validity. For if we can show that a class of frames F is *not* closed under such a transformation, it follows that F is *not* modally definable. Let's take a closer look.

The first step is to find transformations that preserve frame validity. Three lie close to hand: the formation of disjoint unions, generated submodels, and bounded morphic images. In Section 3.2 we defined these constructions at the level of models, and they can be lifted to the level of frames simply by ignoring the requirements imposed on the valuations. For example, a bounded morphism between frames (W, R) and (W', R') is a function f from W to W' that satisfies the morphism condition (if Rwv, then $R'f(w)f(v)$) and the zag condition (if $R'f(w)v'$, then there exists a v such that $f(v) = v'$ and Rwv), and we say that frame (W', R') is a bounded morphic image of frame (W, R) if there is a surjective bounded morphism from (W, R) to (W', R'). Lifting these constructions to the level of frames immediately gives us three validity preservation results:

THEOREM 28. *For all basic modal formulas φ we have that:*

1. *Let $\{\mathfrak{F}_i \mid i \in I\}$ be a family of frames. Then if $\mathfrak{F}_i \models \varphi$ for every i in I, we have that $\biguplus \mathfrak{F}_i \models \varphi$ too. That is, frame validity is preserved under the formation of disjoint unions.*

2. *Let $\mathfrak{F}'$ be a generated subframe of $\mathfrak{F}$. Then if $\mathfrak{F} \models \varphi$, we have that $\mathfrak{F}' \models \varphi$ too. That is, frame validity is preserved under the formation of generated subframes.*

3. *Let $\mathfrak{F}$ and $\mathfrak{F}'$ be frames and f a surjective bounded morphism from $\mathfrak{F}$ to $\mathfrak{F}'$. Then if $\mathfrak{F} \models \varphi$, we have that $\mathfrak{F}' \models \varphi$ too. That is, frame validity is preserved under the formation of bounded morphic images.*

Proof. We prove the result for bounded morphisms; we show the contrapositive. Given frames $\mathfrak{F} = (W, R)$ and $\mathfrak{F}' = (W', R')$ such that $\mathfrak{F}'$ is a bounded morphic image of $\mathfrak{F}$ under f, suppose that $\mathfrak{F}' \not\models \varphi$. This means that for some valuation V' on $\mathfrak{F}'$ and some point $w' \in W'$ we have that $(\mathfrak{F}', V'), w' \not\models \varphi$. Let V be the valuation on $\mathfrak{F}$ defined by $V(p) = \{u \in W \mid f(u) \in V'(p)\}$, for all proposition symbols p. Furthermore, let w be any point such that $f(w) = w'$; there must be at least one such point as f is surjective. Then the model $(\mathfrak{F}', V')$ is a bounded morphic image of the model $(\mathfrak{F}, V)$, and hence $(\mathfrak{F}, V), w \not\models \varphi$. ❑

Applying this theorem immediately gives rise to a crop of non-definability results. Here are some simple ones. Basic modal languages cannot define the class of simply connected frames, that is, the class of frames such that $\forall xy(Rxy \vee Ryx)$. Why not? Because this class is not closed under the formation of disjoint unions: taking the disjoint union of two frames with this property clearly results in a frame without it. As a second example, the basic modal languages cannot define the class of frames containing an isolated reflexive point. Why not? Because this class is not closed under the formation of generated subframes. For consider a frame consisting of two isolated points, one reflexive, the other irreflexive. This frame belongs to the required class, however the subframe generated by the irreflexive point does not. As a third example, the class of irreflexive frames is not modally definable. Why not? Because it is not closed under the formation of bounded morphic images (recall the bounded morphism of Figure 13 which collapses the natural numbers to a single reflexive point). But frame validity is preserved under this transformation, hence no modal formula can define irreflexivity. For more sophisticated applications of these validity preservation results, see van Benthem [137].

These results also give us insight into the semantic ideas behind Theorem 25. For consider a consistent normal logic. Suppose one of the frames on which it is valid contains an isolated irreflexive point; then (appealing to the preservation of validity under generated subframes) the frame consisting of just that single point validates the logic too. So suppose that no frame containing an isolated point validates the logic. But this means that in all frames that validate the logic, every point has at least one successor. But if we map all the points in such a frame to a singleton reflexive point, the mapping is a bounded morphism. Hence it follows that the logic is validated on frames consisting of isolated reflexive points.

As we shall soon see, the three frame transformations just introduced all play a role in the Goldblatt-Thomason Theorem, a characterisation of modally definable classes of elementary frames. But a fourth transformation, namely the formation of *ultrafilter extensions*, is also needed to complete the statement of this celebrated result, so let's take this opportunity to define this (somewhat more complex) frame construction. First we recall a standard mathematical concept. Given a non-empty set W, a *filter* F over W is any subset of 2^W (the power set of W) that contains W and is closed under finite intersection (that is, if $X, Y \in F$ then $X \cap Y \in F$) and set-theoretic inclusion (that is, if $X \in F$ and $X \subseteq Y \subseteq W$ then $Y \in F$). A filter is called *proper* if it is distinct from 2^W. An *ultrafilter* is a proper filter U such that for all $X \in 2^W$, $X \notin U$ iff $(W \backslash X) \in U$. A standard result assures us that any proper filter can be extended to an ultrafilter. Bearing this in mind, we make the following definition:

DEFINITION 29 (Ultrafilter Extensions of Frames). Let $\mathfrak{F} = (W, R)$ be a frame. For any $X \subseteq W$ we define $l(X)$ to be $\{w \in W \mid \text{for all } v \in W, \text{if } Rwv \text{ then } v \in X\}$. Then the ultrafilter extension $ue(\mathfrak{F})$ of $\mathfrak{F}$ is defined to be the frame $(uf(W), R^{ue})$, where $uf(W)$ is the set of all ultrafilters on W and R^{ue} is the relation consisting of all pairs of ultrafilters U, U' such that for all $X \subseteq W$, if $l(X) \in U$, then $X \in U'$.

We can now state the required theorem. Note that the direction of validity preservation is

the reverse of that found in Theorem 28. That is, here frame validity is preserved from the transformed frame (here the ultrafilter extension) back to the original one:

THEOREM 30. *For any basic modal formula φ, if $ue(\mathfrak{F}) \models \varphi$ then $\mathfrak{F} \models \varphi$ does too. That is, frame validity reflects ultrafilter extensions.*

Proof. The use of ultrafilter extensions in modal logic traces back to Goldblatt [57, 58], van Benthem [130], and Fine [44]. For a detailed proof of this theorem, see Proposition 2.59 and Corollary 3.16 of Blackburn, de Rijke and Venema [13]. ❑

Although this transformation is harder to visualise than the previous three, it too gives rise to some simple non-definability results. Here's a nice example, taken from Goldblatt and Thomason [60], showing that the class of frames satisfying $\forall x \exists y(Rxy \wedge Ryy)$ is not modally definable. We can see this as follows. The ultrafilter extension of $(\mathbb{N}, <)$, the natural numbers in their usual order, looks a bit like a gigantic lolly-pop. It has an infinite handle, an isomorphic copy of $(\mathbb{N}, <)$, consisting of all the principal ultrafilters (that is, those ultrafilters which contain a singleton set $\{n\}$, where n is a natural number). This is followed by the lolly: an uncountable collection of non-principal ultrafilters which are all related to one another and reflexively related to themselves. Hence $ue(\mathbb{N}, <)$ has the property $\forall x \exists y(Rxy \wedge Ryy)$. Why? Because every point in the frame is related to the reflexive points in the lolly. However this formula is clearly not valid on the original frame $(\mathbb{N}, <)$. As frame validity reflects ultrafilter extensions, it follows that the class of frames satisfying $\forall x \exists y(Rxy \wedge Ryy)$ is not modally definable. For further discussion of ultrafilter extensions from a model-theoretic perspective, see Chapter 5 of this handbook. There is also an important algebraic perspective on ultrafilter extensions, which is discussed in Chapter 6.

5.3 *Frame correspondence and second-order logic*

Now that we have some idea of what basic modal languages can (and cannot) say about frames, we turn to the second question: how do they say it? And here we encounter something interesting. Note that all four classes of frames mentioned in Proposition 27 are definable by simple first-order formulas — and this is actually rather puzzling. After all, if you think about what it means for a basic modal formula $\varphi(p_1, \ldots, p_n)$ to be valid on a frame, we see that this concept is essentially *second-order*: we quantify across all possible valuations, and valuations assign *subsets* of frames to proposition symbols.

We can make this second-order perspective precise with the help of the standard translation. Let $\mathfrak{F}$ be a frame, let $\mathfrak{M} = (\mathfrak{F}, V)$ be any model over $\mathfrak{F}$, and let w be any point in $\mathfrak{F}$. By Proposition 3 we have that

$$(\mathfrak{F}, V), w \models \varphi(p_1, \ldots, p_n) \text{ iff } (\mathfrak{F}, V) \models \mathrm{ST}_x(\varphi)(P_1, \ldots, P_n)[x \leftarrow w].$$

(Here $P_1, \ldots, P_n$ are the monadic predicate symbols used to translate the proposition symbols $p_1, \ldots, p_n$.) How do we lift this equivalence (which lives at the level of models) to an equivalence at the level of frames (the level where validity is the primary semantic concept)? Very straightforwardly. A formula is valid on a frame iff it is satisfied at any point in the frame under any assignment of subsets of the frame to the proposition symbols. So we only need to universal quantify over the points that can be assigned to x (a first-order quantification) and over the assignments to the monadic symbols $P_1, \ldots, P_n$ (a second-order quantification). Doing so gives us the fundamental correspondence between frame validity and second-order logic:

$$\mathfrak{F} \models \varphi(p_1, \ldots, p_n) \text{ iff } \mathfrak{F} \models \forall P_1 \cdots P_n \forall x \mathrm{ST}_x(\varphi).$$

In short, frame validity systematically treats modal formulas φ as the universal monadic second-order closure of their standard first-order translations on relational models. The second-order upgrade of the first-order correspondence language is often called the *frame correspondence language* or the *second-order correspondence language*.

Let's look at an example. Recall that in Section 2.2 we showed that the standard translation of $p \to \Diamond p$ was $Px \to \exists y(Rxy \wedge Py)$. So if we ask what $p \to \Diamond p$ defines at the level of frames we can give an immediate answer: it defines the class of frames satisfying the following monadic second-order formula:

$$\forall P \forall x(Px \to \exists y(Rxy \wedge Py)).$$

Now, it's certainly pleasant to be able to systematically calculate frame correspondences for modal formulas in this way — but the puzzle remains. Indeed, if anything it has become more acute. For most of the modal formulas encountered in practice correspond to simple first-order conditions on frames, yet these conditions are systematically expressed using rather complex second-order expressions. The translation just considered is a good example. As the reader should check, $p \to \Diamond p$ corresponds to the first-order formula $\forall x Rxx$ (that is, it defines reflexivity). And if you think about it, you will see that $\forall P \forall x(Px \to \exists y(Rxy \wedge Py))$ is indeed a rather roundabout way of expressing reflexivity. For a start, it's easy to see that this sentence is true on any reflexive frame. Conversely, if this sentence is true on a frame (W, R), then $Px \to \exists y(Rxy \wedge Py)$ must be true under any assignment to the free variables x and P. Hence, for any $w \in W$, this formula is true if we assign w to x and $\{w\}$ to P. This assignment makes the antecedent true (indeed, it is the *minimal* valuation required to make the antecedent true; the significance of this remark will become clear when we discuss the Sahlqvist Correspondence Theorem) so we must have that $\exists y(Rxy \wedge Py)$ is true too. But this is only possible if Rww. Hence, as w was arbitrary, this means that R must be reflexive, and thus the original second-order sentence really does express reflexivity. As we said earlier, one of the key questions we are interested in is *how* modal languages talk about frames. And now we have an answer. They do so via a detour through second-order logic.

Moreover, this detour is *not* eliminable. That is, while experience shows that most common modal formulas correspond to first-order conditions on frames, some modal formulas define conditions that are *not* elementary. A famous case is Löb's formula, $\Box(\Box p \to p) \to \Box p$, the characteristic axiom of the logic **GL**. This defines the conjunction of the transitivity of R with the converse well-foundedness of R (that is, it forbids the existence of infinite chains of related points $w_1 R w_2 R w_3 R w_4 R w_5 \ldots$). This condition is non-elementary, as an appeal to the Compactness Theorem for first-order logic shows. Another well-known modal axiom that defines a non-elementary class of frames is the McKinsey formula $\Box\Diamond p \to \Diamond\Box p$. This can be shown by appealing to the Löwenheim-Skolem Theorem for first-order logic. For full proof details for both the Löb and McKinsey examples, see Blackburn, de Rijke and Venema [13].

Summing up, we are confronted with an intriguing situation. At the level of frames, modal formulas systematically correspond to second-order conditions on frames. Nonetheless, in many common cases these second-order conditions turn out to be equivalent to first-order conditions. This raises some interesting questions. Are there criteria that demarcate modal formulas that are essentially first-order at the level of frames from the genuinely second-order ones? And can we characterise the elementary frame classes that are modally definable?

5.4 First-order frame definability

As we have just learned, the link between first-order definable frame classes and modal logic is not straightforward. Nonetheless, some elegant general results are known, and we shall briefly discuss three of them here. We first note two results which bear upon the demarcation issue: the Sahlqvist Correspondence Theorem (which isolates a large class of formulas all of which define elementary classes of frames) and a model-theoretic characterisation of the modal formulas which define elementary frame classes. Following this we discuss the celebrated Goldblatt-Thomason Theorem, a model-theoretic characterisation of the elementary frame classes that are basic modal definable. All three results (and others bearing on the theme of elementary frame definability) are discussed in greater detail in Chapter 5 of this handbook.

Let's start with the Sahlqvist [111] result. Upon closer inspection, first-order frame conditions often arise because of the syntactic shape of the defining modal formula — for example the quantifier shape of the first-order formula for transitivity is matched by the sequence of boxes in $\Box p \to \Box\Box p$. The following theorem gives us a natural account of such correspondences. It trades systematically on the idea (noted when we discussed the second-order definition of reflexivity) of substituting minimal verifying valuations in antecedents.

THEOREM 31 (Sahlqvist Correspondence Theorem). *There is an effective method for computing first-order equivalents for Sahlqvist formulas, that is, formulas of the form $\varphi \to \psi$ with antecedents φ constructed from atoms (possibly prefixed by boxes) using conjunctions, disjunctions and diamonds, while consequents ψ can be any modal formula with only positive occurrences of proposition symbols.*

Proof. The effective method (in the form originally introduced by van Benthem [128, 131]) is usually called the substitution algorithm. The following example will give an idea of how it works. The 4 formula, $\Box p \to \Box\Box p$, is a Sahlqvist formula and its second-order translation is

$$\forall P \forall x(\forall y(Rxy \to Py) \to \forall y(Rxy \to \forall z(Ryz \to Pz))).$$

Now, if we could eliminate all the occurrences of P in this formula, we would render the second-order quantification needed to express validity vacuous. But can P be eliminated in a semantically sensible way? Because of the syntactic restrictions that Sahlqvist formulas conform to, it turns out that it can. We do so by replacing P by a first-order expression describing the *minimal* valuation needed to make the antecedent of $\Box p \to \Box\Box p$ true. Now, the minimal way of making $\Box p$ true is to make p true at all successors of the point of evaluation x, so the required substitution is $Pu := Rxu$. Performing this substitution yields the following first-order expression:

$$\forall x(\forall y(Rxy \to Rxy) \to \forall y(Rxy \to \forall z(Ryz \to Rxz))).$$

The antecedent is now tautologically true, and dropping it leaves us with the expression

$$\forall x \forall y(Rxy \to \forall z(Ryz \to Rxz)).$$

But this is a first-order formula expressing transitivity. For a precise specification of the substitution algorithm, and a proof that it works as required, see Blackburn, de Rijke and Venema [13]. The heart of the proof is to show that a Sahlqvist antecedent is true under any value for its proposition symbols iff it is true under its *minimal* values. ❑

The Sahlqvist Correspondence Theorem and its proof method are very powerful and can be extended to far stronger modal languages. Nevertheless there are also modal formulas which

express first-order conditions on frames that are not covered by the theorem. The **K4.1** axiom

$$(\Box p \to \Box\Box p) \land (\Box\Diamond p \to \Diamond\Box p)$$

is a conjunction of the 4 axiom with the McKinsey axiom. It defines the class of frames with a transitive and atomic relation, that is the class of transitive frames such that $\forall x \exists y (Rxy \land \forall z (Ryz \to z = y))$. But this first-order equivalence cannot be computed using the substitution method. See van Benthem [137] or Blackburn, de Rijke and Venema [13] for further discussion.

So the Sahlqvist result doesn't fully pin down the modal formulas that define elementary frame classes. However model-theoretic characterisations exist. For example we have:

THEOREM 32. *A modal formula defines a first-order frame property iff it is preserved under taking ultrapowers of frames.*

Proof. For the original proof, see van Benthem [131]. For an introduction to ultrapowers, consult Chang and Keisler [23]. ❑

Closure under ultrapowers is an abstract feature, and it is not easy to use it to recognise whether a given modal formula is first-order over frames. But then no simple method can be expected to work: Chagrova [21] shows that the problem of determining whether a modal formula expresses a first-order condition on frames is undecidable.

But now for our other question: which elementary classes of frames are modally definable? The classic result here is the Goldblatt-Thomason Theorem. This tells us that the four frame preservation results noted earlier are not merely necessary, they are also *sufficient* to characterise first-order frame definability:

THEOREM 33 (Goldblatt-Thomason Theorem). *A first-order frame property is modally definable iff it is preserved under taking disjoint unions, generated subframes, bounded morphic images, and reflects ultrafilter extensions.*

Proof. The left-to-right direction is just a restatement of the results noted in Theorems 28 and 30. The real work lies in the converse. The original proof, due to Goldblatt and Thomason [60] was algebraic; we briefly discuss this approach in Section 7.1, and an algebraic proof is given in Chapter 6 of this handbook. Nowadays there are also purely model-theoretic proofs; see van Benthem [133] for the earliest of these. ❑

5.5 Correspondence in richer languages

Throughout this section we have kept our eyes firmly on the goal of understanding modal expressivity with respect to elementary frame classes. This is an important topic (after all, we want to understand as much as possible about the route modal logic over frames takes from monadic second-order logic back to first-order logic) but it is also natural to wonder about the expressivity of modal logic with respect to non-elementary frame classes. Unfortunately, it is harder to come up with elegant answers here. In particular, we can't expect sweeping model-theoretic characterisations. Model-theoretic characterisations of elementary frame definability, such as Theorem 32 and the Goldblatt-Thomason Theorem, rest on the conceptual edifice of first-order model theory. Second-order model theory is nowhere near as well developed.

Nonetheless, some interesting results are known. For example, it turns out that we can apply the ideas underlying the proof of the Sahlqvist Correspondence Theorem beyond the confines of first-order logic. Let's briefly consider what is involved. The following discussion is based on

van Benthem [138]. Chapter 5 of this handbook contains a more detailed discussion of related material.

The substitution algorithm for Sahlqvist formulas runs into difficulties with more complex antecedents; a classic example is Löb's formula $\Box(\Box p \to p) \to \Box p$, which defines a non-elementary class of frames. But let's reflect on *why* we compute the minimal antecedent values for Sahlqvist formulas. In fact there are two reasons. Firstly, because Sahlqvist antecedents are true under any value for their proposition symbols iff they are true under their *minimal* values. Secondly, because such minimal predicates are first-order definable. Now, as it happens, the Löb antecedent does not fulfil the first-order definability criterion, but this does not mean that all that can be said is that the Löb's formula is intrinsically second-order — for, as it turns out, there is a smallest semantic value for the predicate P which will make its antecedent true. This is the set of points in the frame obtained by taking the *intersection* of all predicates P validating $\Box(\Box p \to p)$ where p is interpreted as P. Such a set must exist, because the standard translation of the Löb antecedent has a special syntactic form. Call a first-order formula $\varphi(P)$ *intersective* if it has one of the forms:

1. $\forall x(\psi(P, Q, x) \to Px)$, with P occurring only positively in $\psi(P, Q, x)$.
2. $\psi(P, Q)$, with P occurring only negatively in ψ.

It is easy to show that all formulas $\varphi(P)$ of this form have the above-mentioned *intersection property*: if $\varphi(P)$ holds for any predicate P it holds for the intersection of all predicates P satisfying it.

Thus it makes sense to talk about $minP.\varphi(P)$, the *minimal* satisfying predicate. Of course, such predicates need not be first-order definable, but it is not hard to show that minimal predicates for intersective first-order formulas are definable in a well-known extension of first-order logic, namely *LFP(FOL)*, first-order logic with monotonic fixed-points (we shall introduce the idea of monotonic fixed-points in more detail when we discuss the modal μ-calculus in Section 6). *LFP(FOL)* has many uses in computer science; it lies between first-order and second-order logic, and retains many useful model-theoretic properties such as invariance for potential isomorphism (see Ebbinghaus and Flum [35] for an introduction to *LFP(FOL)*).

Now, once we have such a minimal value for the antecedent predicates, it can be substituted into the consequent to obtain a frame equivalent just as before — though now, of course, we obtain an equivalent in *LFP(FOL)*. To return to our example, the standard translation of the Löb antecedent $\forall y((Rxy \wedge \forall z(Ryz \to Pz)) \to Py)$ is indeed intersective in the above sense. Therefore, the corresponding frame property of the Löb formula can be computed and (as we would expect) the result is an *LFP(FOL)* formula defining the property of transitivity plus converse well-foundedness. As a second example, consider the axiom of cyclic return:

$$(\Diamond p \wedge \Box(p \to \Box p)) \to p.$$

Again, this is not a Sahlqvist formula. But again, the antecedent is intersective (once we have moved out the modal $\Diamond$ to become a prefixed universal quantifier, as before in the substitution algorithm) and gives rise to a simple fixed-point computation for an equivalent frame property:

> *Every point x with an R-successor y can be reached from y by a finite sequence of successive R-steps.*

We can express this condition in *LFP(FOL)* as follows. First we define the concept of transitive closure:

$$R^+xy \;=_{def}\; minS, xy.Rxy \vee \exists z(Rxz \wedge Szy).$$

We can then capture the stated frame condition by insisting that:

$$\forall xy(Rxy \rightarrow R^{+}yx).$$

This is the beginning of a further layering of modal formulas with respect to semantic complexity. For there are also modal formulas with frame equivalents which cannot be expressed in *LFP(FOL)*. One example is the well known axiom in tense logic expressing Dedekind Completeness of linear orders, which is not preserved under the potential isomorphism between the rationals and the reals. And recently, van Benthem and Goranko have shown that the McKinsey formula, whose antecedent is typically non-intersective, does not correspond to any *LFP(FOL)* formula.

We started this chapter by saying that the process interpretation is a fundamental way of viewing modal logic. The present discussion shows that there is a natural link between modal logic and a far more sophisticated logic of processes, namely *LFP(FOL)*. We will return to the process interpretation in Section 6 when we examine Propositional Dynamic Logic and the modal μ-calculus, stronger modal languages which, like *LFP(FOL)*, can express some non-elementary concepts, such as transitive closure.

5.6 *Remarks on computability*

In Section 4 we contrasted the PSPACE decidability of modal logic with the undecidability of first-order logic. But these results concerned satisfiability and validity on the class of all frames. Suppose we restrict attention to particular classes of frames defined by basic modal formulas. There is no reason to suppose that modal satisfiability and validity problems over such frame classes will always be in PSPACE, or even that they will be decidable. And indeed, in many cases they are not not.

In some cases, restricting attention to a certain class of frames may lower the computational complexity. For example, suppose we restrict attention to the frames defined by $\Diamond p \rightarrow \Box p$, that is, the class of frames in which R is a partial function. Then the task of testing basic modal formulas for satisfiability becomes NP-complete, that is, no worse than the satisfiability problem for propositional logic. This is because (as the reader can easily check) if a basic modal formula φ has a model based on a frame in this class, then it not only has a finite model in this class, but a model containing at most $n + 1$ points, where n is the number of modalities in φ. Thus a non-deterministic algorithm which guesses a model, checks that it belongs to the frame class, and verifies that the formula is satisfied on it, runs in time polynomial in the size of φ.

But restricting attention to particular frame classes can easily result in undecidable problems. A recurring theme is the distinction between tree-like and grid-like models. We have already discussed why tree-like models are relevant to modal decidability over the class of all models; here we'll merely add that many more modal decidability results can be proved by appealing to *Rabin's Theorem* (see [107]), which in its simplest form shows that the monadic second-order theory of binary branching trees is decidable. Grid-like models, on the other hand, are (roughly speaking) those that contain regions that look like $\mathbb{N} \times \mathbb{N}$ (the product of the natural numbers with itself) under two orderings: the horizontal ordering (that is, $(j, k)R^{h}(j + 1, k)$), and the vertical ordering (that is, $(j, k)R^{v}(j, k+1)$) which together give rise to the characteristic grid-like shape. Now, it is hard to give precise generalisations, but experience shows that while even very strong modal languages tend to be decidable over tree-like models, even quite weak languages can be undecidable over grid-like models; we shall note such an example in Section 6 when we discuss combinations of modal logics. Such undecidability results ultimately trace back to the possibility

of encoding the $\mathbb{N} \times \mathbb{N}$ *tiling problem*, which is known to be undecidable. For a detailed account of the tiling problem, and a proof that it is undecidable, see Berger [12]. Here we'll simply say that it is essentially a geometrical puzzle. We are presented with a finite collection of square tile types, of fixed orientation. Each edge of each tile type is coloured. The $\mathbb{N} \times \mathbb{N}$ tiling problem asks: is it possible to write an algorithm which, when presented with such a collection of tile types, can correctly determine whether or not $\mathbb{N} \times \mathbb{N}$ can be tiled, using only tiles of the given type, in such a way that colours on adjacent tile edges match? That is, is it possible to place a tile (of one of these types) on each point of $\mathbb{N} \times \mathbb{N}$, in such a way that colours match both vertically and horizontally? For some tile types, this is possible, for others it is impossible. However there is no algorithm for deciding for which tile types this can be done; it is a simple, and elegant, example of a computationally undecidable problem. Showing that a modal logic is strong enough to encode this problem is often a straightforward way of showing its undecidability; see Blackburn, de Rijke and Venema [13] for examples of how to use the tiling problem in this way.

In a slogan: trees tend to be safe, but beware of grids. Somewhat poetically, we can imagine modal logic as a small boat navigating somewhere on the border between decidability and undecidability, as Figure 18 shows.

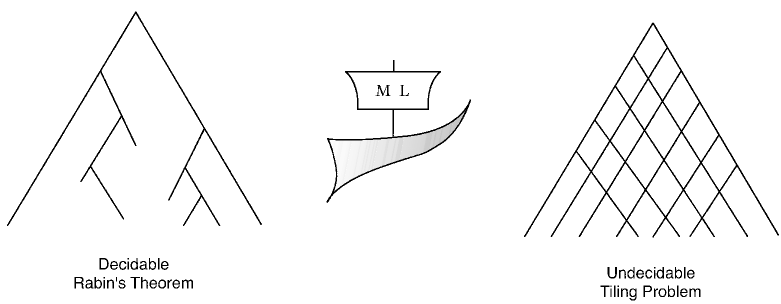

Figure 18. Modal logic: tacking between safety and danger.

Furthermore, it is important to realise that undecidable problems arise even when attention is restricted to finite frames; see, for example, Urquhart [127]. And indeed, even in the finite case, undecidability turns out to be the norm. It is straightforward to show that there are non-denumerably many distinct frame satisfiability problems over finite frame classes (an elegant demonstration of this, due to Spaan [118], is given as Exercise 6.2.4 of Blackburn, de Rijke and Venema [13]). As there are only denumerably many computable functions, undecidability is almost always guaranteed.

So what about recursive enumerability? That is, if we restrict attention to a class of frames F that is defined by a modal formula, is the theory of this frame class (that is, the set of formulas φ valid on all frames F) recursively enumerable? Well, if F is elementary, the answer is yes:

PROPOSITION 34. *Suppose that F is an elementary class of frames defined by a basic modal formula φ. Then the set of basic modal formulas that are valid on all frames in F is recursively enumerable.*

Proof. As F is an elementary class that φ defines, φ corresponds to some first-order formula α. Now a basic modal formula ψ is valid on frames for φ iff its second-order translation

$\forall P_1 \cdots P_n \forall x \text{ST}_x(\psi)$ is true in all models of the first-order formula α, that is, iff

$$\alpha \models \forall P_1 \cdots P_n \forall x \text{ST}_x(\psi),$$

where $\models$ is classical entailment. But as α is first-order, referring to R only, the predicates $P_1 \cdots P_n$ do not occur in α and hence this is equivalent to

$$\alpha \models \forall x \text{ST}_x(\psi).$$

But this is a first-order entailment, and as such entailments are recursively enumerable the result follows. ❑

However once we move beyond the elementary frame classes, even recursive enumerability is lost. A key result here is Thomason's [126] reduction of the standard consequence relation for the second-order correspondence language to the *global frame consequence* relation for a basic modal language with one modality. A basic modal formula φ is a global frame consequence of Γ if for all frames $\mathfrak{F}$, if $\mathfrak{F} \models \Gamma$, then $\mathfrak{F} \models \varphi$. It follows that global frame consequence is not recursively enumerable. Indeed, it is even Σ^1_1-complete, which means it is as hard to decide as the existential second-order theory of the natural numbers under the less-than-or-equal ordering. To put it another way: this is an example of a *highly undecidable* problem. For further discussion of Thomasons's work in this area, see Chapter 7 of this handbook.

6 RICHER LANGUAGES

So far we've been dealing almost exclusively with the basic modal language. We've seen that the key to its expressive power lies in the notion of bisimulation and that (at least when interpreted over the class of all models) it has better computational properties than first-order logic. All in all, the basic modal language is really rather elegant, so we might be tempted to ask: is it possible to lift (at least some of) its attractive properties to stronger languages? That is, can we design richer modal languages that retain, or even enhance, those features that make the basic modal language special? In fact, modal logicians have been experimenting with richer languages for years, and in this section we survey some of their work. As we shall see, this line of work adds a new dimension to our understanding of modal logic and relational semantics.

But what should count as a richer modal language? It's easier to explain what shouldn't. Here's an obvious example. It is straightforward to extend our basic definitions to cover *polyadic modalities* (that is, n-place diamonds and boxes). Simply work with models in which there is an $n+1$-place relation R^m for every n-place diamond $\langle m \rangle$. We interpret $\langle m \rangle$ using the following satisfaction clause:

$$\begin{array}{lll} \mathfrak{M}, w \models \langle m \rangle(\varphi_1, \ldots, \varphi_n) & \text{iff} & \text{for some } v_1, \ldots, v_n \in W \text{ such that } R^m w v_i \ldots v_n \\ & & \text{we have } \mathfrak{M}, v_1 \models \varphi_1 \text{ and } \ldots \text{ and } \mathfrak{M}, v_n \models \varphi_n. \end{array}$$

Now, such n-place modalities are undeniably useful for certain purposes, especially when interpreted over restricted classes of frames. For example, when working with spatio-temporal structures, we might want to add a three place modality to capture the notion of "between", or we might want to explore the logical theory of function composition, as is done in the branch of modal logic known as arrow logic (see Marx and Venema [94]). Nonetheless, when working with the class of all models, developing the basic semantic theory (standard translation, bisimulation,

and so on) of polyadic modal operators is essentially a matter of sprinkling our earlier work with additional indices.

As we shall see, the richer languages explored in this section offer much more. Moreover, their richness takes us in many different directions. Sometimes the enrichment consists of taking a standard language and insisting that a modality be interpreted by some mathematically fundamental relation (the universal modality is a good example). Sometimes the enrichment takes the form of more complex satisfaction definitions (both temporal logic with Until and Since and conditional logic are examples of this). In other cases, syntactic enhancements are introduced to support novel semantic capabilities (hybrid logic, propositional dynamic logic, and the modal μ-calculus all do this) and in one case (the guarded fragment) we enrich by abandoning modal syntax and using first-order syntax instead. Moreover, it is also possible to enrich by combining logics. For example, we might combine two propositional modal logics to enable some application domain to be more accurately modeled, or we might combine modal logic with first-order logic, a move which takes us to the historical heartland of philosophical applications of modal logic. As we shall see, modal logicians have been extremely creative when it comes to devising richer languages.

Of course, this variety raises a question of its own: what, if anything, do all these richer languages have in common? That is, what makes them all modal? This is not an easy question to answer. Nonetheless, as we work our way through this landscape a number of themes will recur: robust decidability, the importance of bisimulations, and characterisations of fragments of first- and second-order logic. As we shall see at the end of the section, the idea of restricted quantification that underlies the guarded fragment goes a long way towards accounting for these properties, for both first- and second-order enrichments. Moreover, it is possible to draw on ideas from abstract model theory and prove Lindström-style characterisation results. In short, we will often be able to lift much of the fundamental semantic theory for basic modal logic to a whole new level, a good indication that the enrichments discussed below are, in an important sense, genuinely modal.

6.1 *The universal modality*

Time to feed the bears again. As we said in Section 4, some problems demand a global perspective. We sometimes want to view a modal formula as a general background constraint, something that must be satisfied at *all* points in a model. Indeed, because of the importance of background constraints, in many practical situations we are primarily interested in the local-global satisfiability problem, which we formulated as follows: given basic modal formulas φ and ψ, is there a model which locally satisfies φ and globally satisfies ψ? Now, description logic, with its two level architecture of TBoxes (which impose general constraints) and ABoxes (which give information about particular individuals), acknowledges the importance of this problem (the information in a TBox has to be globally satisfied, while the information in an ABox only has to be locally satisfied). But the ability to impose global constraints is not incorporated into description logic concept languages (which are essentially notational variants of the basic modal languages we are familiar with) and this raises an interesting question. Is it possible to internalise the notion of global satisfiability in a modal language? And if so, what happens?

Let's introduce the *universal modality* and find out. To keep things simple, suppose we are working in a language with just one modality. We shall add a second modality, and will write E for its diamond form, and A for its box form. The interpretation of E and A is fixed: in any model $\mathfrak{M} = (W, R, V)$, both modalities must be interpreted using the universal relation $W \times W$. That

is, the satisfaction definition for these modalities is:

$$\begin{array}{lll} \mathfrak{M}, w \models E\varphi & \text{iff} & \text{there is a } u \in W \text{ such that } \mathfrak{M}, u \models \varphi \\ \mathfrak{M}, w \models A\varphi & \text{iff} & \text{for all } u \in W \text{ we have } \mathfrak{M}, u \models \varphi. \end{array}$$

Thus $E\varphi$ scans the entire model for a point that satisfies φ, while $A\varphi$ asserts that φ holds everywhere. We have imported the meta-theoretic notion of global truth into our modal object language, or to put it another way, we have internalised the TBox. Accordingly, we call E the *universal diamond*, and A the *universal box*. If it is irrelevant whether we mean E or its dual, we simply talk of the *universal modality*.

How can we be sure that adding the universal modality really increases the expressive power at our disposal? That is, are we certain that E and A are not already definable in the basic modal language? We are. One way to see this is via a bisimulation argument (see Example 2.4 in Blackburn, de Rijke and Venema [13] for such a proof). But an easy complexity-theoretic argument also establishes this. Let φ and ψ be basic modal formulas. Then the formula $A\psi$ expresses the global satisfiability problem (for the basic modal language) in our new language, and the formula $\varphi \wedge A\psi$ expresses the local-global satisfiability problem (for the basic modal language) again in our new language. Now, we remarked in Section 4 that both these problems are EXPTIME-complete. However the satisfiability problem for the basic modal language is PSPACE-complete. Hence (assuming that PSPACE is strictly contained in EXPTIME , the standard assumption) our ability to express these problems in the enriched language shows that the apparent increase in expressive power is genuine.

This in turn raises a new question. Because it can encode these problems, the satisfiability problem for the enriched language is at least EXPTIME-hard. But are some problem-instances even harder? No. Everything is solvable in EXPTIME.

THEOREM 35. *The satisfiability problem for the basic modal language enriched with the universal modality is EXPTIME-complete.*

Proof. See Hemaspaandra [65], or her earlier PhD thesis Spaan [118]. ❑

But the universal modality not only gives us extra expressivity at the level of models, it also increases our ability to define new classes of frames. Moreover, an elegant variant of the Goldblatt-Thomason Theorem holds for the enriched language. We'll discuss this result shortly, but let's first consider two examples of newly definable frame classes.

The class of frames of cardinality less than or equal to some natural number n (that is, frames in which $|W| \leq n$) is not definable in the basic modal language. Why not? Because basic modal validity is closed under the formation of disjoint unions. Hence any basic modal formula φ which allegedly defined this frame class could easily be shown to fail: simply by sticking together enough frames we could validate φ on frames of cardinality greater than n.

But this condition *is* definable with the help of the universal modality:

$$\bigwedge_{i=1}^{n+1} Ep_i \rightarrow \bigvee_{i \neq j} E(p_i \wedge p_j).$$

As the reader can easily check, this formula is valid on any frame where $|W| \leq n$, and can be falsified on any larger frame (in essence, the formula encodes the pigeonhole principle for $n+1$ pigeons and n holes). It follows that validity in the enriched language is not preserved under the

formation of disjoint unions. This, of course, is as it should be. We want a genuine *universal* modality, not something that can be fooled by the addition of new components.

Here's a second example. The condition $\forall x \exists y\, Ryx$ (that is, every point has a predecessor) is not definable in basic modal logic. Why not? Because modal validity is preserved under the formation of generated subframes. Any basic modal formula which putatively defined this class would have to be valid on the frame $(\mathbb{N}, R)$, where Rnm iff $n > m$, the natural numbers under the reverse ordering. But (by preservation under generated subframes) it would then have to be valid on the subframe generated by any number n. But in any such subframe, n has no predecessor, hence the condition is not basic modal definable.

But it *is* definable with the help of the universal modality:

$$p \to E\Diamond p.$$

It is easy to check that this formula defines the required condition, hence it follows that validity in the enriched language is not preserved under generated subframes. Again, this is the way it should be. A genuinely universal modality will not let us throw away points: its purpose is to keep an eye on the entire frame. It should be intolerant of both additions (disjoint unions) and deletions (generated submodels).

And now for the promised result: when it comes to defining elementary frame classes, intolerance towards disjoint unions and generated submodels is precisely what distinguishes the enriched language from the basic modal language. The following result is the Goldblatt-Thomason Theorem for the basic modal language, with closure under disjoint unions and generated subframes stripped away:

THEOREM 36. *A first-order definable class of frames is definable in the basic modal language enriched with the universal modality iff it is closed under taking bounded morphic images, and reflects ultrafilter extensions.*

Proof. See Goranko and Passy [61]. ❑

Three comments. First, adding the universal modality also increases our ability to define non-elementary frame classes. For example, the class of frames where the converse of the accessibility relation R is well-founded (that is, where it is impossible to form infinite R-successorship chains) is not definable in basic modal logic. Löb's formula, $\Box(\Box p \to p) \to \Box p$ doesn't quite pin this condition down (recall that it defines the conjunction of transitivity and converse well foundedness). But the following Löb-like formula in the enriched language does:

$$A(\Box p \to p) \to p.$$

(This example is from Goranko and Passy [61], the key reference on the universal modality.) Second, it is straightforward to extend the definition of bisimulation so that it works for the basic modal language enriched with the universal modality; all that needs to be done is to insist that the bisimulation be *total*, that is, that every element in each model is related to at least one point in the other; see de Rijke [30] for a brief discussion. Third, the universal modality has a big brother, the *difference operator*. The diamond form of this operator is written D, and $D\varphi$ is satisfied at a point w in a model if and only if φ is satisfied at some *different* point v (that is, the difference operator is interpreted using the $\neq$ relation on W). The difference operator is strong enough to define the universal modality ($E\varphi$ is just $\varphi \lor D\varphi$) but D cannot be defined using E (we leave the proof as an exercise). The difference operator arises naturally in many settings and, like the universal modality, has a smooth meta-theory; see de Rijke [29] for more information.

6.2 Hybrid logic

Basic modal languages have an obvious expressive weakness: they cannot name points. We cannot say this happened *then*, or that some *particular* individual has some property, or that two distinct sequences of processes take us from the current state to the *same* state. For example, in Figure 4 we let the nodes represent particular individuals such as Terry and Judy — but the basic modal language doesn't let us pick out these individuals. First-order logic, of course, lets us do this. We use constants to name individuals of interest, and the equality symbol for reasoning about their identity. No analogous mechanisms exist in basic modal logic. The *basic hybrid language* is the result of adding them.

At the heart of hybrid logic lies a simple idea, first introduced by Arthur Prior [104, 105] in the 1960s: sort the proposition symbols, and use *formulas as terms*. Let's do this right away. Take a language of basic modal logic (with proposition symbols p, q, r, and so on) and add a second sort of proposition symbol. The new symbols are called *nominals*, and are typically written i, j, k, and l. Both types of proposition symbol can be freely combined to form more complex formulas in the usual way. And now for the key change: *insist that each nominal be true at exactly one point in any model*. That is, insist (for any valuation V and nominal i) that $V(i)$ be a singleton set. We call the unique point in $V(i)$ the *denotation* of i. A nominal 'names' its denotation by being true there and nowhere else.

This change is far from negligible: already we have a more expressive logic. Consider the following basic modal formula:

$$\Diamond(r \wedge p) \wedge \Diamond(r \wedge q) \rightarrow \Diamond(p \wedge q).$$

This formula can be falsified, as the p-witnessing and q-witnessing points given by the antecedent may be distinct. But now consider the following hybrid formula:

$$\Diamond(i \wedge p) \wedge \Diamond(i \wedge q) \rightarrow \Diamond(p \wedge q).$$

This is identical to the preceding formula, except that we have replaced the proposition symbol r by the nominal i. But the resulting formula is valid. For now we have extra information: the p-witnessing and q-witnessing successors both make i true, so they are true at the same point, namely the denotation of i.

The addition of nominals is the crucial step towards the basic hybrid language, but we need a second ingredient too: *satisfaction operators*. These are operators of the form $@_i$, where i is a nominal. The formula $@_i\varphi$ asserts that φ is satisfied at the (unique) point named by the nominal i. That is:

$$\mathfrak{M}, w \models @_i\varphi \quad \text{iff} \quad \mathfrak{M}, u \models \varphi, \ \text{where } u \text{ is the denotation of } i.$$

Syntactically, satisfaction operators are modalities. And they are semantically well behaved. For a start, all instances of the modal distribution schema are valid:

$$@_i(\varphi \rightarrow \psi) \rightarrow (@_i\varphi \rightarrow @_i\psi).$$

Moreover, satisfaction operators also admit the modal generalisation law: if φ is valid, then so is $@_i\varphi$ (for any choice of i). Hence satisfaction operators are normal modal operators. Moreover, they are self-dual modalities, for all instances of $@_i\varphi \leftrightarrow \neg @_i\neg\varphi$ are valid. So we are free to regard satisfaction operators as either boxes or diamonds.

But for present purposes, the most important point about satisfaction operators is that they give us a modal perspective on the equality relation. To see this, note that formulas like $@_ij$ are

well formed. What does this formula assert? It says that "at the denotation of i, the nominal j is satisfied", or to put it another way, "the point named i is identical to the point named j". Hence the following schemas are valid: $@_i i$ (reflexivity of equality), $@_i j \to @_j i$ (symmetry of equality), $@_i j \wedge @_j k \to @_i k$ (transitivity of equality), and $@_i \varphi \wedge @_i j \to @_j \varphi$ (replacement). As we hoped, a modal theory of equality is emerging.

We will shortly characterise this theory, but before doing so let's glance at what is happening at the level of frames. Here too there is an increase in expressivity. None of the four first-order definable frame conditions listed below can be defined in basic modal logic. But it is easy to check that each is defined by the hybrid formula written next to them:

$$\begin{array}{rll} \forall x \neg Rxx & i \to \neg\Diamond i & \text{(irreflexivity)} \\ \forall xy(Rxy \to \neg Ryx) & i \to \neg\Diamond\Diamond i & \text{(asymmetry)} \\ \forall xy(Rxy \wedge Ryx \to x = y) & i \to \Box(\Diamond i \to i) & \text{(antisymmetry)} \\ \forall xy(Rxy \vee x = y \vee Ryx) & @_j\Diamond i \vee @_j i \vee @_i\Diamond j & \text{(trichotomy).} \end{array}$$

And now for the main result. Hybridisation has given us some sort of modal theory of equality. But how much of the corresponding first-order theory have we captured? Of course, now when we talk about "corresponding first-order theory" we mean: theory in the first-order correspondence language *enriched with constants and the equality symbol*.

The first step towards an answer is to extend the standard translation to cover nominals and satisfaction operators. So enrich the first-order correspondence language with constants and the equality symbol; to keep the notation uncluttered, we'll re-use the nominals as first-order constants. Then add the following clauses to the standard translation:

$$\begin{array}{rcl} \mathrm{ST}_x(i) & = & (x = i) \\ \mathrm{ST}_x(@_i\varphi) & = & \mathrm{ST}_i(\varphi). \end{array}$$

That is, nominals i are translated into first-order constants i, and satisfaction operators are translated by substituting the relevant first-order constant for the free-variable x. Note that this translation returns first-order formulas with *at most* one free variable x, not exactly one. This is because a constant may be substituted for the free occurrence of x. For example, the hybrid formula $@_i i$ translates into the first-order *sentence* $i = i$.

The second step is to extend the notion of bisimulation given in Definition 5 to make it suitable for the basic hybrid language and for the constant-enriched first-order correspondence language:

DEFINITION 37 (Bisimulation-with-names). A bisimulation-with-names between models $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$ is a non-empty binary relation E between their domains (that is, $E \subseteq W \times W'$) such that whenever wEw' we have that:

Atomic harmony: w and w' satisfy the same proposition symbols, and the same nominals.

Zig: if Rwv, then there exists a point v' (in $\mathfrak{M}'$) such that vEv' and $R'w'v'$, and

Zag: if $R'w'v'$, then there exists a point v (in $\mathfrak{M}$) such that vEv' and Rwv.

Closure: All points named by nominals are related by E.

It is easy to check that all basic hybrid formulas are invariant under bisimulations-with-names; the proof is an easy extension of Lemma 9. More interestingly, such bisimulations also give rise to a Characterisation Theorem:

THEOREM 38 (Hybrid Characterisation Theorem). *The following are equivalent for all first-order formulas $\varphi(x)$ in at most one free variable x:*

1. *$\varphi(x)$ is invariant for bisimulation-with-names.*
2. *$\varphi(x)$ is equivalent to the standard translation of a basic hybrid formula.*

Proof. That clause 2 implies 1 is a more or less immediate. The hard direction is showing that clause 1 implies 2. The original proof can be found in Areces, Blackburn and Marx [6]. ❑

In short, basic hybrid logic is a simple notation for capturing *exactly* the bisimulation-invariant fragment of first-order logic with constants and equality, or to put it another way, basic hybridisation is a mechanism for equality reasoning in propositional modal logic. And it comes cheap. Up to a polynomial, the complexity of the resulting decision problem is no worse than for the basic modal language we started with:

THEOREM 39. *The satisfiability problem for the basic hybrid language over arbitrary models is PSPACE-complete.*

Proof. See Areces, Blackburn and Marx [6]. ❑

A number of stronger hybrid languages have also been explored. One of the most interesting extensions is to add $\downarrow$ (the *downarrow binder*). This binds occurrences of nominals within its scope to the point of evaluation. That is, to evaluate $\mathfrak{M}, w \models \downarrow i.\varphi$, we evaluate $\mathfrak{M}, w \models \varphi$ but with all occurrences of the nominal i that were bound by $\downarrow$ now interpreted as naming w (for details on how to make this informal explanation precise, see Chapter 14 of this Handbook). To put it another way, $\downarrow$ lets us create a name for *here*, and this immediately increases the expressive power at our disposal. For example, in any model $\mathfrak{M}$, the formula $\downarrow i.\neg\Diamond i$ is true at precisely the irreflexive points; as we noted earlier, no such formula exists in the basic modal language, and indeed, no such formula exists in the basic hybrid language either.

Moreover, $\downarrow$ interacts beautifully with @. Intuitively, $\downarrow$ stores new values for nominals, and @ allows us to retrieve them. As an example of this interaction, consider the following formula which is true in any model at points with at least two successors:

$$\downarrow i.\Diamond\downarrow j.@i\Diamond\neg j.$$

This formula first names the point of evaluation i, it then declares that i has a successor which it names j, and then (with the help of @) it jumps back to i to assert that i also has a successor distinct from j.

But this increased expressivity comes at a price: by introducing $\downarrow$ we have sailed over the border into undecidability. As we remarked earlier, the ability to create grid-like models is a useful warning sign of undecidability, and the smooth interaction between $\downarrow$ and @ makes it easy to create the unit squares required to build grids:

$$\downarrow i.\Diamond(\neg i \wedge \downarrow j.\Diamond(\neg i \wedge \neg j \wedge \downarrow k.@i\Diamond(\neg i \wedge \neg j \wedge \neg k \wedge \downarrow l.\Diamond k))).$$

If you work through this formula you will see that it demands the existence of four distinct points, which it calls i, j, k, and l, such that Rij, Rjk, Ril and Rlk. Note the characteristic use of the embedded $@_i$ to jump us back to the original point of evaluation i; this enables us to construct a second path from i to k that goes via point l. Of course, moving from this observation to a proof that it is possible to code the tiling problem takes more work, but it can be done, and the upshot is: adding $\downarrow$ has moved us up to an undecidable fragment of first-order logic.

But which fragment? The answer has two natural formulations. The first has the now-familiar form of a Characterisation Theorem: it turns out that adding downarrow has moved us up to precisely that fragment of first-order logic which is *invariant under generated submodels*. The second answer has a more syntactic flavour: we have moved up to the *bounded fragment* of first-order logic. The bounded fragment consist of all first-order formulas built up from atomic formulas using the booleans and bounded quantifications of the form $\exists y(R\tau y \wedge \varphi)$ and $\forall y(R\tau y \rightarrow \varphi)$, where τ is a term that does not contain y. The bounded fragment arises naturally in set theory (see Levy [89]) and arithmetic (see Buss [20]). In the mid-1960s, Feferman and Kreisel [41, 40] characterised the bounded fragment as the fragment of first-order logic invariant under generated submodels. It is intriguing that hybrid logic should have arrived at the same fragment by such a different route.

For full formulations and proofs of these results, see Areces, Blackburn and Marx [6]. For a detailed overview of hybrid logic, covering the results mentioned and much else besides, see Chapter 14 of this handbook.

6.3 Temporal logic with Until and Since operators

We turn now to another historically early enrichment: the addition of the binary U (Until) and S (Since) operators. These were introduced in the late 1960s by Hans Kamp [76], who added them to Arthur Prior's basic (F and P based) tense logic, and proved an elegant result: U and S are expressively complete with respect to Dedekind complete strict total orders (we discuss Kamp's result below). But, beautiful though this is, it is not what led to the present popularity of these operators. Rather, around 1980, Gabbay, Pnueli, Shelah and Stavi [53] observed that Until offers precisely what is required to state what computer scientists call *guarantee properties*, and this led to its widespread adoption for reasoning about programs. Given the number of researchers currently active in temporal logic for program verification, Until may well be the best known and most widely used modal operator of all: it plays a key role in LTL (Linear Time Temporal Logic), CTL (Computational Tree Logic), and CTL* (a highly expressive system that contains both LTL and CTL as sublogics). For an introduction to these logics, see Chapter 11 of this handbook, or Clarke, Grumberg and Peled [25].

Now, we briefly met the Until operator in Section 4 when we discussed model checking. There we defined it in terms of R^+ and R^*, the transitive and reflexive transitive closures of the underlying relation R used by the $\Diamond$ over tree-like models. Here we shall define Until and Since in their most general form:

$$
\begin{array}{rll}
\mathfrak{M}, w \models U(\varphi,\psi) & \text{iff} & \text{there is a } v \text{ such that } Rwv \text{ and } \mathfrak{M}, v \models \varphi, \\
 & & \text{and for all } u \text{ such that } Rwu \text{ and } Ruv \text{ we have } \mathfrak{M}, u \models \psi. \\
\mathfrak{M}, w \models S(\varphi,\psi) & \text{iff} & \text{there is a } v \text{ such that } Rvw \text{ and } \mathfrak{M}, v \models \varphi, \\
 & & \text{and for all } u \text{ such that } Rvu \text{ and } Ruw \text{ we have } \mathfrak{M}, u \models \psi.
\end{array}
$$

Putting this in words, Until asserts that there is *some* point in the future where φ holds, and that at *all* points between the point of evaluation and this future φ-witnessing point, ψ holds. Since functions in the same way, but towards the past. Note the $\exists\forall$ pattern of quantification in the satisfaction definitions. These operators are neither diamonds nor boxes; they are something new and (as we shall see) more powerful.

What can we say with them? For a start, they have all the power of ordinary diamonds: $U(\varphi,\top)$ has the same meaning as $\Diamond\varphi$. But now we can say more: these operators are tailor-made for stating guarantee properties, requirements of the form "*Some event will happen, and*

until that event takes place, a certain condition will hold". For if we represent the event by φ and the condition by ψ, then $U(\varphi, \psi)$ clearly captures what is required.

But how can we be sure that we can't state guarantee requirements in the basic modal language? A simple bisimulation argument demonstrates this. Consider the two models shown in Figure 19. The two models are clearly bisimilar (simply link both points in the right-hand model

Figure 19. Until is not definable in basic modal logic.

to the single point in the left-hand model; all proposition symbols are false at all points in both models, though this is irrelevant to the following argument). This means that the two models agree on the truth of all basic modal formulas at all points. But the models disagree on the value of $U(\top, \bot)$. This formula is false in the model on the left, but true at both points in the model of the right. We conclude that no basic modal formula can capture the effect of Until.

But this is a little too easy. Until is typically used for temporal reasoning tasks, and the two models just shown have little to recommend them as flows of time. But it turns out that Until cannot be defined even if we work with models with more structure. For a start, even if we restrict our attention to transitive models, Until is not basic modal definable. For consider the two models shown in Figure 20; we are interested in the transitive closure of the relation indicated by the arrows. These models are bisimilar (link w_0 and w_1 with w', link t_0 and t_1 with t', and so on). So suppose that there is some formula in the basic modal language that captures the effect of $U(p, q)$. Any such formula would be true in the left-hand model at points w_0 and w_1. For consider what happens at w_0 (the argument for w_1 is analogous). There is a point to its future (namely v_1) that makes p true and at all points lying in between (and there is only one, namely u) we have that q is satisfied. However any such formula would be *false* in the right-hand model at w', for here there are *two* points between w' and v' (namely u' and t') and t' does not satisfy q. As w' is bisimilar to w_0 and w_1, we conclude that no basic modal formula can capture the effect of Until. And this result can be strengthened. Even if we restrict ourselves to linear models, the basic modal language can't define Until, and it can't do so on the real numbers either (see Proposition 7.10 in Blackburn, de Rijke and Venema [13]).

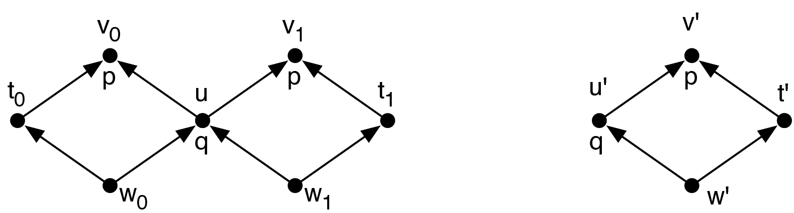

Figure 20. Even on transitive frames, Until is not definable in basic modal logic.

So adding S and U to the basic modal language yields new expressivity — but how much? We shall now discuss Kamp's Theorem, which shows that on certain classes of structures (a class

that includes the real numbers) these operators capture the entire one free variable fragment of the first-order correspondence language. This result was one of the earliest (and is still one of the most striking) purely semantic results in modal logic.

First, note that Until and Since correspond to fragments of the familiar first-order correspondence language that we have been working with throughout the chapter. After all, we can translate them as follows:

$$\begin{array}{rcl} \mathrm{ST}_x(U(\varphi,\psi)) & = & \exists z\,(Rxz \wedge \mathrm{ST}_z(\varphi) \wedge \forall y\,(Rxy \wedge Ryz \rightarrow \mathrm{ST}_y(\psi))) \\ \mathrm{ST}_x(S(\varphi,\psi)) & = & \exists z\,(Rzx \wedge \mathrm{ST}_z(\varphi) \wedge \forall y\,(Rzy \wedge Ryx \rightarrow \mathrm{ST}_y(\psi))). \end{array}$$

Incidentally, observe that we need three variables to specify this translation, whereas we only needed two for the basic modal language. Now, the three variable fragment of first-order logic is known to be undecidable, thus the translation doesn't give us an easy decidability result for the enriched modal language, though its satisfiability problem over arbitrary models is in fact decidable. We'll understand why a little later when we discuss the packed fragment.

So what does Kamp's Theorem say? First some preliminary definitions. Let M be a class of models. We say that a modal language is *expressively complete over* M, if every formula (in one free variable) from the first-order correspondence language is equivalent to a formula in the modal language (when we restrict attention to models from M). Which class of models is Kamp's Theorem about? A *strict total order* is any frame (with one binary relation R) that is transitive, irreflexive, and linear (that is, $\forall xy(Rxy \vee x = y \vee Ryx)$). A strict total order is *Dedekind complete* if every subset with an upper bound has a least upper bound. Standard examples of Dedekind complete strict total orders are the real numbers $(\mathbb{R}, <)$ and the natural numbers $(\mathbb{N}, <)$ under their usual orderings. And now we have:

THEOREM 40 (Kamp's Theorem). *The basic modal language enriched with U and S is expressively complete with respect to models based on Dedekind complete strict total orders.*

Proof. The original proof is in Kamp's thesis [76]. Elegant modern proofs, and proofs of stronger expressive completeness results, can be found in Gabbay, Hodkinson and Reynolds [52]. See also Chapter 11 of this handbook. ❑

Much more could be said about the Until and Since operators, but we will confine ourselves to the following remark. Because of their $\exists\forall$ pattern of quantification, for some time it was unclear how best to define a suitable notion of bisimulation. However Kurtonina and de Rijke [87] and Sturm [120] have given definitions which enable characterisation theorems to be proved.

6.4 Conditional logic

Although formulas of the form $\varphi \rightarrow \psi$ are often glossed as "if φ then ψ", the truth conditions that classical logic gives to the $\rightarrow$ symbol (and in particular, the fact that $\varphi \rightarrow \psi$ is true when φ is false) means that $\rightarrow$ does not mirror the more interesting meanings that conditionals can have in natural language. This has inspired numerous attempts to introduce conditional connectives (say, $>$) that better mimic the logic(s) of natural language conditionals. Indeed, such aspirations have given birth to an entire branch of logic, namely Relevance Logic, which nowadays is a well-established branch of the study of substructural logics (see Restall [108]).

But there is a modal approach to conditionals too. Its motivation comes from the following intuition: a conditional $\varphi > \psi$ can (often) be read as an *invitation* to assume the antecedent (perhaps making some adjustments to accommodate its truth) and check if the consequent is

true. A characteristic inferential feature of this reading is the failure of *monotonicity in the antecedent*. “If I catch the 6.22 train at Amsterdam Central (φ), I will be home on time (ψ)” is true on the most natural reading of the conditional, but adding an unusual further condition may make it false, as the sentence “If I catch the 6.22 train at Amsterdam Central (φ), and the dikes break (θ), I will be home on time (ψ)” demonstrates.

Models for modal-style conditional reasoning are triples $\mathfrak{M} = (W, C, V)$. Here W is a non-empty set (whose elements are usually called worlds), V is a valuation, and C is a ternary relation of *relative similarity* , or (as it is sometimes put in the literature) a relation of relative ‘comparison’ or ‘preference’ between worlds. It is useful to write $Cwuv$ as $C_w uv$ and to read this as saying that “w has more in common with u than v”. It is standard to demand that each C_w satisfies $\forall uvz(C_w uv \wedge C_w vz \rightarrow C_w uz)$, w-centred transitivity, and $\forall u C_w uu$, w-centred reflexivity. Moreover, some authors, most famously David Lewis, also demand w-centred comparability, that is, $\forall uv(C_w uv \vee C_w vu)$. A good way to visualise the relation $C_w uv$ is to think of u and v as two concentric circles around w. If u and v are distinct, then u is a concentric circle *closer* to w than v is.

The simplest truth condition for conditionals is the following, which come from David Lewis’s groundbreaking book “Counterfactuals” [90]. It fits in well with our intuitions (at least on finite models):

$\mathfrak{M}, w \models \varphi > \psi$ iff all minimal worlds in the w-centred ordering $C_w uv$ at which φ is true are also worlds where ψ holds.

This satisfaction clause can be phrased more succinctly as follows: all minimal φ-worlds are ψ-worlds.

Note that the φ-*minimal* worlds around w are the only ones we consider. As the minimal worlds satisfying the stronger condition $\varphi \wedge \theta$ need not be the ones satisfying φ, in this way we get a semantic distinction which accounts for the failure of monotonicity in the antecedent.

But what about *infinite* models? Then there need not be any minimal worlds satisfying the antecedent (we might have a chain of φ-satisfying concentric circles coming ever closer to w). Here’s a way of handling this: switch to the following more complex truth condition (to keep things readable, we shall write use $\varphi(v)$ as shorthand for $\mathfrak{M}, v \models \varphi$, and similarly for ψ):

$$\mathfrak{M}, w \models \varphi > \psi \quad \text{iff} \quad \forall u(\varphi(u) \Rightarrow \exists v(C_w vu \;\&\; \varphi(v) \;\&\; \forall z((C_w zv \;\&\; \varphi(z)) \Rightarrow \psi(z)).$$

This says that the conditional $\varphi > \psi$ holds if, whenever φ holds at some circle u, then there is some smaller circle v where φ holds such that all circles z within v satisfy ψ. This is rather awkward to process in first-order logic, but it can be clearly expressed in modal logic if we make use of a unary modality $\langle c \rangle$ (which looks inwards for a circle closer to the centre) together with the universal modality A. For then we can simply say:

$$\varphi > \psi \;=_{def}\; A(\varphi \rightarrow \langle c \rangle(\varphi \wedge [c](\varphi \rightarrow \psi)).$$

This more complex truth-condition validates a minimal logic which includes such principles as upward monotonicity in the consequent: $\varphi > \psi$ implies $\varphi > (\psi \vee \theta)$. Further properties of the similarity ordering enforce special axioms via standard frame correspondences. Assuming just reflexivity and transitivity yields the minimal conditional logic originally axiomatised by Burgess [19] and Veltman [143], while assuming also comparability of the ordering gives rise to the logics obtained by Davis Lewis.

What about complexity? A number of interesting results are known:

THEOREM 41. *The satisfiability problem for the minimal conditional logic (that is, where $C_w uv$ is transitive and reflexive) is PSPACE-complete when formulas with arbitrary nestings of conditionals are allowed, and NP-complete for formulas with bounded nesting of conditionals.*

Proof. See Friedman and Halpern [50]. These authors also prove that if uniformity is assumed (that is, if all worlds agree on what worlds are possible) the complexity rises to EXPTIME-complete, even for formulas with bounded nesting. Moreover, they show that if absoluteness is assumed (that is, all worlds agree on all conditional statements) the decision problem is NP-complete for formulas with arbitrary nesting. ❑

In general, conditional logic has not been studied semantically in the same style as most modal languages, though there is no reason why it cannot be. For example, bisimulations could be defined for $>$ in much the same spirit as they are defined for temporal logics with Until and Since. Likewise, issues of frame definability beyond the minimal setting can be explored; for example, van Benthem [137] notes correspondences between conditional axioms and triangle inequalities concerning concrete geometrical relations of relative nearness in space. Many recent technical developments in conditional logic, however, have to do with its connection with *belief revision theory* (see Gärdenfors and Rott [55]). In that setting, a conditional $\varphi > \psi$ means "if I revise my current beliefs with the information that φ, then ψ will be among my new beliefs"; see, for example, Ryan and Schobbens [110]. For more on these topics, see Chapters 20 and 21 of this handbook.

6.5 The guarded fragment

The richer modal languages so far examined have clearly been modal in a syntactic sense; all use the typical "apply operator to formula" syntax. The guarded fragment, however, arises as an attempt to *directly* isolate fragments of first-order logic that can plausibly be called modal. So the modal languages we shall consider here are syntactically first-order.

The clue leading to the guarded fragment is the standard translation of the modalities. This treats modalities as macros embodying *restricted* forms of first-order quantification, in particular, quantification restricted to successor states:

$$\begin{array}{rcl} \mathrm{ST}_x(\Diamond\varphi) & = & \exists y(Rxy \wedge \mathrm{ST}_y(\varphi)) \\ \mathrm{ST}_x(\Box\varphi) & = & \forall y(Rxy \rightarrow \mathrm{ST}_y(\varphi)). \end{array}$$

As we saw earlier, it is this restricted form of quantification that lets bisimulation emerge as the key model-theoretic notion. And bisimulation, via the tree model property, leads to decidability. Thus at least one pleasant property of modal logic can plausibly be traced back to its use of a restricted form of quantification. So it is natural to ask whether other first-order fragments defined by restricted quantification have such properties. This line of enquiry leads to the guarded fragment and its relatives.

The first step takes us to the guarded fragment, which was introduced by Andréka, van Benthem, and Németi [5]. Guarded formulas φ are built up as follows:

$$\varphi \quad ::= \quad Q\overline{x} \mid \neg\varphi \mid \varphi \wedge \psi \mid \varphi \rightarrow \psi \mid \exists\overline{y}(G(\overline{x},\overline{y}) \wedge \varphi(\overline{x},\overline{y})) \mid \forall\overline{y}(G(\overline{x},\overline{y}) \rightarrow \varphi(\overline{x},\overline{y})).$$

Here $\overline{x}$ and $\overline{y}$ are finite tuples of variables, Q is a predicate symbol (of appropriate arity for the tuple $\overline{x}$), and G, the symbol used in the guard, is a predicate symbol too (thus the guard is an atomic formula). The key point to observe is that in the clauses for the quantifiers, all the free variables of φ appear in the guard. The set of all guarded first-order formulas is called the guarded fragment.

THEOREM 42. *The guarded fragment is decidable. Its satisfiability problem is 2EXPTIME-complete, and EXPTIME-complete if we have a fixed upper bound on the arity of predicates. Moreover, the guarded fragment has the finite model property.*

Proof. See Grädel [62] for the complexity results and a direct proof of the finite model property. An earlier (algebraic) proof of the finite model property can be found in Andréka, Hodkinson, and Németi [4]. ❑

The guarded fragment is a natural generalisation of the first-order formulas obtainable under the standard translation, but does it go far enough? For example, adding Until to a basic modal language yields a decidable logic, but the standard translation of $U(p, q)$, namely

$$\exists y\,(Rxy \wedge Py \wedge \forall z\,((Rxz \wedge Rzy) \rightarrow Qz)),$$

does not belong to the guarded fragment, and it can be shown that it is not equivalent to a formula in the guarded fragment either. This suggests that it may be possible to pin down richer restricted-quantification first-order fragments that retain decidability, and several closely related extensions of the guarded fragment, such as the loosely guarded fragment (see van Benthem [135]) and the packed fragment (see Marx [93]) have been proposed which do precisely this. Let's take a quick look at the packed fragment.

The packed fragment allows us to use *composite guards* γ instead of just atomic guards G. Let γ be a formula whose free variables are $\{x_1, \ldots, x_k\}$. Then γ *packs* $\{x_1, \ldots, x_k\}$ if γ is a conjunction of formulas of the form $x_i = x_j$, $R(x_{i_1}, \ldots, x_{i_n})$ or $\exists\overline{x}R(x_{i_1}, \cdots, x_{i_n})$, and moreover, for any two distinct free variables x_i and x_j, there is a conjunct in γ in which they both occur free. The packed fragment is the smallest fragment of modal logic that contains all atomic formulas, and is closed under boolean combinations and *packed quantification*. That is, if ψ is a packed formula, and γ packs ψ, and all the free variables of ψ are free in γ, then $\exists\overline{x}(\gamma \wedge \phi)$ and $\forall\overline{x}(\gamma \rightarrow \phi)$ are packed too.

As an example, consider again the standard translation of $U(p, q)$, namely

$$\exists y\,(Rxy \wedge Py \wedge \forall z\,((Rxz \wedge Rzy) \rightarrow Qz)).$$

This is not packed as the guard of the subformula $\forall z\,((Rxz \wedge Rzy) \rightarrow Qz))$ has no conjunct in which x and y occur together. But this is easy to fix. The following (logically equivalent) formula *is* packed:

$$\exists x\,(Rxy \wedge Py \wedge \forall z\,((Rxz \wedge Rzy \wedge Rxy) \rightarrow Qz)).$$

And indeed, the packed fragment turns out to be computationally well behaved:

THEOREM 43. *The packed fragment is decidable. Its satisfiability problem is 2EXPTIME-complete. Moreover, it has the finite model property.*

Proof. The complexity result follows from results in Grädel [62]. The original proof of the finite model property for the packed fragment (and the loosely guarded fragment) can be found in Hodkinson [68]; a more elegant proof can be found in Hodkinson and Otto [69]. ❑

In short, we have isolated two decidable fragments of first-order logic which are expressive enough to generalise many common modal languages. Moreover, these fragments have attractive properties besides decidability. Basic modal logic resembles first-order logic in most of its meta-properties, even those (such as Craig Interpolation, Beth definability, and the standard model-theoretic preservation theorems) that do not follow straightforwardly from the fact that it is a first-order fragment. The guarded fragment shares this good behaviour to some extent, witness the Łos-style preservation theorem for submodels given in Andréka, van Benthem, and Németi [5]. But subsequent work has shown that the picture is somewhat mixed. There is indeed a natural notion of guarded bisimulation (see Andréka, van Benthem, and Németi [5]) which characterises the guarded fragment as a fragment of first-order logic. Moreover, Beth definability holds (see Hoogland, Marx and Otto [71]). However Craig interpolation fails in its strong form, though it holds when we view guard predicates as part of the logical vocabulary (see Hoogland and Marx [70]).

This is a good moment to take stock of some of the first-order fragments we have encountered in the course of this chapter, and their interrelationships. Figure 21 summarises the relationships

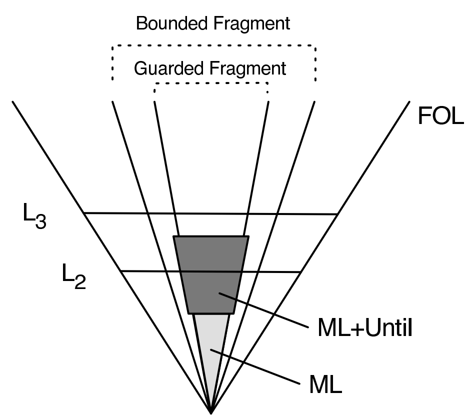

Figure 21. Some modally significant fragments of first-order logic.

between first-order logic, the more restricted (but undecidable) bounded fragment, and the still more restricted (but decidable) guarded fragment. Also shown are the fragments of first-order logic corresponding to the basic modal language, and the fragment corresponding to the basic language enriched with Until. Here L_2 and L_3 indicate the two and three variable fragments respectively; the basic language fits into the former, but the Until enriched language spills over into the latter.

6.6 *Propositional Dynamic Logic*

The richer modal languages so far discussed extend the first-order expressive power available for talking about models: the universal modality adds quantification over $W \times W$, hybridisation gives access to constants and equality, Until and Since and conditional logic add richer quantificational patterns, and the guarded-fragment cheerfully replaces modal syntax with first-order syntax. But the next two languages we shall discuss take us in a different direction: both add *second-order* expressive power. Now, in Section 5 we saw that modal languages have second-order expressive

power (via the concept of validity) at the level of *frames*. But in the languages we now consider, second-order expressivity arises directly: it is hardwired into the satisfaction definitions, and hence is available at the level of *models*. In particular, Propositional Dynamic Logic (henceforth PDL) offers us an (infinite collection of) transitive closure operators, and the modal μ-calculus offers us a general mechanism for forming fixed-points. Significantly, both PDL and the modal μ-calculus were born in theoretical computer science. Finite structures are crucial to the theory and practice of computation, and basic results of finite model theory (see Ebbinghaus and Flum [35]) show that first-order logic is badly behaved when interpreted over finite structures. Nowadays it is standard practice to extend first-order languages with second-order constructs (such as the ability to take transitive closures or form fixed-points) when working with finite models, and in the languages we now consider, such ideas are put to work in modal logic.

Let's start by looking at the weaker of the two languages, namely PDL. The underlying idea (to extend modal logic with a modality for every program) is due to Vaughan Pratt [102], and the language now called PDL was first investigated by Fisher and Ladner [47, 48]. PDL contains an infinite collection of diamonds. Each has the form $\langle\pi\rangle$, where π denotes a non-deterministic program. The intended interpretation of $\langle\pi\rangle\varphi$ is that "some terminating execution of π from the current state leads to a state with the information φ". The dual assertion $[\pi]\varphi$ states that "every terminating execution of π from the current state leads to a state with the information φ". Crucially, the inductive structure of programs is made explicit in PDL's syntax, as complex programs are built out of basic programs using four program constructors. Suppose we have fixed a set of basic programs a, b, c, and so on. We are allowed to define complex programs π over this base as follows:

Choice: if π_1 and π_2 are programs, then so is $\pi_1 \cup \pi_2$. It non-deterministically executes either π_1 or π_2.

Composition: if π_1 and π_2 are programs, then so is $\pi_1 ; \pi_2$. It first executes π_1 and then executes π_2.

Iteration: If π is a program, then so is π^*. It executes π a finite (possibly zero) number of times.

Test: if φ is a formula, then $\varphi?$ is a program. It tests whether φ holds, and if so, continues; if not, it fails.

Hence PDL makes available the following (inductively defined) algebra of diamonds. First we have diamonds $\langle a\rangle$, $\langle b\rangle$, $\langle c\rangle$, and so on, for working with the basic programs. Then, if $\langle\pi_1\rangle$ and $\langle\pi_2\rangle$ are diamonds and φ is a formula, $\langle\pi_1 \cup \pi_2\rangle$, $\langle\pi_1 ; \pi_2\rangle$, $\langle\pi_1^*\rangle$ and $\langle\varphi?\rangle$ are diamonds too. Note the unusual syntax of the test constructor diamond: it makes a modality out of a formula. This means that the sets of PDL formulas and modalities are defined by mutual induction.

How do we interpret PDL? Syntactically we're simply dealing with a basic modal language in which the modalities are indexed by a structured set. So a model for PDL will have the form we are used to, namely

$$(W, \{R^\pi \mid \pi \text{ is a program }\}, V),$$

a suitably indexed collection of relations together with a valuation. Moreover, the usual satisfaction definition is all that is required: diamonds existentially quantify over the relevant transitions, and boxes universally quantify over them. Nonetheless, something more needs to be said. Given the intended interpretation of PDL, most of these models are uninteresting. We want models built over frames which do justice to the intended meaning of our program constructors. Which models are these?

Nothing much needs to be said about the interpretation of the basic programs: any binary relation can be regarded as a transition relation for a non-deterministic program (though if we were interested in *deterministic* programs, we would insist on working with frames in which each basic program was interpreted by a partial function). Nor need much be said about the test operator. Unusual though its syntax is, its intended interpretation in any model $\mathfrak{M}$ is simply

$$R^{\varphi?} \;=\; \{(w,v) \mid w = v \text{ and } \mathfrak{M}, w \models \varphi\}.$$

But the three remaining constructors demand that we impose inductive structure on our frames. Here's what is required:

$$\begin{aligned} R^{\pi_1 \cup \pi_2} &= R^{\pi_1} \cup R^{\pi_2}, \\ R^{\pi_1 ; \pi_2} &= R^{\pi_1} \circ R^{\pi_2} \; (= \{(x,y) \mid \exists z\,(R^{\pi_1}xz \wedge R^{\pi_2}zy)\}), \\ R^{\pi_1^*} &= (R^{\pi_1})^*, \text{ the reflexive transitive closure of } R^{\pi_1}. \end{aligned}$$

These restrictions are the natural set-theoretic ways of capturing the "either-or" nature of non-deterministic choices (for $R^{\pi_1 \cup \pi_2}$), the idea of executing two programs in a sequence (for $R^{\pi_1;\pi_2}$) and the idea of iterating the execution of a program finitely many times (for $R^{\pi_1^*}$). Accordingly, we make the following definition. Let Π be the smallest set of programs containing the basic programs and the programs constructed over them using the constructors $\cup$, ;, and *. Then a *regular frame* over Π is a frame $(W, \{R^\pi \mid \pi \in \Pi\})$ where R^a is a binary relation for each basic program a, and for all complex programs π, R^π is the binary relation constructed inductively using the above clauses. A *regular model* over Π is a model built over a regular frame (that is, regular models are regular frames together with a valuation). When working with PDL over the programs in Π, we will be interested in regular models for Π, for these are the models that capture the intended interpretation. All very simple and natural — but by insisting that $R^{\pi_1^*}$ be interpreted by the reflexive transitive closure of R^{π_1}, we have given PDL genuinely *second-order* expressive power. A straightforward application of the Compactness Theorem shows that first-order logic cannot define the transitive closures of arbitrary binary relations, so with this definition we've moved beyond the confines of first-order logic. Unsurprisingly, compactness fails in PDL. To see this, consider the following infinite set of formulas:

$$\{\langle \pi^* \rangle p, \neg p, [\pi]\neg p, [\pi][\pi]\neg p, [\pi][\pi][\pi]\neg p, \ldots\}.$$

It is clear that every finite subset of this set has a regular model: we simply make p true at a state reachable by taking $n+1$ (non-reflexive) π-steps out from the current state, where n is the maximal level of nesting of boxes. But the entire set cannot be satisfied at any state in any regular model.

So we have genuine second-order expressivity at our disposal. What can we do with it? Well, for a start, at the level of models, we can express some familiar algorithmic constructs:

$(p? \,; a) \cup (\neg p? \,; b)$	`if` p `then` a `else` b.
$a; (\neg p?; a)^*; p?$	`repeat` a `until` p.
$(p?; a)^*; \neg p?$	`while` p `do` a.

Note the crucial role played by * in capturing the effect of the two loop constructors.

Moreover, the second-order expressivity built in at the level of models spills over into the level of frames. Here's a nice illustration. Via the concept of validity, PDL itself is strong enough to

define the class of regular frames (something which cannot be done in a first-order language). Now, it is not hard to give conditions that capture choice and composition. The formula

$$\langle \pi_1 \cup \pi_2 \rangle p \leftrightarrow \langle \pi_1 \rangle p \vee \langle \pi_2 \rangle p$$

is valid on precisely those frames satisfying $R^{\pi_1 \cup \pi_2} = R^{\pi_1} \cup R^{\pi_2}$, and

$$\langle \pi_1 ; \pi_2 \rangle p \leftrightarrow \langle \pi_1 \rangle \langle \pi_2 \rangle p$$

is valid on precisely those frames satisfying $R^{\pi_1 ; \pi_2} = R^{\pi_1} \circ R^{\pi_2}$.

But these are first-order conditions. What about iteration? We demanded that the relation R^{π^*} used for the program π^* be the reflexive transitive closure of the relation R^{π} used for π. This constraint cannot be expressed in first-order logic; how can we impose it via PDL validity?

As follows. First we demand that

$$\langle \pi^* \rangle \varphi \leftrightarrow \varphi \vee \langle \pi \, ; \pi^* \rangle \varphi$$

be valid. This says that a state satisfying φ can be reached by executing π a finite number of times if and only if φ is satisfied in the current state, or we can execute π once and then find a state satisfying φ after finitely many more iterations of π. Second, we demand that

$$[\pi^*](\varphi \rightarrow [\pi]\varphi) \rightarrow (\varphi \rightarrow [\pi^*]\varphi)$$

be valid too. This is called *Segerberg's axiom*. Work through what it says: as you will see, in essence it is an induction schema. A frame validates all instances of the four schemas just introduced if and only if it is a regular frame.

Summing up, at both the level of models and frames, PDL has a great deal of expressive power. Hence the following result is all the more surprising:

THEOREM 44. *PDL has the finite model property and is decidable. Its satisfiability problem is EXPTIME-complete.*

Proof. The finite model property, decidability, and EXPTIME-hardness results for PDL were proved in Fisher and Ladner [47, 48]. The existence of an EXPTIME algorithm for PDL satisfiability was proved in Pratt [103]. ❑

But we are only half-way through our story. With the modal μ-calculus we will climb even higher in second-order expressivity hierarchy, and we will do so without leaving EXPTIME.

6.7 *The modal μ-calculus*

The modal μ-calculus is the basic modal language extended with a mechanism for forming least (and greatest) fixed-points. It is highly expressive (as we shall see, it is stronger than PDL) and computationally well behaved. Moreover it has a beautiful bisimulation-based characterisation. All in all, it is one of the most significant languages on the modal landscape. It was introduced in its present form by Dexter Kozen [80].

The idea underlying the modal μ-calculus is to view modal formulas as *set-theoretic operators*, and to add mechanisms for specifying their fixed-points. Now, a set-theoretic operator on a set W is simply a function $F : 2^W \mapsto 2^W$. But how can we view modal formulas as set-theoretic operators? Consider a formula φ containing some proposition symbol (say p). In any

model, φ will be satisfied at some set of points. If we systematically vary the set of points that the valuation assigns to p, the set of points where φ is satisfied will typically vary too. So we can view φ as inducing an operator over the points of some model, namely the operator that takes as argument the subset of W that is assigned to p, and returns the set of points where φ is satisfied with respect to this assignment.

Let's make this precise. We will work in a language with a collection of diamonds $\langle\pi\rangle$, so models have the form $\mathfrak{M} = (W, \{R^\pi\}_{\pi\in\mathrm{MOD}}, V)$. For any proposition symbol p, $V(p)$ is the set of points in $\mathfrak{M}$ where p is satisfied. Let's extend V to a function that returns, for arbitrary formulas φ, the set of points in $\mathfrak{M}$ that satisfy φ (we won't invent a new name for this extended valuation, we'll simply call it V). The required definition is a simple reformulation of the satisfaction definition for the basic modal language:

$$\begin{array}{rcl} V(p) & = & V(p) \text{ for all proposition symbols } p \\ V(\neg\varphi) & = & W \backslash V(\varphi) \\ V(\varphi\wedge\psi) & = & V(\varphi)\cap V(\psi) \\ V(\langle\pi\rangle\varphi) & = & \{w \mid \text{for some } v\in W,\ R^\pi wv \text{ and } v\in V(\varphi)\}. \end{array}$$

Furthermore, for any proposition symbol p and any $U \subseteq W$ we shall write $V_{[p\leftarrow U]}$ for the (extended) valuation that differs from the (extended) valuation V, if at all, only in that it assigns U to p. That is, $V_{[p\leftarrow U]}(p) = U$, and for any $q \neq p$, $V_{[p\leftarrow U]}(q) = V(q)$. Then the operator induced by a formula φ (relative to a proposition symbol p) is the function that maps any $U \subseteq W$ to $V_{[p\leftarrow U]}(\varphi)$.

Now to bring fixed-points into the picture. A subset X of W is a fixed-point of a set-theoretic operator F on W if $F(X) = X$. This is clearly a special property: which set-theoretic operators have fixed-points, and how do we calculate them? The Knaster-Tarski Theorem (see Knaster [79] and Tarski [123]) gives important answers. Firstly, this theorem tells us that fixed-points exist when we work with *monotone* set-theoretic operators (an operator F is monotone if $X \subseteq Y$ implies that $F(X) \subseteq F(Y)$). Secondly, this theorem tells us that if F is a monotone operator on a set W, then F has a least fixed-point μF, which is equal to

$$\bigcap\{U\subseteq W \mid F(U)\subseteq U\},$$

and also a greatest fixed-point νF, which is equal to

$$\bigcup\{U\subseteq W \mid U\subseteq F(U)\}.$$

That is, both μF and νF are solutions to the equation $F(X) = X$, and furthermore, for any other solution Z, we have that $\mu F \subseteq Z \subseteq \nu F$. The least and greatest fixed-points given by the Knaster-Tarski Theorem are the fixed-points the modal μ-calculus works with.

But how can we specify these fixed-points using modal formulas? By enriching the syntax with an operator μ that binds occurrences of proposition symbols. That is, we shall write expressions like $\mu p.\varphi$, in which all free occurrence of the proposition symbol p in φ are bound by μ. The intended interpretation of $\mu p.\varphi$ is that it denotes the subset of W that is the least fixed-point of the set-theoretic operator induced by φ with respect to p. Fine — but how do we know that this fixed-point exists? If φ is arbitrary, we don't. However if all free occurrences of p in φ occur positively (that is, if they all occur under the scope of an even number of negations) then a simple inductive argument shows that the set-theoretic operator induced by φ is monotone, and hence (by the Knaster-Tarski Theorem) has least (and greatest) fixed-points. Accordingly we impose

the syntactic restriction that the μ operator can only be used to bind a proposition symbol when all free occurrences of the variable occur positively. With this restriction in mind we define:

$$V(\mu p.\varphi) \;=\; \bigcap\{U \subseteq W \mid V_{[p \leftarrow U]}(\varphi) \subseteq U\}.$$

That is, the set assigned to $\mu p.\varphi$ is the least fixed-point of the operator induced by φ.

What can we say with the modal μ-calculus? Consider the expression

$$\mu p.(\varphi \vee \langle\pi\rangle p).$$

Read this as defining "the least property (subset) p such that either φ is in p or $\langle\pi\rangle p$ is in p". What is this set? A little experiment will convince you that it must be

$$\{w \in W \mid \mathfrak{M}, w \models \varphi \text{ or there is a finite } R^{\pi}\text{-sequence from } w \text{ to } v \text{ such that } \mathfrak{M}, v \models \varphi\}.$$

(The reader should check that this set really is the one given to us by the Knaster-Tarski Theorem.) Note that this is exactly the set of points that make the PDL formula $\langle\pi^*\rangle\varphi$ true.

How do we specify greatest fixed-points? With the help of the ν operator. This is defined as follows:

$$\nu p.\varphi \;=_{\mathit{def}}\; \neg\mu p.\neg\varphi(\neg p/p),$$

where $\varphi(\neg p/p)$ is the result of replacing occurrences of p by $\neg p$ is φ. This expression is well-formed: if φ is a formula that we could legitimately apply the μ operator to (that is, if all occurrences of p occur under the scope of an even number of negations), then so is $\neg\varphi(\neg p/p)$. The reader should check that this operator picks out the following set:

$$V(\nu p.\varphi) \;=\; \bigcup\{U \subseteq W \mid U \subseteq V_{[p \leftarrow U]}(\varphi)\}.$$

That is (in accordance with the Knaster-Tarski Theorem) it picks out the greatest fixed-point of the operator induced by φ. As a further exercise, the reader should check that

$$\nu p.(\varphi \wedge [\pi]p)$$

denotes the following set:

$$\{w \in W \mid \mathfrak{M}, w \models \varphi \text{ and at every } v \text{ reachable from } w \text{ by a finite } R^{\pi}\text{-sequence, } \mathfrak{M}, v \models \varphi\}.$$

Note that this is exactly the set of points w that make the PDL formula $[\pi^*]\varphi$ true.

In view of these examples, it should not come as a surprise that PDL can be translated into the modal μ-calculus. Here are the key clauses:

$$\begin{array}{rcl}
(\langle\pi_1 \cup \pi_2\rangle\varphi)^{mu} & = & \langle\pi_1\rangle(\varphi)^{mu} \vee \langle\pi_2\rangle(\varphi)^{mu} \\
(\langle\pi_1 ; \pi_2\rangle\varphi)^{mu} & = & \langle\pi_1\rangle\langle\pi_2\rangle(\varphi)^{mu} \\
(\langle\pi^*\rangle\varphi)^{mu} & = & \mu p.((\varphi)^{mu} \vee (\langle\pi\rangle p)^{mu}), \text{ where } p \text{ does not occur in } \varphi.
\end{array}$$

In fact the modal μ-calculus is strictly more expressive than PDL. The simplest example of a construct that PDL cannot model but that the modal μ-calculus can is the *repeat* operator. The expression *repeat(π)* is true at a state w if and only if there is an infinite sequence of R^{π} transitions leading from w. Proving that this is not expressible in PDL is tricky, but it can be expressed in the modal μ-calculus: the formula $\nu p.\langle\pi\rangle p$ does so. Moreover, the temporal logics

standardly used in computer science, such as LTL, CTL, and CTL*, can also be embedded in the modal μ-calculus. For remarks and references on this topic, see Chapter 12 of this handbook.

All in all, the modal μ-calculus is a highly expressive language. In spite of this, it is extremely well behaved, both computationally and in other respects. For a start we have that:

THEOREM 45. *The modal μ-calculus has the finite model property and is decidable. Its satisfiability problem is EXPTIME-complete.*

Proof. The original decidability proof was given in Kozen and Parikh [81]. The finite model property was first established in Street and Emerson [119]. The complexity result is from Emerson and Jutla [36]. ❑

Furthermore, experience shows that the modal μ-calculus is also well behaved when it comes to model checking — indeed it is widely believed that its model checking task can be performed in polynomial time. However, at the time of writing, this conjecture has resisted all attempts to prove it.

Moreover, the modal μ-calculus has an elegant semantic characterisation. Suppose we add the following clause to the standard translation for basic modal logic:

$$\mathrm{ST}_x(\mu p.\varphi) = \forall P(\forall y((\mathrm{ST}_x(\varphi) \to Py) \to Py)).$$

This clearly captures the intended semantics of μ. But note that by adding this clause we are viewing the standard translation as taking us to monadic second-order logic, for here we bind the unary predicate symbol P. This language is already familiar to us: it's the frame correspondence language introduced in Section 5, but here we're using it to express a correspondence at the level of *models*. Thus (even at the level of models) the modal μ-calculus is a fragment of monadic second-order logic. But which fragment? This one:

THEOREM 46 (Modal μ-Calculus Characterisation Theorem). *The modal μ-calculus is the bisimulation invariant fragment of monadic second-order logic.*

Proof. See Janin and Walukiewicz [73]. ❑

For more on the modal μ-calculus, see Chapter 12 of this handbook. As well as giving a detailed technical overview, the chapter also gives an informal introduction to thinking in terms of fixed-points, which is often a stumbling block when the modal μ-calculus is encountered for the first time.

6.8 Combined logics

We now turn to what is (at first glance) one of the simplest methods of obtaining a richer modal language: combine two pre-existing ones. But for all its apparent simplicity, this method of enrichment swiftly leads to difficult territory.

Many applications lead naturally to the idea of combined logics. A good example is planning. Planning involves a collection of agents who must reason about what they are going to do given that they know the effects of actions, and where getting more information may be important for solving the problem at hand. Hence Robert Moore [98] proposed a combined language for this task. His language offered both epistemic and action modalities, making it possible to say things like

$K_i[a]\varphi$ "agent i knows that doing a has the effect φ"

and

$$[a]K_i\varphi \quad \text{“doing } a \text{ makes agent } i \text{ know that } \varphi\text{”.}$$

Actually, Moore also considered combinations of PDL with epistemic operators, as plans are usually complex actions with program structure.

The fun starts when we ask how the two logics live together. For example, should they simply live side by side, the simple fusion of the two component logics? Or are there interactions between them? Obviously this depends on what we are modeling. For example, should $K_i[a]\varphi$ imply $[a]K_i\varphi$? In general, no. After all, I may know that after drinking I am boring, but unfortunately after drinking I no longer know that I am boring (that is, drinking is not an epistemically transparent action). Nor need the converse implication hold for actions that deliver genuinely new information. After consulting my account manager, I know I am broke, but I do not know now that after the consultation I am broke.

If our application does not require the modeling of such interactions, then we are dealing with the simplest possible combination of two decidable modal logics, and the result is again decidable. But for some applications we might want to enforce these interactions. Let R_a be the accessibility relation for action a, and let $\sim_i$ be the epistemic relation for agent i. The following frame correspondences tell us what these interactions give rise to:

$$\begin{array}{ll} \mathfrak{F} \models K_i[a]p \to [a]K_ip & \text{iff } \forall xyz((R_axy \wedge y \sim_i z) \to \exists u(x \sim_i u \wedge R_auz)) \\ \mathfrak{F} \models [a]K_ip \to K_i[a]p & \text{iff } \forall xyz((x \sim_i y \wedge R_ayz) \to \exists u(R_axu \wedge u \sim_i z)). \end{array}$$

The first principle says that new uncertainty links between the results of an action are inherited from existing ones; this is a version of the game-theoretic principle of *perfect recall*. The other direction is called *no learning*. These are powerful interaction principles. Indeed, they impose a grid-like interaction between the relations interpreting the modalities, hence the possibility arises of showing undecidability by encoding the tiling problem. A good source of information on this topic is Halpern and Vardi [64]. Among other things they show that the combined modal epistemic logic of agents with perfect recall, though still decidable, is highly complex, and that if a common knowledge operator (that is, using PDL notation, a box of the form $[(\sim_1 \cup \cdots \cup \sim_n)^*]$) is added, the problem becomes undecidable. This is a natural example of the bad computational behaviour that combinations of relatively simple decidable modal logics can give rise to. Moreover the air of mystery (“How can a description of well behaved agents get so complex?”) quickly gets dispelled once we realise that the behaviour of special agents may have a rich mathematical structure that makes their logic tough.

In recent years there has been intensive theoretical work on combinations of modal logic. The goal has been to provide general *transfer results*: given two (or more) modal logics, and a method of combining them, when do properties such as decidability, finite model property, and finite axiomatisability transfer from the component logics to the combined logic? The simplest way of combining two modal logics is to take their *fusion*. Given two modal logics L_1 and L_2 (in languages with disjoint sets of modal operators) then their fusion $L_1 \otimes L_2$ is the smallest logic L in their joint language that contains them both. Fusions of modal logic have been investigated in detail (key papers include Kracht and Wolter [82], Fine and Schurz [46], and Wolter [144]), and have some pleasant transfer properties. For example, to axiomatise the fusion logic L, it suffices to take the axioms for each of the components (that is, no interaction axioms involving modalities from both language are required). Moreover, both the finite model property and decidability transfer from the component logics to the fusion.

But this good behaviour reflects the fact that fusion is a combination method designed to minimise the interaction between the component modalities. What of combination methods

which allow strong interaction between the modalities? The best studied combination technique here is the formation of *products* of modal logics. Given two frames $\mathfrak{F}_1 = (W_1, R_1)$ and $\mathfrak{F}_2 = (W_2, R_2)$, their product $\mathfrak{F}_1 \times \mathfrak{F}_2$ is the frame $(W_1 \times W_2, R_h, R_v)$. Here R_h is the binary relation on $W_1 \times W_2$ defined by $(u_1, v_1)R_h(u_2, v_2)$ iff $u_1 R_1 u_2$ and $v_1 = v_2$; and R_v is the relation defined by $(u_1, v_1)R_v(u_2, v_2)$ iff $v_1 R_2 v_2$ and $u_1 = u_2$. The idea of taking products of modal logics is an old one (dating back to at least Segerberg [114]) and is a widely used combination method in many applications of modal logic. But the product construction creates frames which allow for very strong interactions between the modalities, and there are far fewer transfer results for this method of combination; indeed, there are many negative results showing transfer of decidability failures.

Work on combination of logics, from both applied and theoretical perspectives, is one of the liveliest areas of research in contemporary modal logic. For a detailed survey of fusions, products, and methods of combinations between these extremes, see Chapter 15 of this handbook.

6.9 First-order modal logic

We turn now to what is arguably one of the least well behaved modal languages ever proposed: first-order modal logic. However, in one of those twists that make intellectual history so fascinating, first-order modal logic has come to be accepted (at least in philosophical quarters) as the most important modal logic of all. For many philosophers, modal logic *is* first-order modal logic.

This is not to say that first-order modal logic is philosophically uncontroversial. Indeed, as is discussed in Chapter 21 of this handbook, one of the liveliest debates in 20th century analytic philosophy was ignited when Quine [106] questioned the coherence of the enterprise. But two advances led to its acceptance. The first was the development of the relational semantics of first-order modal logic (Kripke [83, 85] are key papers here) and the second was the publication of “Naming and Necessity” (Kripke [86]) which presented what is probably the most widely accepted philosophical interpretation of the technical machinery. While these developments did not dispel all the controversy, nowadays first-order modal logic together with (some form of) relational semantics, is generally regarded as a well understood (perhaps even boringly familiar) tool of philosophical analysis.

Viewed from a mathematical perspective, however, things look rather different. Had first-order modal logic never existed, a logician who proposed its (now standard) syntax and relational semantics might have been regarded as audacious, perhaps downright careless. Why? Because, in essence, first-order modal logic is a combined logic. As we have just seen, combining two modal logics while retaining interesting properties is no easy matter. So it should not come as too much of a surprise that combining propositional modal logic with first-order logic is unlikely to be plain sailing. In what follows we shall sketch the standard syntax and semantics, and mention some of its problematic features.

First the syntax (we omit some of the clauses for the booleans):

$$\varphi \quad ::= \quad P(x_1, \ldots, x_n) \mid x = y \mid \neg\varphi \mid \varphi \to \psi \mid \Diamond\varphi \mid \Box\varphi \mid \exists x\varphi \mid \forall x\varphi.$$

Here P is an n-place predicate symbol and the x_i are individual variables. So (given the clauses for the quantifiers and booleans) it is clear that we have a full first-order language at our disposal, and hence (because of the presence of the modalities) we can now search for first-order information at accessible states in the familiar way. But we can do more. The clauses for the quantifiers hide a subtlety: if a formula φ contains free first-order variables within the scope of a

modality, then formulas of the form $\forall x\varphi$ and $\exists x\varphi$ bind variables within the scope of the modality. This possibility is what led to Quine's philosophical objections ("no binding into intensional contexts"). And from a technical perspective it means we are combining two very different styles of logic in a way that allows a strong form of interaction.

The standard semantics for first-order modal logic comes in a number of variant forms. One basic choice concerns the domain of quantification: should the quantifiers range over some fixed domain of quantification (the *constant domain* semantics), or should each point be associated with its own domain (the varying domain semantics)? Here we shall present the varying domain semantics; for a discussion of the constant domain approach, and of equivalences between the constant domain, varying domain, and other approaches, see Chapter 9 of this handbook, or Fitting and Mendelsohn [49].

DEFINITION 47. A varying domain model is a tuple $(W, R, D, \{\delta_w\}_{w\in W}, \{V_w\}_{w\in W})$. Here W is a non-empty set; R is a binary relation on W; D (the domain of quantification) is a non-empty set; for all $w \in W$, $\delta_w \subseteq D$; and for all $w \in W$, V_w is a function that assigns to each n-place predicate symbol a subset of D^n.

That is, we have the familiar modal machinery from the propositional case (note that (W, R) is just a frame, and the V_w are essentially our familiar valuations upgraded to interpret first-order n-place predicate symbols P rather than proposition symbols p) augmented by a specification (the δ_w) of the individuals the quantifiers at each state w range over. We interpret first-order modal logic by taking such a model, together with an assignment of values to variables (that is, a function g that maps the individual variables to elements of D), and using the following satisfaction definition:

$$
\begin{array}{rll}
\mathfrak{M}, g, w \models P(x_1, \ldots, x_n) & \text{iff} & (g(x_1), \ldots g(x_n)) \in V_w(P), \\
\mathfrak{M}, g, w \models x = y & \text{iff} & g(x) = g(y), \\
\mathfrak{M}, g, w \models \neg\varphi & \text{iff} & \text{not } \mathfrak{M}, g, w \models \varphi, \\
\mathfrak{M}, g, w \models \varphi \rightarrow \psi & \text{iff} & \mathfrak{M}, g, w \not\models \varphi \text{ or } \mathfrak{M}, g, w \models \psi, \\
\mathfrak{M}, g, w \models \Diamond\varphi & \text{iff} & \text{for some } v \in W \text{ such that } Rwv \text{ we have } \mathfrak{M}, g, v \models \varphi, \\
\mathfrak{M}, g, w \models \Box\varphi & \text{iff} & \text{for all } v \in W \text{ such that } Rwv \text{ we have } \mathfrak{M}, g, v \models \varphi, \\
\mathfrak{M}, g, w \models \exists x\varphi & \text{iff} & \text{for some } g' \sim_x g \text{ where } g'(x) \in \delta_w \text{ we have } \mathfrak{M}, g', v \models \varphi, \\
\mathfrak{M}, g, w \models \forall x\varphi & \text{iff} & \text{for all } g' \sim_x g \text{ such that } g'(x) \in \delta_w \text{ we have } \mathfrak{M}, g', v \models \varphi.
\end{array}
$$

(Here $g' \sim_x g$ means that the assignments g and g' are identical save possibly in the value they assign to the variable x.)

This language is capable of expressing some important distinctions. Consider, for example, the formulas $\forall x\Box\varphi$ and $\Box\forall x\varphi$. The first asserts, of each existing entity, that it has the property φ at all accessible states. The second asserts that, at each accessible state, each entity that exists at that particular state has property φ. Should either of these formulas imply the other? That is, should we accept as valid either of the following two principles?

$$
\begin{array}{ll}
\forall x\Box\varphi \rightarrow \Box\forall x\varphi & \text{Barcan formula} \\
\Box\forall x\varphi \rightarrow \forall x\Box\varphi & \text{Converse Barcan formula}
\end{array}
$$

Instead of trying to answer such tricky philosophical questions (which bear on the *de dicto*/*de re* distinction, discussed in Chapter 9 of this handbook) let us consider what they say in the light of

the relational interpretation just given. It is not difficult to see that the Barcan formula is valid in a varying domain model iff that model has *decreasing domains*, that is, if for all $w, v \in W$, Rwv implies $\delta_v \subseteq \delta_w$. And the Converse Barcan formula is valid on precisely *increasing domain* models, that is, models with the property that Rwv implies $\delta_w \subseteq \delta_v$. So to insist on the validity of both principles is to force an even stronger interaction between the quantifiers and modalities: it takes us to a locally constant domain semantics in which Rwv implies $\delta_w = \delta_v$. This is a good example of the clarity that relational semantics can bring to difficult conceptual issues, and shows why first-order modal logic can be useful in philosophical logic and natural language semantics.

So what's the problem? Simply this: for all its analytical utility, first-order modal logic under its standard semantics is not well behaved mathematically. Early signs of trouble appeared in Fine [45], which showed that interpolation and the Beth property fail for first-order **S5** under the varying domain semantics, and for any first-order modal logic between **K** and **S5** under the constant domain semantics. As **S5** is both philosophically central (it is widely considered to embody the logic of "necessarily" and "possibly") and semantically straightforward (it is the logic of frames in which R is an equivalence relation) these are strong negative results indeed. Worse was to come. It turns out that it is possible to take a propositional modal logic that is complete with respect to some class of frames, axiomatically extend it in the manner naturally suggested by the standard semantics, and yet to wind up with an incomplete first-order modal logic (see Ghilardi [56], Shehtman and Skvortsov [117], Corsi and Ghilardi [26], Cresswell [27]).

Now, the issue here is not so much the incompleteness in itself (as we have already discussed, even in the propositional modal logic, frame incompleteness results are the norm) rather it is the *loss* of completeness in the transition from the propositional case to the first-order case that is worrying. To use the terminology introduced when we discussed combinations of logics: the standard relational semantics for first-order logic is a method of combination for which transfer of completeness fails.

Such results have led to renewed technical interest in first-order modal logic. The semantics of first-order modal logic has come under intense scrutiny, and a number of alternative semantics have been proposed which enable completeness results to be transferred. Some of this work has been model-theoretic (see, in particular, van Benthem's [132] use of functional frames) but most of it has been highly abstract, employing the language of category theory; for a detailed account of such work, see Chapter 9 of this handbook. More recently, the hybrid logic community has pointed out that upgrading the underlying propositional modal language to a hybrid language is another way to repair the situation: interpolation is regained (see Areces, Blackburn and Marx [7]), indeed, regained constructively (see Blackburn and Marx [15]) and general positive results on transfer of completeness can be proved (see Blackburn and Marx [14]). All in all, first-order modal logic is one of the most intriguing areas of modal logic: the most venerable system of all poses some of the most interesting questions about what it is to be modal.

6.10 General perspectives

Moving to richer languages better fitted for particular applications is a standard feature of current research. It is true that in some quarters sticking to the poorest modal base language of the founding fathers (despite its evident handicaps in expressive power and mathematical convenience) is still something of a religion. But the idea of designing extensions is not some new-fangled notion; its roots stretch back to the work of von Wright [145] and Prior [104, 105], and the idea was central to the work of the Sofia School (see, for example, Passy and Tinchev [101] for insightful comments on what modal logic is and why one might want to enrich it). Still, pointing to a

noble heritage is not enough. We need to address a tricky question: what makes these languages *modal*? Being precise here is difficult. As we have seen, there is a wide range of extensions. Moreover, each application imposes its own concerns and peculiarities. Nevertheless, there is a guiding idea that lies behind most examples of this form of language design: obtaining a reasonable balance between expressive power and computational complexity. So the question we should focus on is: what makes such natural balances arise?

As we have seen, many richer modal languages are fragments of the full language of first-order logic over some appropriate similarity type of relations and properties. We can see this by translation, just as we did with the basic modal language (we saw that the complex truth conditions for the Until and Since are definable by first-order formulas, and the same is true for the conditional connective, the universal modality, and the apparatus of hybrid logic). Now, there have been various attempts to find general patterns explaining which parts of first-order logic are involved in modal languages. Gabbay [51] observed that modal languages tend to translate into so-called *finite variable fragments* of first-order logics, that is, fragments using only some finite number of variables, fixed or bound. For example, we have seen that the basic modal language can make do with only two variables, and temporal logic with Until and Since, and conditional logic, only require three. Finite variable fragments have some pleasant computational behaviour; for example, their model checking complexity is in PTIME (see Vardi [141]) as opposed to PSPACE for the full first-order language. On the other hand, as we have already mentioned, satisfiability is already undecidable for first-order fragments with three variables, so the real reason for the low complexity of modal languages lies elsewhere. A different type of analysis for the latter phenomenon was given in the paper "Why is modal logic so robustly decidable?" (Vardi [142]). This emphasises the semantic adequacy of the tree-like models obtainable via bisimulation unraveling of arbitrary graph models. This type of explanation is important as it transcends first-order logic; on the other hand it does not provide much in the way of concrete syntactic insight. For the latter, the current best explanation is the one provided by the guarded fragment and its relatives (which are, arguably, the strongest known modal languages).

As we saw, guarded fragments locate the essence of modal logic in the *restriction* on the quantification performed by the modalities. One attractive property of this analysis is its logical resilience: it turns out that it extends beyond the setting of first-order enrichments to second-order enrichment too, something that was not forseen when the guarded fragment was first isolated. A striking example is the result in Grädel and Walukiewicz [63] that the extension of the guarded fragment with the fixed-point operators μ and ν remains decidable. By way of contrast, validity for full first-order logic extended with these operators is non-axiomatisable, indeed, non-arithmetical. This observation shows that the modal philosophy embodied in the idea of guarded fragments is not restricted to first-order extensions: often modal fragments can bear the weight of additional higher-order apparatus (such as fixed-point operators) which would send the full first-order correspondence languages into a tailspin complexity wise. Our discussion of PDL and the modal μ-calculus has shown that this is the case for the basic modal language. Grädel and Walukiewicz's result for the guarded fragment shows that this type of behaviour persists higher up: guarded quantification can support higher-order constructions too.

Perhaps guarding can be a fruitful strategy in even more exotic modal settings? One setting worth exploring is *infinitary* modal logic. This logic (which was used extensively in Barwise and Moss [10] and Baltag [8] for investigating non-well founded set theory; see Chapter 16 of this handbook) provides a perfect match with bisimulation: two pointed models are bisimilar if and only if they satisfy the same formulas in a modal language that allows arbitrary infinite conjunctions and disjunctions. Moreover a modal characterisation theorem holds. Now, decidability is a

non-issue in this setting, but what about existential semantic properties such as interpolation and Beth Definability? It is known that interpolation holds for infinitary modal logic (see Barwise and van Benthem [11]), but can such results be lifted to infinitary guarded fragments? Another setting worth exploring in this way is *second-order propositional modal logic*, in which we can quantify over proposition symbols (see Fine [42] for some early results, ten Cate [124] for a more recent discussion, and Chapter 10 of this handbook for a brief overview). The equation "modality = guarding" should be simultaneously regarded as a hypothesis to be tested in richer settings, and as a useful heuristic for isolating further logics worth calling modal.

Not that we should put all our eggs in one basket. Perhaps the notion of modality is too diffuse for any single approach to exhaust, and in any case it is worth looking for alternatives. Another approach is to apply ideas from abstract model theory (see Barwise and Feferman [9]). This was first done in de Rijke [30], who proved a modal analog of Lindström's [91] celebrated characterisation of first-order logic. The original form of Lindström's theorem says that an abstract logic $\mathcal{L}$ extending first-order logic coincides with first-order logic iff it has the compactness and Löwenheim-Skolem properties. Another way of stating the theorem is that an abstract logic $\mathcal{L}$ extending first-order logic coincides with first-order logic iff it has the compactness and Karp properties. (The Karp property is that all formulas are invariant for potential isomorphism, where a potential isomorphism is a non-empty family of finite partial isomorphisms closed under the usual back and forth extension properties; recall our discussion of partial isomorphisms in Section 3.3). We shall discuss a (slightly reformulated) version of de Rijkes's result and a more recent characterisation due to van Benthem.

What is an abstract modal logic? Here's the conception that underlies our reformulation of de Rijke's result. We give it in terms of pointed models $(\mathfrak{M}, w)$, that is, a model together with a point of evaluation.

DEFINITION 48 (Very abstract modal logics). Let $\mathcal{L}$ be a set of formulas, and $\models_{\mathcal{L}}$ its satisfaction relation, that is, a relation between pointed models and $\mathcal{L}$-formulas. A very abstract modal logic is a pair $(\mathcal{L}, \models_{\mathcal{L}})$ with the following properties:

1. Occurrence property. For each φ in $\mathcal{L}$ there is an associated finite language $\mathcal{L}(\lambda_\varphi)$. The relation $(\mathfrak{M}, w) \models_{\mathcal{L}} \varphi$ is a relation between $\mathcal{L}$-formulas φ and models $(\mathfrak{M}, w)$ for languages $\mathcal{L}$ containing $\mathcal{L}(\lambda_\varphi)$. That is, if φ is in $\mathcal{L}$, and $\mathfrak{M}$ is an $\mathcal{L}$-model, then $(\mathfrak{M}, w) \models_{\mathcal{L}} \varphi$ is either true or false if $\mathcal{L}(\lambda_\varphi) \subseteq \mathcal{L}$, and undefined otherwise.

2. Expansion property. The relation $(\mathfrak{M}, w) \models_{\mathcal{L}} \varphi$ depends only on the restriction of $\mathfrak{M}$ to $\mathcal{L}(\lambda_\varphi)$. That is, if $(\mathfrak{M}, w) \models_{\mathcal{L}} \varphi$ and $(\mathfrak{N}, w)$ is an expansion of $(\mathfrak{M}, w)$ to a larger language, then $(\mathfrak{N}, v) \models_{\mathcal{L}} \varphi$.

A very abstract modal logic $(\mathcal{L}, \models_{\mathcal{L}})$ extends basic modal logic if for every basic modal formula there exists an equivalent $\mathcal{L}$-formula (that is, if for each basic modal formula φ there exists an $\mathcal{L}$-formula ψ such that for any model $(\mathfrak{M}, w)$ we have $(\mathfrak{M}, w) \models \varphi$ iff $(\mathfrak{M}, w) \models_{\mathcal{L}} \psi$).

De Rijke's characterisation centres on the familiar bisimulation invariance property and the *finite depth property*. A very abstract modal logic $\mathcal{L}$ has the *finite depth property* iff for any $\mathcal{L}$-formula φ there is some natural number k such that for all models $\mathfrak{M}$,

$$\mathfrak{M}, w \models \varphi \text{ iff } \mathfrak{M}|k, w \models \varphi,$$

where $\mathfrak{M}|k$ is the model $\mathfrak{M}$ restricted to just those points that can be reached from w in k or fewer R-steps. De Rijke builds invariance for bisimulation into the notion of abstract modal

logic, so his statement of his Lindström-style result has the form: any abstract modal logic with the finite depth property that extends the basic modal language is the basic modal language. Reformulating his result in terms of very abstract modal logics, thereby making the bisimulation invariance condition explicit, results in:

THEOREM 49. *Suppose $\mathcal{L}$ is a very abstract modal logic extending the basic modal language. Then $\mathcal{L}$ coincides with the basic modal language iff $\mathcal{L}$ has the finite depth and invariance for bisimulation properties.*

Proof. See de Rijke [30, 31]. For a textbook-level exposition of the proof, see Theorem 7.60 of Blackburn, de Rijke and Venema [13]. ❑

This is an informative result. Nonetheless, the finite depth property seems somewhat engineered to capture the basic modal language, and it is natural to look for generalisations. However, because of the expressive limitations of modal languages, this is not straightforward. The proof of the Lindström Theorem for first-order logic typically proceeds by contradiction: to show that an abstract first-order formula has a first-order equivalent, one typically builds a model where φ is true in one part, $\neg\varphi$ in another, and uses the expressive power of first-order logic to link the two parts of the model by a chain of partial isomorphisms, thereby reaping the contradiction. This style of argument does not lift easily to modal languages: the basic modal language is too impoverished to encode the chains of bisimulations linking the two parts of the model that would be required to mimic this proof technique directly. However, as van Benthem [139] observed, there is a way around this. The key idea is to strengthen the definition of a very abstract modal language by demanding it fulfils the *relativisation* condition:

DEFINITION 50 (Abstract modal logics). An abstract modal logic $\mathcal{L}$ is a very abstract modal logic that has the *relativisation property*: for any $\mathcal{L}$-formula φ and proposition symbol p not occurring in φ, there is a formula $\mathit{Rel}(\varphi, p)$ which is true at a model $(\mathfrak{M}, w)$ iff φ is true at $(\mathfrak{M}|p, w)$, which is the submodel of $\mathfrak{M}$ consisting of just those points that satisfy p.

Relativisation is a natural property (most logics satisfy it) but the key point is to observe is how it is used in the proof of the following theorem: in essence, it provides a model-theoretic tool which enables us to give an alternative proof without resorting to explicit codings of bisimulations. This leads to van Benthem's version of the Lindström Theorem for modal logic:

THEOREM 51. *Suppose $\mathcal{L}$ is an abstract modal logic extending the basic modal language. Then $\mathcal{L}$ coincides with the basic modal language iff $\mathcal{L}$ satisfies compactness and invariance for bisimulation.*

Proof. We know that the basic modal language satisfies compactness (Proposition 4) and invariance for bisimulation (Lemma 9) so the left to right direction is clear. For the reverse direction, assume that $\mathcal{L}$ has these properties. We claim that the following holds: *in a compact abstract modal logic $\mathcal{L}$ which is invariant for bisimulations, every formula has the finite depth property.* If we can show this, the result follows from Theorem 49.

We prove the claim as follows. Let φ be any formula in $\mathcal{L}$. Suppose for the sake of a contradiction that φ lacks the finite depth property. Then for any natural number k there exists a model $(\mathfrak{M}_k, w)$ and a cut-off version $(\mathfrak{M}_k|k, w)$ which disagree on the truth value of φ. Without loss of generality, assume that the following happens for arbitrarily large k: $(\mathfrak{M}_k|k, w) \models \varphi$, and $(\mathfrak{M}_k, w) \models \neg\varphi$ (here we use the fact that abstract modal logics are closed under negation). Now take a new proposition symbol p, and consider the following set Σ of $\mathcal{L}$-formulas:

$$\{\neg\varphi, \mathit{Rel}(\varphi, p)\} \cup \{\Box^n p \mid \text{for all natural numbers } n\}.$$

(By $\Box^n p$ we mean p prefixed by a sequence of n boxes.) Given our assumptions, this set is finitely satisfiable: we choose k sufficiently large, and make p true in the k reachable part of one of the above sequences of models. But then, by compactness for our abstract modal logic $\mathcal{L}$, there must be a model $(\mathfrak{N}, v)$ for the whole set Σ at once.

But this leads to a contradiction as follows. We focus on the generated submodel $(\mathfrak{N}_v, v)$ consisting of v and all points finitely reachable from it. Now, the identity relation is a bisimulation between any pointed model and its unique generated submodel. Hence, by the assumed invariance for bisimulation, formulas of $\mathcal{L}$ have the same truth value in any pointed model and its generated submodel. Now, given our definition of Σ, $\neg\varphi$ holds in $(\mathfrak{N}, v)$, and hence also in $(\mathfrak{N}_v, v)$. On the other hand, since $(\mathfrak{N}, v) \models Rel(\varphi, p)$, we have $(\mathfrak{N}|p, v) \models \varphi$. But by the truth of all the formulas of the form $\Box^n p$, p holds in the whole generated submodel $(\mathfrak{N}_v, v)$. Therefore we have that φ holds in (N_v, v). Contradiction. Hence the claim is established and the theorem follows. ❑

One surprising consequence of this result is that the Modal Characterisation Theorem (Theorem 13) follows from it; see van Benthem [139] for details.

It remains to be seen how widely applicable this technique is. For example, it is not straightforwardly applicable to languages with the universal modality, as these lack the finite depth property. However it *can* be lifted to the guarded fragment. As we mentioned in Section 6.5, there is a notion of guarded bisimulation. And using this notion, together with the relativisation technique leads to:

THEOREM 52. *Suppose $\mathcal{L}$ is an abstract modal logic extending the guarded fragment. Then $\mathcal{L}$ coincides with the guarded fragment iff $\mathcal{L}$ satisfies compactness and invariance for guarded bisimulation.*

Proof. See van Benthem [139]. ❑

7 ALTERNATIVE SEMANTICS

As we said at the start of this chapter, one of the most instructive ways of thinking about modal logic is to view it as a tool for talking about graphs. But to view modal logic exclusively through the lens of relational semantics would be a mistake; interesting alternatives exist, and in this section we introduce three of them: algebraic semantics, neighbourhood semantics, and topological semantics. As we shall see, each of these semantics has something new to offer. But we shall come across much that is familiar, for all three are linked in various ways with relational semantics.

7.1 Algebraic semantics

The basic idea of algebraic semantics is simple: view modal formulas as terms (or polynomials) and evaluate them in the appropriate type of algebra. So the key question is: what kinds of algebra are appropriate for modal logic? The answer is: *boolean algebras with operators*, or BAOs.

A *boolean algebra* is a triple $\mathfrak{A} = (A, +, \times, -, 1, 0)$ such that both $+$ (*join*) and $\times$ (*meet*) are commutative and associative binary operations, each of which distributes over the other. The unary operation $-$ (*complement*) must satisfy the equations $x + (-x) = 1$ and $x \times (-x) = 0$. The nullary operations (or *constants*) 1 and 0 must satisfy the equations $x \times 1 = x$ and $x + 0 = x$.

Even if you have never encountered boolean algebras before, a moment's reflection should make it clear that they are an algebraic mirror of propositional logic. To see this, read $+$ as $\vee$, $\times$ as $\wedge$, $-$ as $\neg$, 1 as $\top$, 0 as $\perp$, and $=$ as $\leftrightarrow$. So it only remains to provide algebraic structure that mirrors the diamonds. This motivates the following definition.

DEFINITION 53 (Boolean Algebras with Operators). A boolean algebra with operators, or BAO, is a pair $\mathfrak{B} = (\mathfrak{A}, m)$, where $\mathfrak{A}$ is a boolean algebra and m is a unary operator on $\mathfrak{A}$ that satisfies the equations $m(x + y) = m(x) + m(y)$, and $m(0) = 0$.

Note that the logical analogs of these two equations are $\Diamond(\varphi \vee \psi) \leftrightarrow (\Diamond\varphi \vee \Diamond\psi)$, and $\Diamond\perp \leftrightarrow \perp$, both of which are valid in relational semantics. Thus we now have an algebraic mirror for all components of the basic modal language.

We interpret the basic modal language in BAOs in the usual algebraic fashion. That is, given a BAO, we view the proposition symbols as variables ranging across the elements of the algebra, and interpret each logical operator by its corresponding algebraic operation. More precisely, let $\mathfrak{B}$ be a BAO, and V be a function mapping each proposition symbol to an element of $\mathfrak{B}$; we call such a function V an *algebraic valuation*. We extend V to a function that gives the result of evaluating arbitrary basic modal formulas in $\mathfrak{B}$ via the following recursive clauses:

$$\begin{array}{rcl} V(\varphi \vee \psi) & = & V(\varphi) + V(\psi) \\ V(\varphi \wedge \psi) & = & V(\varphi) \times V(\psi) \\ V(\neg\varphi) & = & -V(\varphi) \\ V(\Diamond\varphi) & = & mV(\varphi) \end{array}$$

It is now possible to prove the following algebraic completeness result:

THEOREM 54. *A basic modal formula belongs to the minimal modal logic **K** iff it evaluates to the value* 1 *in all modal algebras under all algebraic valuations.*

Proof. Straightforward. The key point is to use a technique standard in algebraic logic, namely to create the *Lindenbaum-Tarski Algebra* for **K**. The elements of the Lindenbaum-Tarski Algebra are equivalence classes of **K**-provably equivalent formulas; the operations are defined with the aid of the connectives. All and only the **K**-provable formulas evaluate to 1 in this algebra, and hence the result follows. For a detailed discussion, see Chapter 6 of this handbook. ❑

In fact, a far stronger result can be proved: *any* axiomatic extension of **K** (that is, *any* normal modal logic) is complete with respect to some class of algebras. And the proof is not difficult. In essence, one replicates the completeness proof for **K**, but works with the Lindenbaum-Tarski Algebra which satisfies the additional axiomatic constraints. As we saw earlier (recall Theorem 26) there is no general completeness result for normal modal logics with respect to frames. This is an important difference between algebraic and relational semantics.

Nonetheless, it is likely that some readers will feel a little cheated. Isn't the whole approach really just syntax in disguise? After all, algebraic semantics matches the modal language with algebraic operations that transparently mirror fundamental validities of the original logic. This does not seem like genuine semantic analysis: it has more the flavour of linking two distinct, but closely related, syntactic realms. Moreover, the algebraic satisfaction definition has a global rather than a local flavour.

This is true, but somewhat besides the point, for in spite of the general completeness result just noted, we have not yet entered the heartland of algebraic semantics. For what algebraic semantics really provides is a doorway to a larger mathematical universe. The power of algebraic semantics

comes from the wealth of ideas and techniques it enables us to bring to bear on problems in modal logic. Some of these techniques take us back, via a novel path, to the heart of relational semantics, but others take us to new territory. Let's look a little deeper.

An important theme in algebra is the *representation* of abstract mathematical structures by concrete set-theoretic structures. The point of a representation theorem is to show that some abstractly specified class of algebras picks out an intended class of concrete structures. So representation theorems are rather like completeness theorems: they show that the abstract (often equational) specification is strong enough to ensure that every abstract algebra is isomorphic to a concrete algebra. Two classic examples are Cayley's Theorem, which shows that every finite group is isomorphic to a collection of permutations, and the Stone Representation Theorem, which shows that every abstract boolean algebra is isomorphic to a field of sets (that is, a boolean closed collection of subsets of some W that contains W) with $\times$ viewed as intersection, $+$ viewed as union, and $-$ viewed as set-theoretic complement. Now, in 1952, several years before relational semantics was officially invented, Jónsson and Tarski [74, 75] proved a remarkable representation theorem for BAOs: they showed that every abstract BAO could be represented as a relational structure. Inexplicably, their paper made no mention of modal logic. This was unfortunate as their paper contained all the technical machinery needed to define *relational* semantics and prove *relational* completeness results for most commonly occurring modal logics. In essence, their result allows relational completeness proofs to be factored into an algebraic completeness step (which makes use of the Lindenbaum-Tarski Algebra) followed by a representation step (which turns this algebra into a relational structure). Nowadays, the Jónsson-Tarski Theorem is rightly considered a cornerstone of modal logic; for a detailed proof of the theorem, and examples of how to put it to work, see Chapter 6 of this handbook.

Another important theme goes under the name of *duality theory*. As we saw in Section 5, there are four key transformations on frames (disjoint unions, generated submodels, bounded morphisms, and ultrafilter extensions) and, as the Goldblatt-Thomason Theorem tells us, closure of a frame class under these model-theoretic constructions is necessary and sufficient to ensure its basic modal definability. But as we have already remarked (see Theorem 33) the original proof of the Theorem was *algebraic*. What's the algebraic connection? This: each of these four operations on frames corresponds to an operation on classes of algebras. Viewed this way, the Goldblatt-Thomason Theorem can be seen as a modal version of the Birkhoff Theorem, which identifies equationally definable classes of algebras with those classes of algebras that are closed under the formation of subalgebras, homomorphisms, and products. For a detailed discussion, we again refer the reader to Chapter 6.

But important as these two examples are, they merely hint at the wealth of techniques made available by the algebraic connection. Algebraic semantics has repeatedly proved itself a powerful analytical tool. To give another classic example, Blok [16] was able to give a detailed analysis of frame incompleteness by drawing on algebraic methods. In particular, he did so by investigating *splittings* (a concept from lattice theory) of the lattice of normal modal logics; for a discussion of Blok's work, see Chapter 7 of this handbook. Moreover, in many cases algebraic methods have been adapted to richer modal languages. A nice example is provided by the universal modality. In the algebraic setting, the universal modality allows us to define a *discriminator term*, that is, a term denoting an operator that maps 0 to 0 and all other elements to 1. Algebras with discriminator terms are particularly straightforward to work with (see Chapter 6 of this handbook) thus here algebraic semantics sheds interesting light on a relationally-natural extension of the basic modal language. But algebraic semantics also illuminates areas where relational semantics has little to say. For example, it turns out that the boolean structure of the

underlying algebras is not particularly significant. That is, it is possible to analyse modalities algebraically even if we *don't* have full classical propositional logic at our disposal. Such logics can be important in various settings, and relational semantics at present offers little in the way of insight. For further remarks and references on this application of algebraic semantics, see Chapter 6 of this handbook.

7.2 Neighbourhood semantics

For some applications, relational semantics is too strong. For example, $\Diamond(\varphi \vee \psi) \to (\Diamond\varphi \vee \Diamond\psi)$ is valid under relational semantics. But if we read $\Diamond\varphi$ as making the game-theoretic assertion that the player has a strategy forcing the outcome to satisfy φ, we might be inclined to reject it: why should possession of a strategy for a disjunction imply possession of a strategy for one of the disjuncts? For example, suppose we play a game with the following moves: you have the right to decide whether we go to a movie or a concert, and I can decide which particular movie or concert we go to. Suppose the movie I want to see is *Crash*, and that my favourite music is *Mozart*. It follows that I can force *Crash* $\vee$ *Mozart*, but (because it's you who determines the movie/concert option) I can't determine which of these two options will actually take place. Similarly, if we interpret $\Box\varphi$ epistemically we have further grounds for objection. For a start, relational semantics validates the following principle:

$$\Box(\varphi \to \psi) \to (\Box\varphi \to \Box\psi).$$

Moreover, it validates the following pattern of inference: if $\models \varphi$ then $\models \Box\varphi$. These work together to enforce a strong form of logical omniscience: if an agent knows φ, then she knows all its logical consequences.

Such considerations have led to a search for weaker semantics. Perhaps the best known of these is neighbourhood semantics (introduced in Montague [96, 97] and Scott [112] and explored in Segerberg [113]). The key idea of neighbourhood semantics has a topological flavour: each point w in a model is associated with a collection of subsets of the domain (the neighbourhoods of w) and a formula of the form $\Box\varphi$ is true at w iff the set of points in a model satisfying φ is a neighbourhood of w. Let's make this precise. A neighbourhood model is a triple (W, R, V) where W is a non-empty set of states, V is a valuation, and R relates points $w \in W$ to subsets of W (that is, $R \subseteq W \times 2^W$). For any $w \in W$, let N_w be $\{U \subseteq W \mid wRU\}$; we call N_w the set of neighbourhoods of w. We interpret boxed formulas as follows:

$$\mathfrak{M}, w \models \Box\varphi \text{ iff } \{u \in W \mid \mathfrak{M}, u \models \varphi\} \in N_w,$$

and use the dual definition for diamonds:

$$\mathfrak{M}, w \models \Diamond\varphi \text{ iff } \{u \in W \mid \mathfrak{M}, u \not\models \varphi\} \notin N_w.$$

Neighbourhood semantics is a generalisation of relational semantics. To see this, note that given any relational model $\mathfrak{M} = (W, R, V)$ we can form a neighbourhood model $\mathfrak{M}^n = (W, R^n, V)$ by stipulating, for each $w \in W$ and $U \subseteq W$, that $R^n wU$ iff $U = \{u \in W \mid Rwu\}$. That is, for each $w \in W$, N_w is the singleton set containing the set of points that are R-accessible from w. Hence, for all $w \in W$ and all basic modal formulas φ, we have that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}^n, w \models \varphi$. In short, we can turn any relational model into an equivalent neighbourhood model.

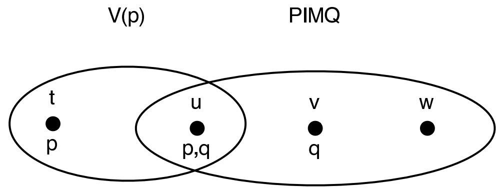

Figure 22. Neighbourhood model that falsifies $\Box(\varphi \to \psi) \to (\Box\varphi \to \Box\psi)$ at u.

But we cannot do the reverse. Consider a model $\mathfrak{M} = (W, R, V)$ such that $W = \{t, u, v, w\}$, $V(p) = \{t, u\}$ and $V(q) = \{u, v\}$, and $N_u = \{V(p), \mathit{PIMQ}\}$, where $\mathit{PIMQ} = \{u, v, w\}$. Such a model is shown in Figure 22; note that *PIMQ* is the set of points where $p \to q$ is true. Hence $\mathfrak{M}, u \models \Box(p \to q)$, as $\mathit{PIMQ} \in N_u$. Furthermore, $\mathfrak{M}, u \models \Box p$, as $V(p) \in N_u$. However $\mathfrak{M}, u \not\models \Box q$, for $V(q) \notin N_u$. So $\mathfrak{M}, u \not\models \Box(\varphi \to \psi) \to (\Box\varphi \to \Box\psi)$. As this formula is valid under relational semantics, no relational model equivalent to $\mathfrak{M}$ exists.

Moreover, the inferential principle characteristic of relational semantics (if $\models \varphi$ then $\models \Box\varphi$) no longer holds. To see this, it suffices to consider a model $\mathfrak{M}$ consisting of a single point w such that $N_w = \emptyset$. Then $\mathfrak{M}, w \models \top$, but $\mathfrak{M}, w \not\models \Box\top$. In fact, all that remains in neighbourhood semantics is the weaker principle: if $\models \varphi \leftrightarrow \psi$ then $\models \Box\varphi \leftrightarrow \Box\psi$. Thus neighbourhood semantics does not enforce logical omniscience.

Neighbourhood semantics has been criticised as under-motivated. It may banish the spectre of logical omniscience, but does it do so in a principled way? After all, isn't there something stipulative, indeed ad-hoc, about simply asserting that certain subsets and not others are in the neighbourhood of a given point? There is a grain of truth in such criticisms, nonetheless we should not be too quick to dismiss the approach. For some applications, asserting that certain neighbouring regions are important is probably the best we can do in the way of semantic analysis. Furthermore, like relational semantics, neighbourhood semantics offers an entire *framework* for semantics; imposing further restrictions on neighbourhoods (for example, demanding that neighbourhoods be superset closed) is a mechanism which permits finer-grained semantic analyses to be attempted. See Chellas [24] for an introduction to some of the options here.

Neighbourhood semantics has some pleasant properties. For a start (if NP $\neq PSPACE$, the standard assumption) it is better behaved computationally than relational semantics:

THEOREM 55. *The satisfiability problem for neighbourhood semantics is NP-complete.*

Proof. See Vardi [140]. The key observation is that if a formula φ is satisfiable in a neighbourhood model, then it is satisfied in a model with at most $|\varphi|^2$ states, where $|\varphi|$ is the number of symbols in φ. ❑

Moreover, neighbourhood semantics meshes well with the algebraic and co-algebraic approaches discussed in Chapter 6 of this handbook.

7.3 Topological semantics

Topological semantics is one of the oldest modal semantics, and the first in which deep technical results were proved. In 1938, Tarski [122] showed that **S4** (the logic which in relational semantics is complete with respect to transitive and reflexive frames) is complete with respect to

topological spaces. Then, in 1944, McKinsey and Tarski [95] showed that **S4** is the modal logic of the real numbers, and indeed of any metric separable space without isolated points. Since this pioneering work, topological semantics has been deeply (if somewhat sporadically) studied, and many interesting results have been proved (see for example Esakia [38] and Shehtman [115]) but for many years it was rather isolated from the modal mainstream. More recently, however, partly because of the growing interest in logics of space, there has been a revival of interest. For an overview of developments in topological semantics since the time of Tarski, see Chapter 16 of this handbook; here we will introduce its basic ideas in a way that emphasises connections with our account of relational semantics. Our discussion is based on Aiello, van Benthem, and Bezhanishvili [2].

A *topological space* is a pair (W, τ), where W (the *domain*) is a non-empty set and τ (the *topology*) is a collection of subsets of W that contains both $\emptyset$ and W, is closed under finite intersections (that is, if $O, O' \in \tau$ then $O \cap O' \in \tau$) and closed under arbitrary unions (if $\{O_i\}_{i \in I} \in \tau$ then $\bigcup_{i \in I} O_i \in \tau$). A topology τ such that $\tau = 2^W$ is called *discrete*, and a topology such that $\tau = \{\emptyset, W\}$ is called *trivial*. If (W, τ) is a topological space and $O \in \tau$ then O is called an *open set*. If w is a point in an open set O, then O is called an *open neighbourhood* of w. A *closed set* is the complement of an open set.

A *topological model* is a triple $\mathfrak{M} = (W, \tau, V)$ where (W, τ) is a topological space and V is a valuation (in the sense familiar from relational semantics). We interpret proposition symbols and booleans in the usual way, but what about the modalities? Boxed formulas are handled as follows:

$$\mathfrak{M}, w \models \Box\varphi \text{ iff } (\exists O \in \tau)(w \in O \text{ and } (\forall u \in O)(\mathfrak{M}, u \models \varphi)).$$

That is, $\Box\varphi$ is true at w iff it is true at all the points of some open neighbourhood of w. Diamonds are handled dually:

$$\mathfrak{M}, w \models \Diamond\varphi \text{ iff } (\forall O \in \tau)(w \in O \text{ implies } (\exists u \in O)(\mathfrak{M}, u \models \varphi)).$$

That is, $\Diamond\varphi$ is true at w iff it is true at some point in each open neighbourhood of w.

At first blush, this looks very different from relational semantics. And there *are* some obvious semantic differences. For example, the characteristic axioms of **S4**, namely $\Box p \to p$ and $\Box p \to \Box\Box p$, are valid on all topological models, so the minimal logic is stronger than in relational semantics. But a closer look reveals the similarities. For a start, like relational semantics, topological semantics is local: the truth value of a formula at a point only depends on what happens inside the open neighbourhoods of that point. More precisely, suppose that w is a point in a topological model $\mathfrak{M}$, and that O is an open neighbourhood of w. Let $\mathfrak{M}|O$ be the model with domain O whose open sets are all the open subsets of O in $\mathfrak{M}$, and whose valuation is the restriction of the valuation V of $\mathfrak{M}$ to O (that is $V|O(p) = V(p) \cap O$). Then a simple induction shows that for all basic modal formula φ, and all points $w \in O$, $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}|O, w \models \varphi$. Nor is it hard to find other similarities. For example, the fact that **S4** has the finite model property with respect to relational semantics is neatly matched by the fact that the basic modal language has the finite model property with respect to topological semantics.

But the similarities run deeper than these examples might suggest. In particular, topological semantics gives rise to a natural notion of bisimulation:

DEFINITION 56 (Topo-bisimulation). A topo-bisimulation between two topological models $\mathfrak{M} = (W, \tau, V)$ and $\mathfrak{M}' = (W', \tau', V')$ is a non-empty binary relation E between their domains (that is, $E \subseteq W \times W'$) such that whenever wEw' we have that:

Atomic harmony: w and w' satisfy the same proposition symbols,

Zig: if $w \in O \in \tau$, then there is an open set $O' \in \tau'$ such that $w' \in O'$ and $(\forall u' \in O')(\exists u \in O)(uEu')$, and

Zag: if $w' \in O' \in \tau'$, then there is an open set $O \in \tau$ such that $w \in O$ and $(\forall u \in O)(\exists u' \in O')(uEu')$.

If there is a topo-bisimulation between two topological models $\mathfrak{M}$ and $\mathfrak{N}$, then we say that $\mathfrak{M}$ and $\mathfrak{N}$ are topo-bisimilar. Moreover, we say that two states are topo-bisimilar if they are related by some topo-bisimulation.

Let's restate the zig clause informally: it says that for two points w and w' to be topo-bisimilar, then for any open neighbourhood O of w it must be possible to find an open neighbourhood O' of w' such that every point u' in O' is topo-bisimilar to some u in O. Figure 23 illustrates this idea (the dotted line connecting u and u' needs to be interpreted universally: *every* u' is linked to some u).

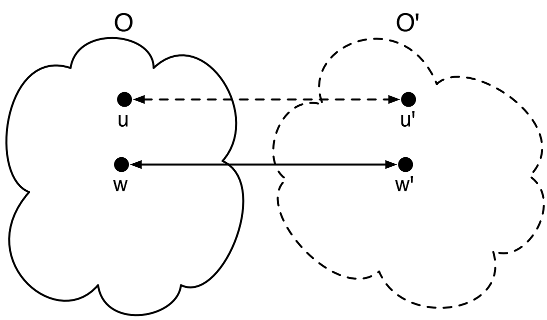

Figure 23. Zig (and zag) for topo-bisimulations

Such bisimulations are topologically natural. Two basic concepts of topology are *open maps* and *continuous maps*. For any topological spaces (W, τ) and (W', τ'), a function f from W to W' is called open if for all $O \in \tau$ we have that $f(O) \in \tau'$, and it is called continuous if for all $O' \in \tau'$ we have that $f^{-1}(O') \in \tau$. It is easy to see that every open and continuous map induces topo-bisimulations: given a valuation on one space, take its image in the other, and the resulting models are topo-bisimilar. But topo-bisimulations are also modally natural. For a start, we have the following analog of Lemma 9:

LEMMA 57 (Topo-bisimulation Invariance Lemma). *If E is a topo-bisimulation between $\mathfrak{M} = (W, \tau, V)$ and $\mathfrak{M}' = (W', \tau', V')$, and wEw', then w and w' satisfy the same basic modal formulas.*

Proof. A routine induction. ❑

As a simple illustration, we noted above that $\mathfrak{M}$ and $\mathfrak{M}|O$ (the localisation of $\mathfrak{M}$ to some open set O) were equivalent. But this is unsurprising. The identity relation between the domains of the two models is a topo-bisimulation, hence the result is a special case of this lemma.

What about the converse? Characterisation results for the general case are tricky to state (we would need to discuss what a suitable correspondence language for topological semantics is, and this would take us too far afield). But we *do* have an analog of Proposition 11:

PROPOSITION 58. *If points w and w' from two finite topological models $\mathfrak{M}$ and $\mathfrak{N}$ satisfy the same modal formulas, then there is a topo-bisimulation E between $\mathfrak{M}$ and $\mathfrak{N}$ such that wEw'.*

So far so good. But just how expressive is the basic modal language in the new setting? To pose the question a little more forcefully: what (interesting) topological conditions can the basic modal language enforce via the concept of validity? Here's one example. The formula

$$p \leftrightarrow \Box p$$

is valid on a topological model iff that model bears the discrete topology (that is, iff every subset of the domain is open). This is pleasant, but many fundamental properties lie beyond the reach of the basic language. For example, a topological space (W, τ) is *connected* iff the only elements of τ that are both open and closed are W and $\emptyset$. But this condition is not basic modal definable. For suppose for the sake of a contradiction that some formula φ does define connectedness. Consider the topological space with domain $\{1, 2\}$ under the discrete topology; this space is *not* connected as $\{1\}$ and $\{2\}$ are both open and closed. Hence we can define a model $\mathfrak{M}$ on this space that will falsify φ at some point, say 1. But then $\mathfrak{M}|\{1\}$ will falsify φ at 1 too, as $\mathfrak{M}$ and $\mathfrak{M}|\{1\}$ are topo-bisimilar. But $\mathfrak{M}|\{1\}$ bears the trivial topology, hence it is a connected space, so it should validate φ. We conclude that connectedness is undefinable.

All in all, the basic modal language turns out to be disappointingly weak when it comes to standard topological conditions. But then why stick with the basic modal language? As readers of this chapter are well aware, there are interesting ways of augmenting modal expressivity, and recently these have begun to be explored in the topological setting. For example, Shehtman [116] and Aiello and van Benthem [1] observe that connectivity becomes definable when the universal modality is added to the language:

$$A(\Diamond p \to \Box p) \to (Ap \vee A\neg p).$$

And Gabelaia notes that the T_0 condition (for any two points x and y there exists either an open neighbourhood O_x of x such that $y \notin O_x$ or an open neighbourhood O_y of y such that $x \notin O_y$) is definable in the basic hybrid language by

$$@_i\neg j \to (@_j\Box\neg i \vee @_i\Box\neg j),$$

and that the T_1 condition (every singleton set is closed) is definable by

$$i \leftrightarrow \Diamond i.$$

Gabelaia [54] proves an analog of the Goldblatt-Thomason Theorem for the basic modal language with respect to topological semantics, and Sustretov [121] has extended the result to the basic hybrid language enriched with the universal modality. However Sustretov also shows that the T_2 condition (every distinct pair of points is contained in disjoint open neighbourhoods) is not definable in this richer language.

8 MODAL LOGIC AND ITS CHANGING ENVIRONMENT

Traditional motivations for and applications of modal logic came from philosophy, and dealt with such topics as modality, knowledge, conditionals, and obligations. Other strands dealt with more mathematical topics, leading to modal logics of time, space, or provability. As time went by,

additional influences made modal logic even more diverse. Sources included computer science (for modal logics of computation and general processes), Artificial Intelligence (for modal logics for knowledge representation, non-monotonic reasoning, and belief revision), linguistics (for modal logics of grammatical structure), and the internet (for modal logics of trees). This web of new interfaces is still growing. Modern computer science, with its emphasis on new information carriers and networks of intelligent computing agents, also brings in modal logics of image processing, agency and security. And the empirical social sciences are joining in too, witness current applications of modal logic in economic game theory, or for modeling the powers of agents in social choice theory.

In the face of this diversity, the resilience of relational semantics is quite remarkable. Although nearly half a century old, its central ideas remain applicable, and applicable even when we enrich our conception of what a modal logic actually is. But what *are* the central ideas of relational semantics? In essence, this chapter has tried to make the following point clear: during the 50 or so years that relational semantics has existed, our understanding of it has become both broader and deeper. Originally conceived as a way of distinguishing and characterising logics (via soundness and completeness theorems) modal logicians have gradually unearthed the deeper mathematical themes that lie behind the seemingly modest facade of relational semantics; themes such as expressivity at the level of models versus the level of frames, the importance of bisimulation and other game-like constructions, the systematic links between the modal universe and many varieties of classical logic, ranging from first-order logic, through second-order logic, to the farther reaches of infinitary logic. Turning this perceived semantic unity into theorems is not always easy; work on combined modal logic still tends to be heavy on negative results, and first-order modal logic remains difficult territory. But unifying themes, such as guarding, and the possibility of applying ideas from abstract model theory, have emerged.

Indeed, we are tempted to conclude by playing devil's advocate: even the alternative semantics we have encountered indicate that something semantically central lies at the heart of relational semantics. For example, the Jónsson-Tarski Theorem reveals that relational semantics has an important algebraic core, and our excursion to the land of topological semantics revealed the centrality of the concept of bisimulation. Prediction is always a dangerous game (especially when it is about the future) but we believe that the interplay between theory and practice that has characterised research on modal logic throughout its history will continue to deepen our understanding of its semantic core. And, forced to place our bets, we would probably say: modal logics of games (see Chapter 20 of this handbook) will be a deep source of further insight, as will the co-algebraic semantics (discussed in Chapter 6).

ACKNOWLEDGEMENTS

We are extremely grateful to Carlos Areces for his painstaking editorial advice, to Aleksander Chagrov for his detailed list of corrections and recommendations, to Eric Kow for his patient work on the diagrams and formatting, to Sara Hobin for her meticulous proofreading and assistance with the cross-referencing, and to Dmitry Sustretov for checking Section 7. Special thanks to Daniel Gorín, Sergio Mera, Diego Figueira, and Santiago Figueira (the Buenos Aires crew) for giving the chapter its final trial.

1 INTRODUCTION

We have an interest in those modal formulas that are valid, relative to some suitable notion of validity. But verifying directly that a formula meets a validity condition is generally non-constructive. In part to get around this non-constructivity, formal proof procedures have been created, using a rich variety of mechanisms. A formal proof is a finitary certificate of validity for a formula, and a proof procedure is a specification of the requirements for being a proof. A proof procedure is sound if only valid formulas have proofs—we probably would say an unsound proof procedure is simply not a proof procedure. A proof procedure is complete if all valid formulas have proofs. For modal logics, historically, proof procedures preceded semantics, so the description above is a little anachronistic. But this is not an historical account, and anyway relational semantics is now well-developed, so let us continue as if history never happened.

It will be helpful to settle some terminology first. We assume we have an infinite list of *propositional letters*, typically P, Q, ... Formulas are built up from these in the usual way. For the time being we take as primitive implication ($\supset$), falsehood ($\bot$), and necessity ($\Box$), with negation defined by $\neg X = (X \supset \bot)$, truth by $\top = \neg\bot$, disjunction by $(X \vee Y) = (\neg X \supset Y)$, conjunction by $(X \wedge Y) = \neg(X \supset \neg Y)$, equivalence by $(X \equiv Y) = ((X \supset Y) \wedge (Y \supset X))$, and possibility by $\Diamond X = \neg\Box\neg X$. We'll use X, Y, ... for arbitrary formulas.

A *normal modal logic* is a set of formulas $\mathbf{L}$ meeting the following conditions. First, $\mathbf{L}$ contains all tautologies and all instances of the formula $\Box(X \supset Y) \supset (\Box X \supset \Box Y)$. Second, $\mathbf{L}$ contains Y if it contains X and $X \supset Y$. Third, $\mathbf{L}$ contains $\Box X$ if it contains X. Fourth and finally, with each formula X, $\mathbf{L}$ also contains all substitution instances of X—the result of uniformly replacing propositional letters with more complex modal formulas.

A large variety of formal proof procedures have been created over the years. No proof procedure suffices for every normal modal logic. Well then, what about semantically determined ones? Given any collection of frames, it is not hard to see that the set of formulas valid in all of them is a normal modal logic. No proof procedure suffices for every normal modal logic determined by a class of frames. Certain families of frames meeting special mathematical conditions determine normal logics that have had applications, and these have been given standard names—the same names are commonly used for the frame families and for the normal modal logics they determine. These normal logics tend to have proof procedures, though not every kind of proof procedure may be applicable, even to the most used of these logics. Table 1 shows the frame conditions that are most common in the literature. When traditional names are available I have employed them, but other naming conventions are in use as well. For instance, **B** is also known as **KTB**. In this chapter I will present several kinds of proof procedures, using the logics of Table 1 as examples. I will not attempt to say, for each proof procedure, exactly what range of logics it is good for. Such things are often difficult to determine. But some proof procedures apply to a fairly broad range of normal logics, others to a narrower range. Some provide proofs that humans find intuitively appealing, others are better for machine implementation. I merely wish to display something of the variety available.

Name	Frame Condition
K	none
T	reflexive
K4	transitive
S4	reflexive, transitive
KB	symmetric
B	reflexive, symmetric
S5	reflexive, transitive, symmetric
D	serial
KD4	serial, transitive

Table 1. Some Frame Families for Normal Modal Logics

2 MODAL AXIOMATICS

Axiomatic proof procedures are perhaps the easiest to explain to people. Rules are simple to state and motivate. Candidates for proofs are easily checked for correctness. Unfortunately, axiomatic proofs are generally hard to discover. Today, when automatibility of proof procedures is an important concern, axiomatic systems receive increasingly short shrift. Nonetheless, axiomatic characterizations often make it relatively easy to compare modal logics, and knowing the axioms and rules for a logic supplies a special understanding, even if one does not spend much time constructing axiomatic proofs. And there are modal logics with axiom systems but no decent automatable proof procedures. Let us begin our discussion of proof procedures with axiom systems, then.

An axiomatic proof is a sequence of formulas, each of which is from a specified collection, called *axioms*, or follows from earlier terms of the sequence by a *rule of derivation*. An axiomatic proof proves its last line, or equivalently, proves each of its lines. A proved formula is a *theorem* of the axiomatic system. Of course there is an *effectiveness* requirement—we should be able to tell whether a formula is an axiom or not, and whether a rule of inference is applicable or not. This will be obvious for the axiom systems considered here. Axiom systems differ from each other in the choice of axioms and rules of derivation. They also differ in which propositional connectives and modal operators are taken as primitive, but this is not a deep issue. Early modal axiom systems differed considerably from modern ones in their choices, but this is not an historical account. All current axiom systems for normal modal logics follow the style introduced in [31], so this will be the approach here.

Axioms are particular formulas. It is common to specify them by giving *axiom schemes*. An axiom scheme is a pattern, and any formula matching that pattern is an axiom. When axiom schemes are used, typically a proof procedure will have a finite number of axiom schemes but an infinite number of axioms. An alternative method is to specify a finite number of axioms, and adopt substitution of formulas for propositional letters as an explicit rule of inference. This tends to be more complicated, and we will follow the axiom scheme approach.

2.1 Normal Axiom Systems

Ever since [31], modal axiom systems have been *modular*–whenever possible, systems build on other ones instead of starting over. In particular, modal axiom systems (usually) build on classical propositional logic. Since classical logic is well-understood, we can skip detailed consideration of it. Among our axioms will be the following.

Classical Logic All tautologies, or at least enough of them to ensure the derivability of all the rest.

In addition we will always assume we have the following axiom scheme.

Normality Scheme All formulas of the form $\Box(X \supset Y) \supset (\Box X \supset \Box Y)$

And as rules of inference, there is the familiar *modus ponens*, plus the essentially modal *necessitation rule*, introduced by Gödel.

Modus Ponens Conclude Y from X and $X \supset Y$

Necessitation Conclude $\Box X$ from X

The Rule of Necessitation requires some comment. It does not say X is necessary if it is true—it says X is necessary if it has a proof. The idea is, things that are provable are surely necessary—they must hold under all circumstances.

It is standard to call the minimal axiom system in the sense above K, for Kripke—in fact it axiomatizes the normal modal logic **K**, as will be shown below. All other axiom systems we consider will be obtained by adding extra axioms to K. First examples of modal axiomatic proofs are almost always the same, so let us round up the usual suspects. To begin, $\Box(X \wedge Y) \supset \Box X$ is a theorem of K. Better said, any formula of this form is a theorem, but we won't be so precise from now on. Here is a proof.

1.	$(X \wedge Y) \supset X$	tautology
2.	$\Box((X \wedge Y) \supset X)$	from 1 by Necessitation
3.	$\Box((X \wedge Y) \supset X) \supset (\Box(X \wedge Y) \supset \Box X)$	Normality Scheme
4.	$\Box(X \wedge Y) \supset \Box X$	Modus Ponens on 2, 3

Having seen this, it should be easy for you to show that the following is a *derived rule* in the axiom system—that is, any proof making use of it can be expanded to a proper proof not using it.

Regularity Conclude $\Box X \supset \Box Y$ from $X \supset Y$

With Regularity, it is trivial to show that $\Box(X \wedge Y) \supset \Box Y$ is a theorem, and consequently so is $\Box(X \wedge Y) \supset (\Box X \wedge \Box Y)$, using classical reasoning. Here is an *abbreviated* proof of the converse. We thus have $\Box(X \wedge Y) \equiv (\Box X \wedge \Box Y)$.

1.	$X \supset (Y \supset (X \wedge Y))$	tautology
2.	$\Box X \supset \Box(Y \supset (X \wedge Y))$	from 1 by Regularity
3.	$\Box(Y \supset (X \wedge Y)) \supset (\Box Y \supset \Box(X \wedge Y))$	Normality Scheme
4.	$\Box X \supset (\Box Y \supset \Box(X \wedge Y))$	from 2 and 3 by classical logic
5.	$(\Box X \wedge \Box Y) \supset \Box(X \wedge Y)$	from 4 by classical logic

Other common modal axiom systems are obtained by adding axiom schemes to K. The standard names for several of these schemes are given in Table 2. If scheme T, say, is added to K, we will call the resulting axiom system T, and similarly for the other cases.

Name	Axiom Schemes
K	no additional axioms
T	$\Box X \supset X$
$K4$	$\Box X \supset \Box\Box X$
$S4$	$T + K4$
KB	$X \supset \Box\Diamond X$
B	$T + KB$
$S5$	$T + K4 + KB$
D	$\Box X \supset \Diamond X$ or $\Diamond\top$
$KD4$	$D + K4$

Table 2. Some Normal Modal Logics

Incidentally, there is a whole class of modal logics called *regular* that are weaker than the normal modal logics. They are axiomatized by replacing the Necessitation Rule by the Regularity Rule. They too have a semantics, and the usual variety of proof procedures, but we will not be considering them further here—[19] has a treatment.

2.2 Soundness and Completeness

Suppose we have a normal modal logic that is characterized semantically, as the set of formulas valid in a certain class of frames. Let us call the modal logic **L**, the frames **L**-frames, and models based on them **L**-models. So, $X \in \mathbf{L}$ if and only if X is true at every possible world of every **L**-model. And suppose we have a candidate for an axiomatization of **L**: a collection of axiom schemes, L, which we add to the axiomatic system K. How might one show soundness and completeness for the axiomatization L, relative to the class of **L**-models?

Soundness is generally a simple matter for axiom systems. One establishes that every line of a proof in L is valid in all **L**-models, and hence all theorems are valid. To do this it is enough to show all axioms are valid, and the rules preserve validity. That the rules of L (that is, of K) preserve validity is immediate. The Rule of Necessitation corresponds directly to one of the conditions for a normal modal logic, and Modus Ponens to another. All that is left is to verify the validity of the axioms. And clearly, all tautologies, and instances of the Normality Scheme, are valid in every model—this is simple to check.

So soundness comes down to the following straightforward issue: is it the case that all instances of L axiom schemes are valid in **L**-frames? It is easily checked that instances of scheme T are valid in **T**-frames, instances of $K4$ are valid in **K4**-frames, and so on. This kind of thing gives all the 'standard' soundness results—in particular, for all the axiomatic systems of Table 2 with respect to the corresponding frame classes of Table 1.

Completeness is more work—sometimes much more—but often the method of *canonical models* works uniformly and well. Suppose, as above, that L is a set of axiom schemes. We construct the canonical model $\mathcal{M}$ for L.

Call a set S of formulas *L-inconsistent* if there is a finite subset $\{X_1, \ldots, X_n\}$ of S such that $(X_1 \wedge \ldots \wedge X_n) \supset \bot$ is a theorem of L. Call S *L-consistent* if it is not L-inconsistent, and *maximally L-consistent* if it is L-consistent and has no proper extension that is L-consistent. Lindenbaum's Lemma applies, in the usual way, to say that every L-consistent set has a maximal L-consistent extension. Since the proof of Lindenbaum's Lemma is by a construction that will come up several times, in various forms, let me remind you of how it goes.

Lindenbaum Construction Suppose S is L-consistent. Enumerate the (countably many) formulas of the language, Z_1, Z_2, …, and define the following sequence of sets.

$$S_1 = S$$
$$S_{n+1} = \begin{cases} S_n \cup \{Z_n\} & \text{if } L\text{-consistent} \\ S_n & \text{otherwise} \end{cases} \tag{1}$$

One then shows that $S_1 \subseteq S_2 \subseteq S_3 \subseteq \ldots$, each S_n is L-consistent, $\cup_n S_n$ is L-consistent, and $\cup_n S_n$ is maximally L-consistent.

In fact, this construction is more general than it would first seem. Say a collection $\mathcal{C}$ of sets is of *finite character* provided $S \in \mathcal{C}$ if and only if every finite subset of S is in $\mathcal{C}$. (It is immediate from the definition above that the collection of L-consistent sets is of finite character.) The Lindenbaum construction can easily be adapted to show: if $S \in \mathcal{C}$ and $\mathcal{C}$ is of finite character, then S can be extended to a maximal member of $\mathcal{C}$. This observation makes things a little easier for us later on.

Now, let $\mathcal{M} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ be the model constructed as follows. $\mathcal{G}$ is the set of all maximally L-consistent sets of formulas. For $w, w' \in \mathcal{G}$, $w\mathcal{R}w'$ provided $\{X \mid \Box X \in w\} \subseteq w'$. And finally, $w \in \mathcal{V}(P)$ provided $P \in w$. This is the *canonical model* for L. The chief fact concerning it is the so-called *Truth Lemma*: for every formula X and possible world $w \in \mathcal{G}$

$$X \in w \text{ if and only if } \mathcal{M}, w \Vdash X \tag{2}$$

The Truth Lemma is proved by induction on the degree of X. The atomic case is by definition, and the propositional connective cases are straightforward. Here is a sketch of the modal case. We wish to show (2) is true for $\Box Z$ under the assumption that it holds for simpler formulas, in particular, for Z. Half is simple. Suppose $\Box Z \in w$, and let w' be an arbitrary world such that $w\mathcal{R}w'$. By definition of $\mathcal{R}$, $Z \in w'$; by the induction hypothesis, $\mathcal{M}, w' \Vdash Z$; so since w' was arbitrary, $\mathcal{M}, w \Vdash \Box Z$. The other direction requires more work.

Suppose $\Box Z \notin w$. Consider the set $S = \{X \mid \Box X \in w\} \cup \{\neg Z\}$. This is L-consistent, because if not, there would be a finite subset $\{\Box X_1, \ldots, \Box X_n\}$ of w such that

1.	$(X_1 \wedge \ldots \wedge X_n \wedge \neg Z) \supset \bot$	definition of inconsistent
2.	$(X_1 \wedge \ldots \wedge X_n) \supset Z$	by classical reasoning from 1
3.	$\Box(X_1 \wedge \ldots \wedge X_n) \supset \Box Z$	Regularity on 2
4.	$(\Box X_1 \wedge \ldots \wedge \Box X_n) \supset \Box Z$	using results shown earlier

But each $\Box X_i \in w$, and it follows from the maximal L-consistency of w that $\Box Z \in w$, which is a contradiction. Thus we know that S is L-consistent. Extend it to a maximal

L-consistent set w'. By definition, $w' \in \mathcal{G}$ and clearly $w\mathcal{R}w'$. And $\neg Z \in w'$ so $Z \notin w'$ and by the induction hypothesis, $\mathcal{M}, w' \not\Vdash Z$, hence $\mathcal{M}, w \not\Vdash \Box Z$.

With the Truth Lemma established, it follows that the canonical model is a universal counter-model for L—it provides counterexamples for all non-theorems of L. For, suppose X is not a theorem of axiom system L. Then $\{\neg X\}$ is **L**-consistent, and so can be extended to a maximal L-consistent set w. w is a world of the canonical model and, since $X \notin w$, by the Truth Lemma, $\mathcal{M}, w \not\Vdash X$.

If the canonical model for L happens to be an **L**-model, this establishes completeness since, if X is not a theorem of L, there is an **L**-model in which X fails—the canonical one. Since **K** imposes no conditions on frames, we now have the completeness of axiom system K relative to **K**. As a matter of fact, the canonical model for T is a **T**-model, for $K4$ is a **K4**-model, and so on for the various entries in Tables 1 and 2. Here is a sketch of the verification for one case—$K4$. Let $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V} \rangle$ be the canonical model for $K4$—I'll show it is transitive. Well, suppose $w_1, w_2, w_3 \in \mathcal{G}$ and $w_1\mathcal{R}w_2$ and $w_2\mathcal{R}w_3$. And say $\Box X \in w_1$. Since $\Box X \supset \Box\Box X$ is an axiom of $K4$, and possible worlds of the canonical model are maximally consistent, hence deductively closed, it follows that $\Box\Box X \in w_1$. By definition of $\mathcal{R}$ in the canonical model, $\Box X \in w_2$, and hence $X \in w_3$. It has been shown that $\{X \mid \Box X \in w_1\} \subseteq w_3$, so $w_1\mathcal{R}w_3$, and thus we have transitivity. I'll leave it to you to check the other cases. Thus in one construction we have completeness for a large class of axiom systems, relative to a large class of frame families.

2.3 Difficulties, and **GL**

One should not go away with the impression that canonical models solve all problems. There are standard axiomatically formulated logics for which completeness results can be proved relative to a class of frames, but not by a direct canonical model technique. A simple example is the well-known provability logic GL, axiomatized by adding the GL schema $\Box(\Box X \supset X) \supset \Box X$ to $K4$ (or equivalently, to K, though this takes some work to show). See [8, 9, 56] for the full story. GL is sound and complete with respect to two different classes of frames. One class, call it $\mathbf{GL}^w$, consists of transitive, well-founded frames—well-founded frames are those in which there are no infinite sequences of worlds w_1, w_2, w_3, ..., with $w_i\mathcal{R}w_{i+1}$. (Technically, it is the relation that is converse to $\mathcal{R}$ that is well-founded, but we can ignore the point here.) The other class, call it $\mathbf{GL}^f$, consists of frames that are transitive, irreflexive, and finite. For applications to arithmetic the class $\mathbf{GL}^f$ is the more interesting, but clearly one cannot prove completeness of GL with respect to $\mathbf{GL}^f$ using canonical models for the simple reason that a canonical model is infinite, and hence not a member of the designated class of frames. In this section I'll briefly sketch how the logic can be handled axiomatically. We will see it again after tableaus have been introduced.

Every $\mathbf{GL}^f$ frame is also a $\mathbf{GL}^w$ frame, so a soundness proof with respect to $\mathbf{GL}^w$ establishes soundness with respect to both. And for this it is enough to show all instances of the schema $\Box(\Box X \supset X) \supset \Box X$ are valid in $\mathbf{GL}^w$ frames. Well, suppose we had a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V} \rangle$, based on a $\mathbf{GL}^w$ frame, and a possible world w_1 of it, such that $\mathcal{M}, w_1 \Vdash \Box(\Box P \supset P)$ but $\mathcal{M}, w_1 \not\Vdash \Box P$. By the latter, there must be a world w_2 with $w_1\mathcal{R}w_2$ and $\mathcal{M}, w_2 \not\Vdash P$. Of course we also have $\mathcal{M}, w_2 \Vdash \Box P \supset P$. It follows that $\mathcal{M}, w_2 \not\Vdash \Box P$. Hence there exists a world w_3 with $w_2\mathcal{R}w_3$ and $\mathcal{M}, w_3 \not\Vdash P$. Since $\mathcal{R}$ is transitive, $\mathcal{M}, w_3 \Vdash \Box P \supset P$. It follows that $\mathcal{M}, w_3 \not\Vdash \Box P$. So we can repeat the

argument, getting a world w_4 accessible from w_3, at which we have $\mathcal{M}, w_4 \not\Vdash P$ and $\mathcal{M}, w_4 \Vdash \Box P \supset P$, and so on. This contradicts well-foundedness of the frame. Hence there can be no such model $\mathcal{M}$, so $\Box(\Box P \supset P) \supset \Box P$ must be valid in all $\mathbf{GL}^w$ frames.

Once again, every $\mathbf{GL}^f$ frame is also a $\mathbf{GL}^w$ frame, so a completeness proof with respect to $\mathbf{GL}^f$ will show completeness with respect to both. As noted above, a canonical model construction cannot work. But something not radically different from it does. Let Z be a formula that is not provable—I will construct a $\mathbf{GL}^f$ model, $\mathcal{M}_Z$, that invalidates it.

Define $\mathbf{sub}(Z)$ to be the set of all subformulas of Z, and negations of subformulas of Z—a finite set. Now, let $\mathcal{G}_Z$ be the collection of all *maximally GL-consistent subsets of* $\mathbf{sub}(Z)$—again a finite set. It is easy to see that any GL-consistent subset of $\mathbf{sub}(Z)$ can be extended to a maximal such set. Next I'll define an auxiliary relation (used shortly to define the actual accessibility relation): for $w, w' \in \mathcal{G}_Z$, set $w\mathcal{R}_0 w'$ if $\{X, \Box X \mid \Box X \in w\} \subseteq w'$. Now, here is the real thing: for $w, w' \in \mathcal{G}_Z$, set $w\mathcal{R}_Z w'$ if $w\mathcal{R}_0 w'$ but not $w'\mathcal{R}_0 w$. Finally, let $w \in \mathcal{V}_Z(P)$ provided $P \in w$. We thus have our model $\mathcal{M}_Z = \langle \mathcal{G}_Z, \mathcal{R}_Z, \mathcal{V}_Z \rangle$.

It is obvious that $\mathcal{G}_Z$ is finite. It is equally obvious that $\mathcal{R}_Z$ is irreflexive. If we had that $\mathcal{R}_Z$ was transitive, we would know that $\mathcal{M}_Z$ was a $\mathbf{GL}^f$ model. In fact, this is the case, but for readability I'll give the argument in a separate paragraph.

Suppose $w_1\mathcal{R}_Z w_2$ and $w_2\mathcal{R}_Z w_3$; I'll show $w_1\mathcal{R}_Z w_3$. I'll leave the key step to you: show that $\mathcal{R}_0$ is transitive. Given this, we must have $w_1\mathcal{R}_0 w_3$, since we have $w_1\mathcal{R}_0 w_2$ and $w_2\mathcal{R}_0 w_3$, and $\mathcal{R}_0$ is transitive. If we had $w_3\mathcal{R}_0 w_1$, since we have $w_1\mathcal{R}_0 w_2$ and $\mathcal{R}_0$ is transitive, we would have $w_3\mathcal{R}_0 w_2$, and we do not. Thus we do not have $w_3\mathcal{R}_0 w_1$. It follows that $w_1\mathcal{R}_Z w_3$.

Thus $\mathcal{M}_Z$ is an $\mathbf{GL}^f$ model. To show it is a counter-model to Z we need an analog of the *Truth Lemma* stated earlier as (2). The original version must be replaced with the following

$$\text{For } X \in \mathbf{sub}(Z),\ X \in w \text{ if and only if } \mathcal{M}_Z, w \Vdash X \tag{3}$$

The proof of (3) is almost the same as that of (2), by induction on the complexity of X. I'll just give one step, but it is the most significant one. Suppose that (3) is known for the formula X, $w \in \mathcal{G}_Z$, $\Box X \in \mathbf{sub}(Z)$, and $\Box X \notin w$. I'll show $\mathcal{M}_Z, w \not\Vdash \Box X$.

We are assuming $\Box X \notin w$. Let S be the set $\{Y, \Box Y \mid \Box Y \in w\} \cup \{\Box X, \neg X\}$. This is GL-consistent, because if not, there would be a finite subset $\{\Box Y_1, \ldots, \Box Y_n\}$ of w such that

1. $(Y_1 \wedge \ldots \wedge Y_n \wedge \Box Y_1 \wedge \ldots \wedge \Box Y_n \wedge \Box X \wedge \neg X) \supset \bot$
   definition of inconsistent
2. $(Y_1 \wedge \ldots \wedge Y_n \wedge \Box Y_1 \wedge \ldots \wedge \Box Y_n) \supset (\Box X \supset X)$
   by classical reasoning from 1
3. $\Box(Y_1 \wedge \ldots \wedge Y_n \wedge \Box Y_1 \wedge \ldots \wedge \Box Y_n) \supset \Box(\Box X \supset X)$
   Regularity on 2
4. $(\Box Y_1 \wedge \ldots \wedge \Box Y_n \wedge \Box\Box Y_1 \wedge \ldots \wedge \Box\Box Y_n) \supset \Box(\Box X \supset X)$
   distributing $\Box$ over $\wedge$ (Section 2.1)
5. $(\Box Y_1 \wedge \ldots \wedge \Box Y_n) \supset \Box(\Box X \supset X)$
   using the $K4$ axiom
6. $(\Box Y_1 \wedge \ldots \wedge \Box Y_n) \supset \Box X$
   using the GL axiom

But each $\Box Y_i \in w$, and so $\Box X \in w$, a contradiction. Thus we know that S is GL-consistent. Extend it to a maximal GL-consistent subset w' of $\mathbf{sub}(Z)$. By definition, $w' \in \mathcal{G}_Z$. Also by definition, $w\mathcal{R}_0 w'$. And we do not have $w'\mathcal{R}_0 w$ since $\Box X \in w'$ but $\Box X \notin w$. Thus $w\mathcal{R}_Z w'$. And $\neg X \in w'$ so $X \notin w'$ and by the induction hypothesis, $\mathcal{M}_Z, w' \not\Vdash X$, hence $\mathcal{M}_Z, w \not\Vdash \Box X$.

With (3) established, there must be a possible world in the model $\mathcal{M}$ at which the unprovable formula Z is false (a maximal consistent extension of $\{\neg Z\}$). Thus we have completeness.

A canonical model is a universal counter-model—it invalidates all unprovable formulas. The present construction, while very similar, does not produce any such thing. Each formula, Z, is invalidated in a counter-model, $\mathcal{M}_Z$, of its own.

The construction above makes use of a variant of a technique known as *filtration*. A more standard version would begin by constructing a model in which worlds are maximal consistent sets, in the usual sense, and then identifying those worlds that agree on the subformulas of Z. This is one technique among many for constructing models when the canonical construction does not work. These constructions are often ingenious, often intricate, and beyond the scope of the present chapter.

2.4 Sahlqvist Formulas

Though canonical models do not solve all completeness problems, they do for the logics considered in Section 2.2. One naturally wonders what these logics have in common that makes them so nice. In [54] a remarkable answer to this question was given—see [6] for an insightful, elegant treatment. Sahlqvist defined syntactically a class of modal formulas having two important properties. First, there is an algorithm (Sahlqvist-van Benthem) for associating with each formula of the class a first-order condition on frames. These frames will validate the corresponding modal formulas. And second, the canonical model for a logic axiomatized by Sahlqvist formulas will satisfy the first-order conditions determined by the formulas. Thus, the canonical model technique must work for modal logics whose axioms are Sahlqvist formulas.

All formulas in Table 2 are Sahlqvist formulas, and the frame conditions they determine using the Sahlqvist-van Benthem algorithm are those in Table 1. On the other hand, the GL scheme, $\Box(\Box X \supset X) \supset \Box X$ is not Sahlqvist, the frame classes $\mathbf{GL}^f$ and $\mathbf{GL}^w$ are not first-order definable, and canonical models do not work.

A full discussion of the fundamental Sahlqvist results (and their limitations) can be found elsewhere in this book, in Chapters 1 and 7, so I will say no more about them here.

3 DEDUCTION, AND THE DEDUCTION THEOREM

In many logics (classical logic is the classical example) one introduces a notion of *derivation*, or *deduction*, or *consequence*—besides what is provable, what follows from what. Typically, Y follows from a set S of formulas, *premises*, in some axiomatic system if Y becomes provable when members of S are added to the system's axioms. Then one connects deduction and provability by showing a *deduction theorem*: Y is a consequence of the set $S \cup \{X\}$ if and only if $X \supset Y$ is a consequence of S. Taking S to be empty we have the important special case: Y has a derivation from X if and only if $X \supset Y$ follows

from $\emptyset$, that is, if and only if $X \supset Y$ is a theorem of the original axiomatic system. This is an important tool, both theoretically and practically, because it allows us to prove an implication $X \supset Y$ by carrying out a derivation, of Y from X, and such a derivation is often easier to discover since we have more material to work with, namely we have X.

Modal logic raises problems for the notion of deduction. Suppose we want to show $X \supset Y$ in some modal axiom system by deriving Y from X. So we add X to our axioms. Say, to make things both concrete and intuitive, that X is "it is raining" and Y is "it is necessarily raining." Since X has been added to the axiom list the necessitation rule applies, and from X we conclude $\Box X$, that is, Y. Then the deduction theorem would allow us to conclude that if it is raining, it is necessarily raining. This does not seem right—nothing would ever be contingent. On the other hand, if we are working in the modal logic **K**, and we want to see what happens if we strengthen it to **T** by adding all instances of the scheme $\Box X \supset X$, we certainly want the necessitation rule to apply to these instances. Things are not simple.

In the examples above, instances of the axiom scheme $\Box X \supset X$ are clearly intended to be understood as logical truths, and we would expect the necessitation rule to apply to them. But "it is raining" is a contingent truth, and necessitation should not apply. In modal logics, a proper notion of deduction must allow two kinds of premises, *global*, to which the necessitation rule applies, and *local*, to which it does not. The following definition is from [21].

DEFINITION 1. Let L be a set of axiom schemes for a normal modal logic—extending K. Let S and U be sets of formulas (not schemes) and X be a single formula (also not a scheme). The formula X *is deducible from* the set S of *global* premises and the set U of *local* premises in L if there is a sequence of formulas ending with X, consisting of a global part, coming first, and a local part, coming last. In the global part each formula is an instance of a member of L, a member of S, or follows from earlier formulas by modus ponens or necessitation. In the local part each formula is an instance of a member of L, a member of U, or follows from earlier formulas by modus ponens (necessitation is not allowed in this part). If X is so deducible, this is symbolized by $S \vdash_L U \to X$.

The working content of the definition above is simple: in an axiomatic derivation of X in L one can proceed as one does in a proof, using members of S and U as additional axioms, except that once we start using members of U, the necessitation rule can no longer be applied.

Since we have two kinds of premises, we have two versions of the deduction theorem. Here they are.

THEOREM 2 (Deduction). *Let S and U be sets of formulas, X and Y be single formulas, and L be a set of axiom schemes extending K.*

1. $S \vdash_L U \cup \{X\} \to Y$ *if and only if* $S \vdash_L U \to (X \supset Y)$.
2. $S \cup \{X\} \vdash_L U \to Y$ *if and only if* $S \vdash_L U \cup \{X, \Box X, \Box^2 X, \Box^3 X, \dots\} \to Y$.

The proof of the theorem above is a variation on that of the classical deduction theorem. I'll omit it here. The significant thing is that there are two versions. In reading the literature in modal logic it is important to notice, when an author talks of deduction, whether the premises are local or global. Both versions appear, often without the local/global qualification, and this can lead to some confusion.

There is a semantic counterpart of the local/global distinction, which accounts for the terminology.

DEFINITION 3. Let **L** be a family of frames, thus characterizing a normal modal logic. Let S and U be sets of formulas (not schemes) and X be a single formula (also not a scheme). The formula X is a *semantic consequence* of the set S of *global* premises and the set U of *local* premises in **L** provided, for every **L**-model $\mathcal{M}$ in which all members of S are valid (true at every possible world), for each possible world w of $\mathcal{M}$ at which all members of U are true, X is true. This is symbolized by $S \models_{\mathbf{L}} U \to X$.

In Section 2.2 soundness and completeness issues were discussed. There is a more general notion, taking deduction into account.

DEFINITION 4. Let L be a set of axiom schemes, extending K, and let **L** be a class of frames. L is *strongly complete* (and sound) with respect to **L** provided, for all sets S and U of formulas, and for all formulas X:

$$S \vdash_L U \to X \Longleftrightarrow S \models_{\mathbf{L}} U \to X.$$

Completeness arguments using canonical models tend to actually establish strong completeness. This is the case for all the axiom systems of Table 2 relative to the corresponding classes of frames in Table 1. It is not always so straightforward, however. In Section 2.3 I mentioned axiomatically formulated GL, and a corresponding class of frames **GL**. This is an instance where completeness, but not strong completeness is the case. Strong completeness cannot be taken for granted.

4 NATURAL DEDUCTION

Someone once said that in mathematics every important theorem eventually becomes a definition. Well, the Deduction Theorem is sufficiently important that proof systems have been created with it as part of the basic machinery, rather than being a derived rule. Such systems are called *natural deduction* systems, and were originally introduced by Gentzen, [29], and Jaskowski, [40]. Prawitz wrote a classic study of these systems, [52]. Modal versions have been introduced, with those of Fitch being the best-known [16, 55]. Here I'll briefly sketch a classical and several modal natural deduction systems.

4.1 Classical Natural Deduction

Recall that our basic classical connectives are $\supset$ and $\bot$, with other connectives taken as defined. In particular, $\neg X$ is $X \supset \bot$. I'll only give rules for these, though rules for other connectives can be introduced. In a natural deduction proof, *assumptions* are made, then eventually these assumptions are *discharged* using a principle like that embodied in the Deduction Theorem. Parts of proofs involving assumption, reasoning, and assumption discharge are called *subordinate proofs*, and are characteristic of natural deduction systems. Notation differs for indicating a subordinate proof. I'll enclose it in a box. The rules are given in Table 3.

There is some variety to what is called a natural deduction system in the literature. Sometimes proofs have a tree structure, as in [52]. Here natural deduction proofs are Fitch-style, [17], in which a proof is a sequence of formulas, as in axiom systems. In

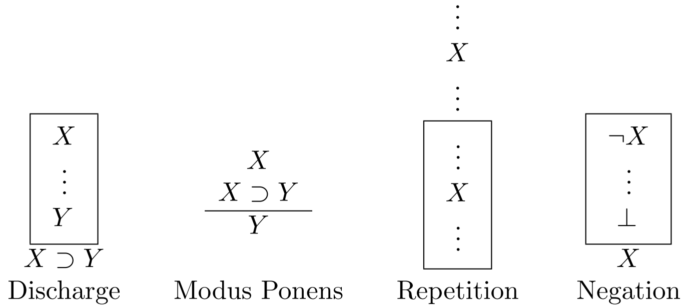

Table 3. Classical Natural Deduction Rules

addition, subordinate proofs can be started at any point—parts of a proof might be boxed, and boxes can be nested, but they cannot overlap. *The first formula in a box is understood to be an assumption—a premise.* Then the Discharge rule in Table 3 incorporates the principle of the Deduction Theorem: having assumed X as a premise, and having deduced Y, the premise X can be *discharged* and $X \supset Y$ concluded. Premise discharge is symbolized by closing off a box, thus ending a subordinate proof. Before explaining the other rules, one more notion is needed. I'll say that in a proof, two formulas, or a formula and a box, are at the *same level* if they are inside the same (nested) boxes. Modus Ponens, in Table 3, can only be applied if X and $X \supset Y$ are at the same level (though the order of the two formulas does not matter). Likewise in the Repetition rule, the upper occurrence of X must be at the same level as the box into which X is shown being repeated. A formula is a *theorem* of this natural deduction system if it is the last line of a proof and does not occur inside a box.

Figure 1 contains an example of a simple classical proof, in this system, of $(\neg Q \supset P) \supset ((\neg Q \supset \neg P) \supset Q)$. In this, 1, 2, and 4 are premises; 3 is from 1 by Repetition; 5 is from 2 by Repetition; 6 is from 4 and 5 by Modus Ponens; $6'$ is just 6 unabbreviated; 7 is from 3 by Repetition; 8 is from 4 and 7 by Modus Ponens; 9 is from 6' and 8 by Modus Ponens; 10 is by Negation; 11 and 12 are by Discharge.

If we drop the Negation rule, exactly intuitionistic implication is captured. If Negation is replaced by a rule allowing us to conclude X from $\bot$, this gives us intuitionistic negation. Other intuitionistic connectives can be captured as well, but this is too far afield for present purposes. Also, various derived rules will probably have occurred to you—for instance, Repetition can involve deeply nested boxes, instead of just going 'one box in.' Conditions were stated as they were to allow the easy addition of modal rules. I'll leave simplifications to you.

4.2 Modal Natural Deduction

Recall that whether or not the necessitation rule applied to premises in an axiomatic deduction led us to distinguish between two kinds of premises, local and global. A similar point comes up with natural deduction proofs, and we are led to create two kinds of subordinate proofs. One kind is as before, and follows the standard rules. The other kind is called a *strict* subordinate proof. I will symbolize it by enclosing it in a double-walled box. Think of a strict subordinate proof as an argument taking place in

1. $\neg Q \supset P$
2. $\neg Q \supset \neg P$
3. $\neg Q \supset P$
4. $\neg Q$
5. $\neg Q \supset \neg P$
6. $\neg P$

6′. $P \supset \bot$

7. $\neg Q \supset P$
8. P
9. $\bot$
10. Q
11. $(\neg Q \supset \neg P) \supset Q$
12. $(\neg Q \supset P) \supset ((\neg Q \supset \neg P) \supset Q)$

Figure 1. Classical Natural Deduction Proof

an arbitrary alternative world. Equivalently, think of it as an argument taking place within the scope of a necessitation operator. *A strict subordinate proof does not have an initial premise*, as ordinary subordinate proofs do, and one can be started at any point. Whatever is shown in a strict subordinate proof has actually had its *necessity* established, consequently the Discharge rule is different. The Repetition rule is also different, since strict subordinate proofs involve alternative worlds. The basic rules are in Table 4.

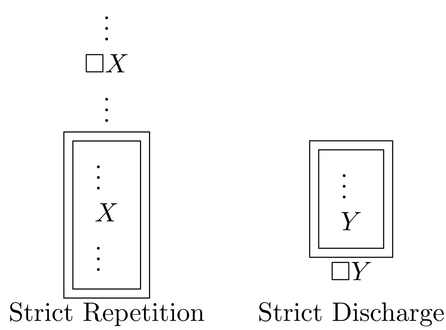

Table 4. Modal Natural Deduction Rules for **K**

An example of a proof using the classical and the modal natural deduction rules can be found in Figure 2. It is a proof of $\Box(X \supset Y) \supset (\Box X \supset \Box Y)$. In it, 1 and 2 are premises; 3 is by Repetition from 1; then a strict subordinate proof is started; 4 and 5 are from 2 and 3 by Strict Repetition; 6 is from 4 and 5 by Modus Ponens; 7 is from 6 by Strict Discharge; 8 is by Discharge; and 9 is by Discharge.

The logic captured by these rules is **K**. Certain other logics can also be treated this way, by suitable additions to the rules. In fact the underlying idea serves us as a lead-in to other proof procedures, starting in the next section. I'll give rules for some, but not

1. $\Box(X \supset Y)$
2. $\Box X$
3. $\Box(X \supset Y)$
4. X
5. $X \supset Y$
6. Y
7. $\Box Y$
8. $\Box X \supset \Box Y$
9. $\Box(X \supset Y) \supset (\Box X \supset \Box Y)$

Figure 2. Modal Natural Deduction Proof

all of the logics from Table 1—treatments of other logics can be found in [10, 17, 55].

If S is a set of formulas, I define a set $S^\sharp$ in a logic-dependent way, in Table 5. The motivation is, if all members of S are true at a possible world of an **L** model, all members of $S^\sharp$ will be true at any alternative world, for **L** being any of the logics listed in Table 5.

Logic	$S^\sharp$
K, **T**, **D**	$\{X \mid \Box X \in S\}$
K4, **S4**, **KD4**	$\{X \mid \Box X \in S\} \cup \{\Box X \mid \Box X \in S\}$
KB, **B**, **S5**	$\{X \mid \Box X \in S\} \cup \{\Box X \mid \Box X \in S\} \cup \{\neg\Box\neg X \mid X \in S\}$

Table 5. Definition of $S^\sharp$

For each of the logics covered in Table 5, the Strict Repetition rule of Table 4 should be replaced by the following. Note that the new rule for **K** coincides with the one stated in Table 4.

Strict Repetition Rule If S is the set of formulas in a proof, that are above a strict subordinate proof, and at the same level as it, any member of $S^\sharp$ can be entered into the strict subordinate proof.

For **K**, **K4**, and **KB**, the rules given so far are complete. For **T**, **B**, **S4**, and **S5**, we add a rule allowing us to infer X from $\Box X$. and for **D** and **KD4**, we instead add a rule allowing us to infer $\neg\Box\neg X$ from $\Box X$.

Figure 3 displays a proof using the rules for **K4**. In it, 1 and 2 are premises; 3 is from 1 by Repetition; 4 is from 2 and 5 is from 3 by Strict Repetition; 6 is from 4 and 7 is from 5 by Strict Repetition; 8 is from 6 and 7 by Modus Ponens; 9 is from 8 by Strict Discharge, as is 10 from 9; 11 is by Discharge, as is 12.

Completeness is easy to show. Begin by giving natural deduction proofs of all (appropriate) axioms. Modus Ponens is one of the rules. And it is easy to show that theorems are closed under a Necessitation Rule (carry out a proof of X inside a strict box, and conclude $\Box X$ outside it). Then natural deduction completeness follows from axiomatic completeness. Soundness is a bit more work; see [19] for details.

1. $\Box(X \supset Y)$
2. $\Box X$
3. $\Box(X \supset Y)$
4. $\Box X$
5. $\Box(X \supset Y)$
6. X
7. $X \supset Y$
8. Y
9. $\Box Y$
10. $\Box\Box Y$
11. $\Box X \supset \Box\Box Y$
12. $\Box(X \supset Y) \supset (\Box X \supset \Box\Box Y)$

Figure 3. **K4** Natural Deduction Proof

While I have been discussing proofs, these natural deduction systems encompass derivations as well. A *local* premise can be added to a derivation provided it is not added inside a strict subderivation. A *global* premise can be added at any point, even inside a strict subderivation. Then soundness and strong completeness can be shown for the logics of Table 5.

5 SEMANTIC TABLEAUS

Both axiom systems and natural deduction are *forward reasoning* systems. One starts with axioms and rules, and finishes with the desired theorem. Such systems, while elegant, are often difficult for proof discovery, and are not good candidates for automation. Various *backward reasoning* systems have been invented. These begin with the desired result and work backward from there to create a proof. For classical logic, *resolution* is such a system—it was designed for machine implementation, and over the years has been the basis for very efficient classical theorem provers, [22, 43]. However, resolution does not tend to adapt well to non-classical logics (though see [20]). Semantic tableaus, or *tableaus* for short, were introduced in [5], and took on their current form independently in [44] and [57]. They too have also had successful computer implementations, and have turned out to be more flexible than resolution in adapting to a rich variety of logics. A very thorough presentation of tableaus can be found in [11]. This section presents tableau systems for several propositional modal logics, but naturally, I'll begin classically.

5.1 *A Classical Tableau System*

Tableaus can be developed using signed or unsigned formulas. I'll present a signed version, and briefly discuss an unsigned one afterward. A *signed* formula is simply $T\,X$ or $F\,X$, where X is a formula. Intuitively, these signed formulas assert that X is true or false respectively, in some context. One begins a proof search with $F\,X$, and

attempts to produce a contradiction, thus showing that X cannot be false under any circumstances. Tableaus take the form of trees, customarily written with the root at the top, and branching downward. Intuitively, each branch represents one 'case.' There are rules for "growing" trees—one for each connective and sign. For axiom systems it was convenient to have a small number of connectives, with others defined from them. There is no corresponding advantage for tableaus, so I'll take $\neg$, $\wedge$, $\vee$, and $\supset$ as primitive from now on, and also $\top$ (truth constant) as well as $\bot$ (falsehood constant). However, $\equiv$ is still best thought of as a defined connective.

'Tree growing' rules involving negation are straightforward, and are given in Table 6. For each, if the signed formula above the line occurs (anywhere) on a tableau branch, the signed formula below can be added to the branch end. Rules for the binary connectives come in groups, and I'll make use of Smullyan's unifying notation here [57]. Table 7 defines what are called *alpha* and *beta* signed formulas and for each, two components. Using this, the binary connective rules are summarized in Table 8. These rules say: if an *alpha* formula occurs on a branch, its two components can be added successively to the branch end; if a *beta* formula occurs, the branch can be split, with one component added to each of the new branch ends.

$$\frac{T\,\neg X}{F\,X} \qquad \frac{F\,\neg X}{T\,X}$$

Table 6. Negation Rules

α	α_1	α_2
$T\,X \wedge Y$	$T\,X$	$T\,Y$
$F\,X \vee Y$	$F\,X$	$F\,Y$
$F\,X \supset Y$	$T\,X$	$F\,Y$

β	β_1	β_2
$T\,X \vee Y$	$T\,X$	$T\,Y$
$F\,X \wedge Y$	$F\,X$	$F\,Y$
$T\,X \supset Y$	$F\,X$	$T\,Y$

Table 7. Alpha and Beta Formulas

$$\frac{\alpha}{\begin{array}{c}\alpha_1\\ \alpha_2\end{array}} \qquad \frac{\beta}{\beta_1 \mid \beta_2}$$

Table 8. Alpha and Beta Rules

Figure 4 contains an example of a tree, constructed by starting with the signed formula $F\,\neg(X \wedge Y) \supset (\neg X \vee \neg Y)$. In it, 2 and 3 are from 1 by α; 4 is from 2 by negation; 5 and 6 are from 4 by β, 7 and 8 are from 3 by α, just as 9 and 10 are, on the right branch; 11 is from 7 by negation; 12 is from 10 by negation. Not every applicable rule has been used—neither 8 nor 9 has had a negation rule applied to it.

A tableau branch is called *closed* if it contains $T\,Z$ and $F\,Z$ for some formula Z, or if it contains $F\,\top$, or $T\,\bot$. A tableau is closed if every branch is closed. Intuitively, a closed branch represents an impossible situation, and a closed tableau tells us that every

$$
\begin{array}{ll}
F\,\neg(X \wedge Y) \supset (\neg X \vee \neg Y) & 1. \\
T\,\neg(X \wedge Y) & 2. \\
F\,\neg X \vee \neg Y & 3. \\
F\,X \wedge Y & 4.
\end{array}
$$

$$
\begin{array}{ll}
F\,X & 5. \\
F\,\neg X & 7. \\
F\,\neg Y & 8. \\
T\,X & 11.
\end{array}
\qquad\qquad
\begin{array}{ll}
F\,Y & 6. \\
F\,\neg X & 9. \\
F\,\neg Y & 10. \\
T\,Y & 12.
\end{array}
$$

Figure 4. Propositional Tableau Example

situation is impossible. The tableau of Figure 4 is closed, because of 5 and 11, and 6 and 12.

A *tableau proof* of X is a closed tableau beginning with $F\,X$. Thus Figure 4 constitutes a tableau proof of $\neg(X \wedge Y) \supset (\neg X \vee \neg Y)$. It can be shown that exactly the classical tautologies have tableau proofs in this system, but I'll postpone any discussion of soundness and completeness until modal rules have been introduced. A tableau version of consequence—deduction from premises—is easy. One says X follows from a set S of formulas if there is a closed tableau starting with $F\,X$, allowing the additional rule that for any $Z \in S$, $T\,Z$ can be added to the end of any branch.

Finally, I have used signed formulas, but one could just as well work with an unsigned version. Instead of $F\,X$ use $\neg X$, and instead of $T\,X$, just use X. I'll leave a full formulation to you (or see [22, 57]). The use of signs brings some additional power, however. It is easier to establish a connection with the Gentzen sequent calculus, as we will do in Section 7. There is a simple signed tableau system for intuitionistic logic, something that is not possible without signs. And one can add extra signs to create proof systems for many-valued logics.

5.2 Destructive Modal Tableaus

Modal tableaus come in more than one version. Some logics have *destructive* tableau systems, [19, 33]. These will be presented in this section—a different approach is given in Section 6. The terminology comes from the fact that some destructive tableau rule applications lose information. Destructive tableau proofs tend to be more useful metatheoretically than other kinds of tableaus—for example, one can devise a simple proof of interpolation theorems using such tableau systems.

To continue the uniform treatment begun with the *alpha*/*beta* grouping, two new categories, *nu* and *pi*, and their components are introduced in Table 9, to take care of the modal operators—both $\Box$ and $\Diamond$ are taken as primitive now.

In Table 5 I gave a definition of $S^\sharp$ for several modal logics. As it happens, logics whose semantics involve symmetry don't have simple (or any) destructive tableau systems, so these must be dropped. And I'm now allowing more connectives and modal operators as primitive than before. So a definition appropriate for this section is given in Table 10—

ν	ν_0
$T\,\Box X$	$T\,X$
$F\,\Diamond X$	$F\,X$

π	π_0
$T\,\Diamond X$	$T\,X$
$F\,\Box X$	$F\,X$

Table 9. Nu and Pi Formulas

connections with the earlier version should be clear. A few observations about this definition. First, for all six of the logics we have monotonicity: $S_1 \subseteq S_2$ implies $S_1^\sharp \subseteq S_2^\sharp$. And second, for the **K4**, **S4**, **D4** group we have $S^\sharp \subseteq S^{\sharp\sharp}$. Both of these are easily checked, and both play a role in later soundness and completeness proofs.

Logic	$S^\sharp$
$\mathbf{K}, \mathbf{T}, \mathbf{D}$	$\{\nu_0 \mid \nu \in S\}$
$\mathbf{K4}, \mathbf{S4}, \mathbf{D4}$	$\{\nu_0, \nu \mid \nu \in S\}$

Table 10. Revised Definition of $S^\sharp$

Destructive tableau rules for the logics of Table 10 are as follows. First, all the classical rules of the previous section continue to apply. And in addition there are the rules given in Table 11. These rules require some comment. The second, from ν to get ν_0, is of the same general kind as earlier tableau rules: a branch containing ν can have ν_0 added to the end. The third is slightly different since it is premiseless: at any point on a tableau branch we can add $T\,\Diamond\top$. The first, however, is of a very different nature. Let us call it the π *rule*, though technically what is displayed is actually several rules, depending on the definition of $S^\sharp$. The π rule says that, given a branch containing π, and with S as the entire set of (other) signed formulas on it, that branch can be *replaced* with a new one containing the members of $S^\sharp$, and π_0. The π rule is the reason for the terminology *destructive*—application of this rule removes formulas.

For all logics: $\dfrac{S, \pi}{S^\sharp, \pi_0}$ For **T** and **S4**: $\dfrac{\nu}{\nu_0}$ For **D** and **D4**: $\dfrac{}{T\,\Diamond\top}$

Table 11. Destructive Modal Rules

An example of a destructive tableau can be found in Figure 5. It provides a tableau proof, in the **K4** system, of $(\Box\Diamond X \wedge \Box Y) \supset \Box\Diamond(X \wedge Y)$. In it, 2 and 3 are from 1, and 4 and 5 are from 2 by α. Then a destructive π rule applies, with 3 as the π formula. The original branch is replaced by a new one, shown below the line, with 6 from 3, 7 and 8 from 4, and 9 and 10 from 5; formulas 1 and 2 disappear entirely. Another π rule application now happens, with 8 as the π formula, producing the new branch shown below the second line. Item 11 is from 8; 12 and 13 are from 6; 14 and 15 are from 7; 16 and 17 are from 9. Finally β applied to 13 produces 18 and 19, and both branches are closed.

Destructive rules add a level of complexity to tableaus. Tableau rules are non-deterministic—they say what can be done, but the order of rule application is not specified. It can be shown that, for the classical system of Section 5.1, a kind of Church-Rosser

$$
\begin{array}{l}
F\,(\Box\Diamond X \wedge \Box Y) \supset \Box\Diamond(X \wedge Y) \quad 1. \\
T\,\Box\Diamond X \wedge \Box Y \quad 2. \\
F\,\Box\Diamond(X \wedge Y) \quad 3. \\
T\,\Box\Diamond X \quad 4. \\
T\,\Box Y \quad 5. \\
\hline
F\,\Diamond(X \wedge Y) \quad 6. \\
T\,\Box\Diamond X \quad 7. \\
T\,\Diamond X \quad 8. \\
T\,\Box Y \quad 9. \\
T\,Y \quad 10. \\
\hline
T\,X \quad 11. \\
F\,\Diamond(X \wedge Y) \quad 12. \\
F\,X \wedge Y \quad 13. \\
T\,\Box\Diamond X \quad 14. \\
T\,\Diamond X \quad 15. \\
T\,\Box Y \quad 16. \\
T\,Y \quad 17.
\end{array}
$$

$$
\begin{array}{cc}
F\,X \quad 18. & \qquad\qquad F\,Y \quad 19.
\end{array}
$$

Figure 5. **K4** Destructive Tableau Example

property applies. If a formula X is a tautology, any attempt to provide a closed tableau for $F\,X$ will succeed, no matter in what order the rules are applied, provided only that on each branch, every non-atomic formula eventually has a rule applied to it. The π rule changes things. We might have a tableau branch containing, among other things, both $T\,\Diamond X$ and $T\,\Diamond Y$. Either could be used as π in a π-rule application, but when so used, it will cause the deletion of the other formula. It can happen that a proof is obtainable when one choice is made, but not the other—we can choose badly. This means that a systematic proof search must allow backtracking, and so will be inherently more time-consuming than a systematic search in the classical system—see Chapter 3 for a full discussion.

5.3 Soundness and Completeness

A proof of soundness can also serve to motivate the rules of Table 11. We'll say a signed formula is *realized* at a possible world w of a model $\mathcal{M}$ if the formula is $T\,X$ and $\mathcal{M}, w \Vdash X$, or the formula is $F\,X$ and $\mathcal{M}, w \nVdash X$. Let **L** be one of the six logics for which tableau rules have been provided. Call a set S of signed formulas **L**-*satisfiable* if there is some **L** model $\mathcal{M}$, and some possible world, w, of it that realizes all the members of S. Call a tableau branch **L**-satisfiable if the set of signed formulas on it is **L**-satisfiable. And call a tableau **L**-satisfiable if some branch is. The key fact is that satisfiability is an invariant for tableau construction. That is, each tableau rule preserves **L**-satisfiability. Let us call a rule *sound* if it has this satisfiability preserving feature. It is the need to have sound rules that dictates some of the features of the systems we have seen—for

instance, this is why the version of $S^\sharp$ that works for **K4** will not serve for **K**.

PROPOSITION 5. *Suppose $\mathcal{T}$ is an* **L** *tableau that is* **L***-satisfiable. If any* **L** *tableau rule is applied to $\mathcal{T}$ the resulting tableau is still* **L***-satisfiable.*

Proof. Suppose branch θ of $\mathcal{T}$ is **L**-satisfiable, say its members are realized at world w of model $\mathcal{M}$. And say a tableau rule is applied to $\mathcal{T}$. If it is applied on a branch other than θ, the resulting tableau is trivially **L**-satisfiable, so now assume the tableau rule has been applied on θ.

If the applied rule was a β rule, then θ branches, technically it is replaced with two new branches which we'll call θ, β_1 and θ, β_2, using the obvious notation. Since β was realized at w, a check of each case in the definition of β shows that either β_1 is realized at w, or β_2 is. Consequently, either the branch θ, β_1 is satisfied, at w, or the branch θ, β_2 is. Either way the resulting tableau is **L**-satisfiable. The argument if the rule application was an α or a negation rule is even simpler, and is omitted.

Now suppose the applied rule was the π rule from Table 11. The key thing we need is this. For each of the logics under consideration, if members of S are realized at world w of an **L** model $\mathcal{M}$, and if w' is any world of $\mathcal{M}$ that is accessible from w, then members of $S^\sharp$ are realized at w'. Verification of this is left to you. Now, suppose θ consists of the members of S, and the signed formula π, and w realizes all the signed formulas on θ. Since π is realized at w, there must be an alternate world w' at which π_0 is realized. As we just noted, at w' all members of $S^\sharp$ are realized. Then in the resulting tableau there is still a satisfiable branch, though its members are realized at a different world than the one realizing the members of the original branch.

The other rules from Table 11 are straightforward. ❑

PROPOSITION 6. *If X has a proof using the tableau rules for* **L***, then X is* **L** *valid.*

Proof. I'll show the contrapositive. Suppose X is not **L** valid; so there is some world of some **L**-model at which X is false, Then $\{F\,X\}$ is **L**-satisfiable. Any tableau proof of X must start with the tree with only $F\,X$, at its root. This is an **L**-satisfiable tableau, so Proposition 5 says only **L**-satisfiable tableaus will be produced. An **L**-satisfiable tableau cannot be closed. Hence X can have no **L** tableau proof. ❑

Next we turn to completeness. A common way of showing completeness for tableau systems involves devising a systematic way of applying tableau rules. Such a systematic approach is presented for classical logic in [57], for instance. While such a method has utility when computer implementations are involved, it is often hard work. Fortunately the method used to show completeness for axiom systems in Section 2.2 can also be applied, and is much simpler.

First we need a small generalization of the notion of tableau. So far we have started tableau constructions with a single signed formula. From now on, if S is a finite set of signed formulas, a tableau for S will be any tableau starting with a single branch containing the members of S, and continuing using the usual tableau rules. Then, a tableau proof of a formula X is a closed tableau for the set $\{F\,X\}$.

Let **L** be one of the logics for which tableau rules have been provided in Table 11. Call a set S of *signed* formulas **L**-*inconsistent* if there is a closed **L** tableau for some finite subset of S, and call S **L**-*consistent* if it is not **L**-inconsistent. Clearly this notion of

L-consistency is of finite character, and so the Lindenbaum construction applies, see (1). Every **L**-consistent set of signed formulas can be extended to a maximal **L**-consistent set.

We construct a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V} \rangle$ much like we did in Section 2.2. $\mathcal{G}$ is the collection of all maximal **L**-consistent sets of signed formulas. For $w_1, w_2 \in \mathcal{G}$, $w_1 \mathcal{R} w_2$ provided $w_1^\sharp \subseteq w_2$. And finally, $w \in \mathcal{V}(P)$ provided $T\,P \in w$. One cannot, at this point, show an exact counterpart of (2) (though it is, in fact, true). But one can show the following, involving an implication instead of an equivalence. For every *signed* formula $\mathcal{X}$ and possible world $w \in \mathcal{G}$

$$\mathcal{X} \in w \Longrightarrow w \text{ realizes } \mathcal{X} \text{ in the model } \mathcal{M} \tag{4}$$

The proof is by induction on the complexity of signed formulas. Since we have several connectives as primitive now, I'll make use of uniform notation. Here are the cases needed to establish (4).

Suppose P is atomic. If $T\,P \in w$ then $\mathcal{M}, w \Vdash P$ by definition of $\mathcal{V}$, so $T\,P$ is realized at w. Likewise if $F\,P \in w$, since w is **L**-consistent, $T\,P \notin w$, and so $\mathcal{M}, w \nVdash P$, and again $F\,P$ is realized at w.

The negation cases are straightforward, and are omitted.

Suppose we have a β signed formula, $\beta \in w$, and (4) and is known for β_1 and β_2. Since w is **L**-consistent, it follows from the tableau rules that one of $w \cup \{\beta_1\}$ or $w \cup \{\beta_2\}$ is **L**-consistent. Then it follows by maximality of w that either $\beta_1 \in w$ or $\beta_2 \in w$. By the induction hypothesis, either β_1 or β_2 is realized at world w of $\mathcal{M}$. And an examination of the cases in the definition of β formulas shows this is enough for β to be realized at w as well.

The α case is similar, and is omitted.

Suppose we have a ν formula, $\nu \in w$, and (4) is known for ν_0. Let w' be any member of $\mathcal{G}$ with $w \mathcal{R} w'$. For each choice of **L**, $\nu_0 \in w^\sharp$ and since $w^\sharp \subseteq w'$ by definition of $\mathcal{R}$, $\nu_0 \in w'$. By the induction hypothesis, w' realizes ν_0. A check of cases in the definition of ν shows that, since w' was arbitrary, ν is realized at w.

Finally, suppose we have a π formula, $\pi \in w$, and (4) is known for π_0. Using the π rule from Table 11, it follows that $w^\sharp \cup \{\pi_0\}$ is consistent. Let w' be a maximal **L**-consistent extension of this. Then $w' \in \mathcal{G}$ and since $\pi_0 \in w'$, the induction hypothesis gives us that π_0 is realized at w'. Finally, since $w \mathcal{R} w'$, it follows, for each case in the definition of π, that π is realized at w.

Now that (4) has been established, putting the final pieces together is easy. For **L** being any of the six logics from Tables 10 and 11, one can easily check that the construction described above produces a model $\mathcal{M}$ that is, in fact, an **L**-model. Here is part of such a verification. For any of the six logics being treated, $S_1 \subseteq S_2$ implies $S_1^\sharp \subseteq S_2^\sharp$. For **L** being one of **K4**, **S4**, or **D4**, $S^\sharp \subseteq S^{\sharp\sharp}$. Now, suppose $w_1 \mathcal{R} w_2$ and $w_2 \mathcal{R} w_3$. Then $w_1^\sharp \subseteq w_2$ and $w_2^\sharp \subseteq w_3$, so $w_1^{\sharp\sharp} \subseteq w_2^\sharp \subseteq w_3$. So if **L** is one of **K4**, **S4**, or **D4**, $w_1^\sharp \subseteq w_3$, and hence $w_1 \mathcal{R} w_3$. Thus for these three logics, the model is transitive. I'll leave the other conditions to you.

Now, if X is not provable by **L**-tableaus, $\{F\,X\}$ is **L**-consistent. Extend it to a maximal **L**-consistent set w, which will be a world of the **L** model constructed above. It is a world at which X is false, by (4). Thus X is not **L**-valid. This establishes the following.

PROPOSITION 7. *For* **L** *being one of* **K**, **T**, **D**, **K4**, **S4**, **D4**, *the* **L** *tableau rules are complete.*

5.4 The Logic **GL**

In Section 2.3 we saw that, while a straight canonical model argument was not able to prove completeness for **GL**, still a completeness argument could be given. A variation of that argument works for an appropriate destructive tableau system for **GL** as well. I'll sketch this here.

First of all, what are the **GL** destructive tableau rules? Use the definition of $S^\sharp$ for **K4**, from Table 10. In addition, the π-rule itself needs modification. Following [57], define the *conjugate* of a signed formula as follows: $\overline{T\,X} = F\,X$ and $\overline{F\,X} = T\,X$. Thus conjugation amounts to switching the sign. Now, here is the curious but appropriate π rule for **GL**, [8, 19].

$$\frac{S, \pi}{S^\sharp, \pi_0, \overline{\pi}}$$

An example of a proof in this system appears in Figure 6, of the Löb formula $\Box(\Box P \supset P) \supset \Box P$. In it, 2 and 3 are from 1 by α. Then a π-rule application is made, with 3 as the π formula. This replaces the original branch with a new one, shown below the line in the Figure. Formulas 4 and 5 are from 3 and 6 and 7 are from 2. Then 8 and 9 are from 7 by β, and both branches are closed.

$$\begin{array}{ll}
F\,\Box(\Box P \supset P) \supset \Box P & 1. \\
T\,\Box(\Box P \supset P) & 2. \\
F\,\Box P & 3. \\
\hline
F\,P & 4. \\
T\,\Box P & 5. \\
T\,\Box(\Box P \supset P) & 6. \\
T\,\Box P \supset P & 7.
\end{array}$$

$$\begin{array}{lcl}
F\,\Box P \quad 8. & \qquad & T\,P \quad 9.
\end{array}$$

Figure 6. **GL** Destructive Tableau Example

Soundness is shown by the same method as earlier, Proposition 5, and the argument now is just like before, except for the new π rule. So, I'll just show the following: if $S \cup \{\pi\}$ is $\mathbf{GL}^w$-satisfiable, so is $S^\sharp \cup \{\pi_0, \overline{\pi}\}$. Well, suppose $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V} \rangle$ is a $\mathbf{GL}^w$ model in which the members of $S \cup \{\pi\}$ are realized at possible world w_1, but there is no world at which the members of $S^\sharp \cup \{\pi_0, \overline{\pi}\}$ are realized. Since w_1 realizes π there must be a world, w_2, with $w_1 \mathcal{R} w_2$, with w_2 realizing π_0. And since w_1 realizes the members of S, it is easy to see that w_2 must realize the members of $S^\sharp$. Since no world in $\mathcal{M}$ realizes the members of $S^\sharp \cup \{\pi_0, \overline{\pi}\}$, it must be that w_2 cannot realize $\overline{\pi}$, and hence must realize π—that is, w_2 realizes all members of $S^\sharp \cup \{\pi_0, \pi\}$. But now, since π is realized at w_2, there must be a world w_3 with $w_2 \mathcal{R} w_3$ such that π_0 is realized at w_3. Since $S^\sharp$ is realized at w_2 then $S^{\sharp\sharp}$ is realized at w_3, but for the **K4** definition, $S^\sharp \subseteq S^{\sharp\sharp}$, so all of $S^\sharp$ is realized at w_3. Then, as at w_2, we must have that π is realized at w_3. That is, at w_3, just as at w_2, we have all the members of $S^\sharp \cup \{\pi_0, \pi\}$ realized. This pattern repeats—there must be an accessible world w_4 realizing this set, and so on. But

this contradicts the non-existence of infinite chains in $\mathbf{GL}^w$ models. Thus if $S \cup \{\pi\}$ is $\mathbf{GL}^w$-satisfiable, so is $S^\sharp \cup \{\pi_0, \overline{\pi}\}$, and soundness follows.

For completeness, a modification of the proof in Section 2.3 will work. Let Z be a formula with no **GL** tableau proof—I'll construct a $\mathbf{GL}^f$ counter-model. This time, let $\mathbf{sub}(Z)$ be the set of all signed subformulas of Z—all $T\,X$ and $F\,X$ with X a subformula of Z. Define consistency the way we did in Section 5.3—a set of signed formulas is **GL**-consistent if no **GL** tableau for a finite subset closes. Now, construct a model $\mathcal{M}_Z = \langle \mathcal{G}_Z, \mathcal{R}_Z, \mathcal{V}_Z \rangle$ as follows. $\mathcal{G}_Z$ is the set of all maximally consistent subsets of $\mathbf{sub}(Z)$. A consistent subset of $\mathbf{sub}(Z)$ extends to a maximally consistent subset. Define $w \in \mathcal{V}_Z(P)$ if $T\,P \in w$. Set $w_1 \mathcal{R}_0 w_2$ provided $w_1^\sharp \subseteq w_2$. Then define $w_1 \mathcal{R}_Z w_2$ if $w_1 \mathcal{R}_0 w_2$ but not $w_2 \mathcal{R}_0 w_1$. We now have a model $\mathcal{M}_Z$. Just as in Section 2.3, it is finite, irreflexive, and transitive. Finally, a variant of (3) holds for it. I state it as (5) and leave its proof to you. With it, completeness (but not strong completeness) follows in the usual way.

$$\text{For a signed formula } \mathcal{X} \in \mathbf{sub}(Z),\ \mathcal{X} \in w \text{ implies } w \text{ realizes } \mathcal{X} \tag{5}$$

5.5 Tableau Remarks

Unlike the proof procedures examined earlier in this chapter, tableau systems obey a *subformula principle*—all formulas occurring in a proof are subformulas of the formula being proved. Often this is expressed by saying tableaus are *analytic*. The modus ponens rule of axiom systems and of natural deduction systems is the reason they do not obey a subformula principle. Analyticity makes the finding of proofs a simpler thing and accounts for why tableau systems have frequently been automated while natural deduction and axiom systems have rarely been. Indeed, proofs of decidability for logics having tableau systems can often be based on analyticity.

There is an important non-analytic rule that is sometimes added to tableau systems, the *cut* rule. It says, at any point in a tableau construction we can split the end of a branch, labeling the two new branch nodes with $T\,X$ and $F\,X$, for an *arbitrary* formula X. Since X can be any formula, obviously analyticity is violated. There is a more restricted version of the rule, in which X is required to be a subformula of the formula being proved—this is called *analytic cut.*

Why consider an unrestricted cut rule? Historically, it was introduced by Gentzen [29] in the closely related context of the *sequent calculus* (see Section 7). Gentzen wanted to constructively establish that tableau (sequent calculi) and axiom systems were equivalent for both classical and intuitionistic logic. The presence of a cut rule makes it easy to show this—cut roughly corresponds to modus ponens. Then Gentzen gave a complicated constructive argument that showed any application of a cut rule in a proof could be eliminated. This fact, and its constructive proof, have been very influential, with important consequences, but it is not appropriate to go into this here. Suffice it to say that a cut rule can be added to any of the tableau systems of Section 5.2 without changing the class of provable formulas—that is, cut elimination can be proved for these systems, with proofs going back to [47, 48].

Proofs using cut, at least classically, can be significantly shorter than cut-free proofs. Cut elimination for classical first-order logic can introduce a non-elementary blow-up in proof depth. The corresponding situation for modal logics seems not to have been much studied, but is probably similar. There has been recent work on designing proof systems

making proofs of cut elimination easier to establish. These go under the name *display logics*. See [4, 58].

Cut elimination for our modal systems can be shown constructively by extending Gentzen's argument, but the arguments are fussy. A non-constructive proof is quite simple, however. The cut rule is easily seen to be a sound rule—it preserves **L**-satisfiability, for each **L** we have considered. Then the soundness proof of Section 5.3 extends—if X has an **L**-tableau proof, allowing the cut rule, X must be **L** valid. But by our completeness result, Proposition 7, if X is **L** valid it must have an **L**-tableau proof without cut. Consequently, if X is provable using **L**-tableaus plus cut, X is provable using **L**-tableaus without cut.

A rule that can be added to a proof procedure without changing the class of theorems is called an *admissible* rule. What we have just shown is that cut is an admissible rule. Incidentally, now that we know this, it is easy to see that the implication (4) is actually an equivalence. This follows since, using cut, for each formula X, either $T\,X$ or $F\,X$ must be in any maximal **L**-consistent set, and closed tableaus using cut can be replaced by closed tableaus not using cut.

Why consider analytic cut? For one thing, it can shorten proofs, and does not violate the subformula principle, so proof search procedures can incorporate it in a reasonable way. It has sometimes been included in tableau implementations for this reason. The reader cannot fail to have noticed that while nine representative modal logics were introduced in Table 1, tableau systems were given for only six of them. Tableau systems for the other three are missing, though if analytic cut is allowed, destructive tableau systems can be created, [33]. In this respect our representative normal modal logics are actually representative—more logics have axiom systems than have cut-free destructive tableau systems. Since tableau systems are useful for automation, a number of attempts have been made to augment tableaus with additional machinery so that more logics can be covered. We will see more of this starting in Section 6.

Finally there is the matter of deduction, and the possibility of a strong completeness theorem. For the logics of Section 5.2, this is an easy matter. If a formula X is a *global* premise, one is allowed to add $T\,X$ to any open tableau branch at any point. If X is a *local* premise, one can add it to any open tableau branch provided the π-rule in Table 11 has not yet been applied on that branch. Then our soundness and completeness arguments do, in fact, extend to prove strong soundness and completeness—I omit the proof. It should be noted that there are logics, **GL** is an example, that have sound and complete tableau systems, but which do not extend to allow these additional premise-adding rules. (Otherwise one could establish compactness for **GL**, and there is a simple example in [19] showing that local compactness fails.) Things must be carefully checked.

6 PREFIXED TABLEAUS

In a destructive modal tableau an application of a π rule corresponds to a move to an alternative world—this appears explicitly in the argument for the soundness of the π rule. But the π rule loses information. If we are attempting to apply such a rule in a logic whose semantics involves symmetry, we can expect problems. With symmetry we can leave a world and return to it, so to speak. But in a destructive tableau, having lost information, there is no mechanism to regain it (except, sometimes, analytic cut). In order to get around this problem various mechanisms have been introduced to retain

information about other worlds during a proof—for instance in [37] a method of *semantic diagrams* is presented, in which multiple-world information is retained by the use of multiple boxes. *Prefixed tableaus* provide additional machinery using a device that is especially syntactic in nature. These tableau systems were introduced in [18, 19], but took on their present modular form in [46, 33]. They can also be seen as a particular kind of *labeled deductive system*, see [27].

6.1 A Prefixed System for **K**

A *prefix* is a finite sequence of positive integers, which I will write using a dot as separator, for example, 1.2.3.2.3. The informal idea is that a prefix names a possible world, with 1.2.3.2.1, 1.2.3.2.2, 1.2.3.2.3, and so on, all naming worlds accessible from 1.2.3.2. A *prefixed (signed) formula* is $\sigma\,T\,X$ or $\sigma\,F\,X$, where σ is a prefix and X is a formula. The informal idea is that a prefixed formula asserts the underlying formula is true/false at the world named by the prefix.

A prefixed tableau proof of X begins with $1\,F\,X$, informally asserting that X is false in some world, named by 1. It continues using branch extension rules to be given in a moment. The goal is to produce a closed tableau, where now a branch is closed if it contains $\sigma\,T\,X$ and $\sigma\,F\,X$ for some formula X (note that the prefix is the same in both cases). A branch is also closed if it contains $\sigma\,T\,\bot$ or $\sigma\,F\,\top$. And a tableau is closed if each branch is closed, as usual.

The branch extension rules for the propositional connectives are as before, except that prefixes are carried along. They are given in Table 12.

$$\frac{\sigma\,T\,\neg X}{\sigma\,F\,X} \qquad \frac{\sigma\,F\,\neg X}{\sigma\,T\,X} \qquad \frac{\sigma\,\alpha}{\begin{array}{c}\sigma\,\alpha_1\\ \sigma\,\alpha_2\end{array}} \qquad \frac{\sigma\,\beta}{\sigma\,\beta_1 \quad \mid \quad \sigma\,\beta_2}$$

Table 12. Prefixed Classical Rules

The modal rules for **K** are given in Table 13. A prefix has been *used* on a branch if it already occurs on the tableau branch. It is *new* if it does not occur. The intuition should be fairly clear. If a π formula is true at a world named by prefix σ, then π_0 must be true at an alternative world. We want to pick a name for that world, a prefix. Since the world is accessible from the world named by σ, we want a prefix that extends σ by one number, and otherwise it should be uncommitted, hence the newness requirement. The ν rule is similarly motivated.

$$\frac{\sigma\,\nu}{\begin{array}{c}\sigma.n\,\nu_0\\ \text{for } \sigma.n \text{ used}\end{array}} \qquad \frac{\sigma\,\pi}{\begin{array}{c}\sigma.n\,\pi_0\\ \text{for } \sigma.n \text{ new}\end{array}}$$

Table 13. Modal Tableau Rules for **K**

Figure 7 contains an example of a proof in this **K** tableau system, of $(\Diamond\Box P \wedge \Box\Diamond Q) \supset \Diamond\Diamond(P \wedge Q)$. In it, 2 and 3 are from 1, and 4 and 5 are from 2 by α, 6 is from 4 by π, 7

is from 5 by ν, 8 is from 7 by π, 9 is from 3 and 10 is from 9 by ν, 11 and 12 are from 10 by β, and 13 is from 6 by ν. Closure is by 11, 13 and 8, 12.

$$\begin{array}{lll}
1 & F\,(\Diamond\Box P \wedge \Box\Diamond Q) \supset \Diamond\Diamond(P \wedge Q) & 1. \\
1 & T\,\Diamond\Box P \wedge \Box\Diamond Q & 2. \\
1 & F\,\Diamond\Diamond(P \wedge Q) & 3. \\
1 & T\,\Diamond\Box P & 4. \\
1 & T\,\Box\Diamond Q & 5. \\
1.1 & T\,\Box P & 6. \\
1.1 & T\,\Diamond Q & 7. \\
1.1.1 & T\,Q & 8. \\
1.1 & F\,\Diamond(P \wedge Q) & 9. \\
1.1.1 & F\,P \wedge Q & 10.
\end{array}$$

$$\begin{array}{lll|lll}
1.1.1 & F\,P & 11. & 1.1.1 & F\,Q & 12. \\
1.1.1 & T\,P & 13. & & &
\end{array}$$

Figure 7. Prefixed **K** Tableau

Prefixed tableaus can be used for derivations as well as for proofs, in quite a simple way. To use X as a *global* premise, one may add $\sigma\,T\,X$ to the end of any open branch, for any prefix σ that appears on the branch. To use X as a *local* premise, one may add $1\,T\,X$ only.

6.2 Soundness and Completeness

So far I have only given prefixed rules for **K**. But rules for other logics do not change the basic ideas very much, so I'll prove soundness and completeness now, while things are at their simplest.

Soundness is by the usual tableau argument—see Section 5.3 for details in the destructive tableau setting. For prefixed formulas, I'll say a set S of prefixed, signed formulas is *satisfiable* (properly speaking, **K** satisfiable) if there is a model $\mathcal{M}$, and a mapping $\mathcal{N}$ from the prefixes in S to possible worlds in $\mathcal{M}$, such that if $\sigma\,\mathcal{X} \in S$ then $\mathcal{X}$ is realized at $\mathcal{N}(\sigma)$ in $\mathcal{M}$, where $\mathcal{X}$ is a signed formula. As before, a tableau branch is satisfiable if the set of prefixed formulas on it is satisfiable, and a tableau is satisfiable if some branch is. I'll leave it to you to establish that each tableau rule converts a satisfiable tableau into another satisfiable tableau. And trivially, a closed tableau cannot be satisfiable. Now soundness follows exactly as in Section 5.3.

Modal operators have strong similarities to quantifiers, and that observation plays a role now. For starters, the Lindenbaum construction of (1) needs to be 'Henkinized.' We'll say a set S of prefixed signed formulas is **K**-*consistent* if no **K**-tableau for a finite part of S is closed; S is π-*complete* provided, if $\sigma\,\pi \in S$ then for some integer k, $\sigma.k\,\pi_0 \in S$; and S *omits infinitely many integers* if the set of integers that do not appear in prefixes in S is infinite. It is a fact that every **K**-consistent set S of prefixed sentences that omits infinitely many integers can be extended to a set that is maximally **K**-consistent and

π-complete. This can be done via the following Henkin-style modification of the earlier construction, (1).

Lindenbaum-Henkin Construction Suppose S is a **K**-consistent set of prefixed sentences that omits infinitely many integers. Enumerate the (countably many) prefixed signed formulas of the language, $\sigma_1\,\mathcal{X}_1$, $\sigma_2\,\mathcal{X}_2$, ..., and define the following sequence of sets.

$$S_1 = S$$

$$S_{n+1} = \begin{cases} S_n \cup \{\sigma_n\,\mathcal{X}_n\} & \text{if } \mathbf{K}\text{-consistent and } \mathcal{X}_n \text{ is not } \pi \\ S_n \cup \{\sigma_n\,\pi, \sigma_n.k\,\pi_0\} & \text{if } \mathbf{K}\text{-consistent, } \mathcal{X}_n \text{ is } \pi\text{, and } \sigma_n.k \text{ is new} \\ S_n & \text{otherwise} \end{cases} \tag{6}$$

In this construction, 'new' means $\sigma_n.k$ does not occur in S_n or in $\pi(=\mathcal{X}_n)$.

It is not hard to see that if S omits infinitely many integers, this will also be the case with each S_n. Also, if $S \cup \{\sigma_n\,\pi\}$ is **K**-consistent, then $S_n \cup \{\sigma_n\,\pi, \sigma_n.k\,\pi_0\}$ will also be **K**-consistent provided $\sigma_n.k$ is new, and if S_n omits infinitely many integers, there will be such a prefix that is new. I'll leave it to you to check that if S is **K**-consistent and omits infinitely many integers, then $\cup_n S_n$ will be maximally **K**-consistent and π-complete.

Suppose X is not provable using the prefixed **K**-tableau rules. Then $\{1\,F\,X\}$ is **K**-consistent, and obviously omits infinitely many integers. Extend it to a maximally **K**-consistent, π-complete set, S, using the construction above. Let $\mathcal{G}$ be the set of prefixes that occur in S. For prefixes σ and τ in $\mathcal{G}$, set $\sigma\mathcal{R}\tau$ if τ is $\sigma.n$ for some integer n. For a propositional letter P, let $\sigma \in \mathcal{V}(P)$ if $\sigma\,T\,P \in S$. This gives us a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V}\rangle$. Incidentally, note that the model is constructed from a single maximally consistent set, rather than a family of them, as was the case with destructive tableaus. This is a key difference between the two types of tableaus: prefixed tableau branches keep track of multiple worlds; destructive tableau branches have information about a single world at a time.

Now we need a truth lemma. It says: for every signed formula $\mathcal{X}$, the following is true.

$$\sigma\,\mathcal{X} \in S \Longrightarrow \sigma \text{ realizes } \mathcal{X} \text{ in the model } \mathcal{M} \tag{7}$$

Equation (7) has a straightforward proof, which I'll leave to you. Once we have it completeness is immediate, since $\{1\,F\,X\} \in S$ and so X is false at world 1 of the model $\mathcal{M}$.

The completeness proof just given is simple, but there is another way of proving completeness that provides additional information. One can give an algorithm that systematically expands **K** tableaus. If the algorithm is properly crafted, one can show that either it will produce a proof, or it will terminate with an unclosed tableau. If it terminates, the set of formulas on any open branch can play the role of the set S in the proof above; (7) can be proved for it. In this way we not only get completeness, but a concrete decision procedure as well. Such an algorithm is given in [19, Ch 8, sect 4]. With some of the other logics to be discussed in the next section, termination is not as simple as it is with **K**, and may involve loop-checking. I do not pursue this further here.

T	$\dfrac{\sigma\,\nu}{\sigma\,\nu_0}$	$4r$	$\dfrac{\sigma.n\,\nu}{\sigma\,\nu}$		
4	$\dfrac{\sigma\,\nu}{\sigma.n\,\nu}$	D	$\dfrac{\sigma\,T\,\Box X}{\sigma\,T\,\Diamond X}$	$\dfrac{\sigma\,F\,\Diamond X}{\sigma\,F\,\Box X}$	
B	$\dfrac{\sigma.n\,\nu}{\sigma\,\nu_0}$				

For prefixes σ and $\sigma.n$ already occurring on the tableau branch:

Table 14. Modal Tableau Rules

6.3 Other Modal Logics

Following [46, 33], other standard modal logics can be handled in a modular fashion. First, some additional tableau rules, and their names, are given in Table 14.

Next, some common modal logics can be given prefixed tableau proof systems by adding various combinations of these rules to those for **K**. How to do this for several modal logics is summarized in Table 15. I omit proofs of soundness and completeness—they are straightforward variants of what worked for **K**.

Logic	Special Rules
T	T
K4	4
S4	T, 4
KB	B
B	B, 4
S5	T, 4, $4r$
D	D
D4	D, 4
DB	D, B

Table 15. Prefixed Tableau Systems

Note that, unlike with destructive modal tableaus, there are straightforward prefixed tableau systems for logics involving symmetry in their semantics. In particular, there is a system for **S5**. In this case, and this case only, there is actually a simpler version that will also serve—let us call it the *Simple* **S5** *System*. Instead of taking prefixes to be sequences of positive integers, take them to be *single* positive integers. And replace the modal rules of Tables 13 and 15 with those in Table 16. Essentially, this works because there is an alternate Kripke semantics for **S5** in which the accessibility relation holds between any two worlds.

Figure 8 displays a proof using these Simple **S5** Rules, of $P \supset \Box\Diamond P$.

$$\frac{n\,\nu}{k\,\nu_0}\ \text{for } k \text{ used} \qquad \frac{n\,\pi}{k\,\pi_0}\ \text{for } k \text{ new}$$

Table 16. Simple Tableau Rules just for **S5**

$$\begin{array}{l}
1\,F\,P \supset \Box\Diamond P \quad 1.\\
1\,T\,P \quad 2.\\
1\,F\,\Box\Diamond P \quad 3.\\
2\,F\,\Diamond P \quad 4.\\
1\,F\,P \quad 5.
\end{array}$$

Figure 8. A Prefixed **S5** Tableau Proof

It was shown in [42] that for **K**, **T**, and **S4**, satisfiability is PSpace complete (more generally, for modal logics between **K** and **S4**). It was also shown that for **S5** it drops to NP complete. This is reflected in the existence of the simple tableau system for **S5** given here. On the other hand, for multi-modal logics, which will be considered in Section 9, satisfiability is PSpace complete, [34], even for multi-modal **S5**, and so we should not expect a simple multi-modal version for this logic, unlike in the mono-modal case. A thorough discussion of complexity issues can be found in this volume, in Chapter 3.

7 GENTZEN SYSTEMS

A *sequent* is written $X_1, \ldots, X_n \longrightarrow Y_1, \ldots, Y_k$, where the X_i and Y_j are formulas. It is informally taken to mean the conjunction of the formulas on the left of the arrow has the disjunction of the formulas on the right as a consequence. Either n or k can be 0, with an empty conjunction treated as true, and an empty disjunction as false. A sequent calculus is a specification of rules for deriving sequents from sequents. But how something is *written* does not determine its mathematical properties. What actually is a sequent?

A list of formulas, $X_1, \ldots, X_n$ say, in a sequent can represent at least three different mathematical objects: a *set*, a *multiset*, or a *sequence*. In Gentzen's original treatment, [29], a formula list represented a sequence. Gentzen provided rules permitting, for example, the permutation of members of a list, or the duplication of members. If a formula list is taken to represent a multiset, permutation need not be specified, but formula duplication still must be provided for. If a formula list is taken to represent a set, even duplication rules can be omitted. Rules like permutation, duplication, and a few others, are called *structural* rules. By using a multiset or a sequence, and at the same time omitting various structural rules, a family of *substructural* logics has been created, with linear logic and relevance logic as the best-known representatives, [14, 50, 53]. By restricting the right side of a sequent to have at most one formula, *intuitionistic* logic can be captured. This is not the place to go into what is a very extensive subject—here we are interested in modal logic over a classical logic base. Consequently here lists will be thought of as designating *sets*, which means structural rules are not needed—they are

built into the data structure, so to speak.

7.1 Classical Propositional Sequents

With it understood that lists represent sets, the Gentzen system rules for classical propositional logic will now be given. I use boldface letters, with and without subscripts, to denote formula lists, which represent sets. If I write $\mathbf{S}, X$ I mean the list consisting of the members of $\mathbf{S}$, together with X, and similarly for other obvious notational conventions. A sequent calculus is a forward reasoning system: certain sequents are taken as axioms, and there are rules for deducing a sequent from others. Note that the rules each introduce exactly one connective, and there is one rule for an introduction on the left of the arrow, and one for the right.

Axioms

$$\mathbf{S}_L, X \longrightarrow \mathbf{S}_R, X$$
$$\mathbf{S}_L, \bot \longrightarrow \mathbf{S}_R$$
$$\mathbf{S}_L \longrightarrow \mathbf{S}_R, \top$$

Negation Rules

$$\frac{\mathbf{S}_L, X \longrightarrow \mathbf{S}_R}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, \neg X}$$

$$\frac{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X}{\mathbf{S}_L, \neg X \longrightarrow \mathbf{S}_R}$$

Conjunction Rules

$$\frac{\mathbf{S}_L, X, Y \longrightarrow \mathbf{S}_R}{\mathbf{S}_L, X \wedge Y \longrightarrow \mathbf{S}_R}$$

$$\frac{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X \qquad \mathbf{S}_L \longrightarrow \mathbf{S}_R, Y}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X \wedge Y}$$

Disjunction Rules

$$\frac{\mathbf{S}_L, X \longrightarrow \mathbf{S}_R \qquad \mathbf{S}_L, Y \longrightarrow \mathbf{S}_R}{\mathbf{S}_L, X \vee Y \longrightarrow \mathbf{S}_R}$$

$$\frac{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X, Y}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X \vee Y}$$

Implication Rules

$$\frac{\mathbf{S}_L, Y \longrightarrow \mathbf{S}_R \qquad \mathbf{S}_L \longrightarrow X, \mathbf{S}_R}{\mathbf{S}_L, X \supset Y \longrightarrow \mathbf{S}_R}$$

$$\frac{\mathbf{S}_L, X \longrightarrow \mathbf{S}_R, Y}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X \supset Y}$$

A Gentzen system proof of a sequent is a tree having the sequent at its root—customarily the root is written at the bottom—with axioms at leaves, and with each non-leaf following from its children by one of the rules above. A proof of a formula X is taken to be a proof of the sequent $\longrightarrow X$. Figure 9 shows a proof in this system, of $\neg(X \wedge Y) \supset (\neg X \vee \neg Y)$. I'll leave it to you to supply reasons for the steps.

Soundness for this sequent calculus is easily established. Define a mapping from se-

$$\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{X \longrightarrow \neg Y, X}{\longrightarrow \neg X, \neg Y, X}}{\longrightarrow \neg X \vee \neg Y, X} \qquad \dfrac{\dfrac{Y \longrightarrow \neg X, Y}{\longrightarrow \neg X, \neg Y, Y}}{\longrightarrow \neg X \vee \neg Y, Y}}{\longrightarrow \neg X \vee \neg Y, X \wedge Y}}{\neg(X \wedge Y) \longrightarrow \neg X \vee \neg Y}}{\longrightarrow \neg(X \wedge Y) \supset (\neg X \vee \neg Y)}$$

Figure 9. Gentzen Sequent Proof

quents to formulas as follows.

$$\begin{aligned} [X_1, \ldots, X_n \longrightarrow Y_1, \ldots, Y_k]^f &= [(X_1 \wedge \cdots \wedge X_n) \supset (Y_1 \vee \cdots \vee Y_k)] \\ [X_1, \ldots, X_n \longrightarrow]^f &= [(X_1 \wedge \cdots \wedge X_n) \supset \bot] \\ [\longrightarrow Y_1, \ldots, Y_k]^f &= [\top \supset (Y_1 \vee \cdots \vee Y_k)] \end{aligned} \tag{8}$$

This mapping is in keeping with the remarks at the beginning of the section about the informal meaning of a sequent—conjunctions entailing disjunctions. It is easy to show that if images of the premises of a sequent rule are classically valid formulas, so is the image of the conclusion. Also, images of all sequent axioms are classically valid formulas. So the image of every provable sequent, under this mapping, is valid. If a formula X has a sequent proof, the sequent $\longrightarrow X$ is provable, hence its image is valid. But $[\longrightarrow X]^f$ is $\top \supset X$, and it follows that X is valid.

Gentzen systems predate tableaus by many years. They were introduced as a tool for the analysis of proofs, while tableaus were introduced as a convenient mechanism for proof search. But tableaus were heavily influenced by Gentzen systems—indeed there is a simple correspondence between sequents and sets of signed (unprefixed) formulas. Define a mapping from finite sets of signed formulas to sequents as follows.

$$\{T\,X_1, \ldots, T\,X_n, F\,Y_1, \ldots, F\,Y_k\}^s \text{ is the sequent } X_1, \ldots, X_n \longrightarrow Y_1, \ldots, Y_k \tag{9}$$

Thus the mapping puts T-signed formulas on the left and F-signed formulas on the right. Now, a key fact is the following.

LEMMA 8. *Let S be a finite set of signed formulas. If there is a closed tableau for S using the classical tableau rules of Section 5.1, then the sequent S^s is provable using the sequent rules of this section.*

Proof. Let us say S *closes with depth* d if d is the smallest number such that there is a closed tableau for S with d tableau rule applications. The proof is by induction on d.

If S closes with depth 0, it must contain $T\,X$ and $F\,X$ for some X, or $T\,\bot$, or $F\,\top$. In each case S^s is a sequent calculus axiom.

Now suppose S closes with depth d and the result is known for sets that close with depth less than d. Say that $T\,X \wedge Y \in S$ and in a d-step tableau for S the first rule application is to this signed formula. It follows that there must be a closed tableau for $S \cup \{T\,X, T\,Y\}$ with fewer than d rule applications. By the induction hypothesis, the sequent image of this set must have a sequent calculus proof. Let $\mathbf{S}_L$ be the list

of formulas that occur in S with a sign of T, and let $\mathbf{S}_R$ be the list of formulas in S with a sign of F. Then $[S \cup \{T\,X, T\,Y\}]^s$ is the sequent $\mathbf{S}_L, X, Y \longrightarrow \mathbf{S}_R$, and so this must be provable. Then by one of the two sequent rules for conjunction, the sequent $\mathbf{S}_L, X \wedge Y \longrightarrow \mathbf{S}_R$ is provable, but this is S^s.

The other cases are similar. ❑

With this established, we quickly get the following.

PROPOSITION 9. *The classical propositional sequent calculus is complete.*

Proof. For Proposition 7 a completeness proof for a destructive modal tableau system was given. It is easy to see that a completeness proof for the non-modal part is extractable. Leaving this to you, we have that if X is classically valid, there must be a closed classical tableau for $\{F\,X\}$. By the Lemma above, the sequent $\longrightarrow X$ must then be provable, and hence X has a sequent calculus proof. ❑

It is important to understand what is behind the proof of Lemma 8. In the one induction case given in detail, a tableau and a sequent rule for conjunction were involved. Here they are, side by side.

$$\frac{T\,X \wedge Y}{\begin{array}{c}T\,X\\ T\,Y\end{array}} \qquad\qquad \frac{\mathbf{S}_L, X, Y \longrightarrow \mathbf{S}_R}{\mathbf{S}_L, X \wedge Y \longrightarrow \mathbf{S}_R}$$

Notice that, via the mapping from sets of signed formulas to sequents, these rules correspond in a fairly obvious way, except that each is an upsidedown version of the other. This is the case with every tableau and sequent rule. It is what makes Lemma 8 work. Once this correspondence is understood, it is easy to see that the sequent proof in Figure 9 and the tableau proof in Figure 4 are just presentations, in their respective systems, of the same construction. The correspondence between tableaus and Gentzen system proofs is worked out in detail in [57], where the two systems are developed simultaneously.

7.2 Modal Propositional Sequents

Now that the correspondence between tableau proofs and sequent proofs is clear in the classical case, we have a guiding principle to follow in turning destructive modal tableau rules into modal sequent rules. We want them to be 'upside down' counterparts. If we do it properly we are guaranteed completeness, since we already have tableau completeness proofs. Here is a sequent version for **K** that does this. First, the definition of $S^\sharp$ needs a dual version.

$$S^\sharp = \{X \mid \Box X \in S\} \qquad\qquad S^\flat = \{X \mid \Diamond X \in S\}$$

And now, the additional rules needed for **K** are the following.

$$\frac{\mathbf{S}_L^\sharp, X \longrightarrow \mathbf{S}_R^\flat}{\mathbf{S}_L, \Diamond X \longrightarrow \mathbf{S}_R} \qquad\qquad \frac{\mathbf{S}_L^\sharp \longrightarrow \mathbf{S}_R^\flat, X}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, \Box X}$$

For **K4** the definitions above must be replaced with the following, though the form of the rules stays the same.

$$S^\sharp = \{\Box X, X \mid \Box X \in S\} \qquad\qquad S^\flat = \{\Diamond X, X \mid \Diamond X \in S\}$$

For **S4** we use the system for **K4** together with the following additional rules, the **T** ones.

$$\frac{\mathbf{S}_L, X \longrightarrow \mathbf{S}_R}{\mathbf{S}_L, \Box X \longrightarrow \mathbf{S}_R} \qquad \frac{\mathbf{S}_L \longrightarrow \mathbf{S}_R, X}{\mathbf{S}_L \longrightarrow \mathbf{S}_R, \Diamond X}$$

Clearly, any of the modal logics with a destructive tableau system also has a sequent calculus proof system.

8 HYPERSEQUENTS

Just as tableaus have been fitted out with extra machinery, such as prefixes, sequent calculi have also been enhanced. *Hypersequents* add machinery that makes it possible to provide proof systems for several well-known non-classical logics—see [3]. While they provide a uniform mechanism that can deal with a rich variety of logics, here I will only discuss the hypersequent calculus for **S5**.

8.1 Hypersequents for **S5**

A hypersequent is written $\mathbf{X}_1 \longrightarrow \mathbf{Y}_1 \mid \mathbf{X}_2 \longrightarrow \mathbf{Y}_2 \mid \cdots \mid \mathbf{X}_n \longrightarrow \mathbf{Y}_n$. In this expression each *component*, $\mathbf{X}_i \longrightarrow \mathbf{Y}_i$, is a sequent (so each $\mathbf{X}_i$ and $\mathbf{Y}_i$ is a list of formulas), and the expression itself is a list of sequents. Intuitively a hypersequent should be read disjunctively—one of the sequents is the case—though exact details vary from logic to logic. Various non-classical logics can be captured by imposing special conditions on how lists behave, but for **S5** things are rather simple. As we did in Section 7, a list will be thought of as designating a *set*, and hence permutation and repetition is built in.

A proof of a formula X is a proof of the hypersequent with the single component $\rightarrow X$, where the notion of a proof of a hypersequent is about to be defined. Much as with a Gentzen system, there are axioms, and rules for deducing hypersequents from hypersequents.

Axioms are component-wise versions of those in Section 7.1: a hypersequent $\mathcal{C}_1 \mid \mathcal{C}_2 \mid \cdots \mid \mathcal{C}_n$ is an axiom if some $\mathcal{C}_i$ is an axiom in the sequent sense. The rules for the classical propositional connectives also carry over component-wise. Here are the rules for conjunction, as an example. In them, the $\mathcal{C}_i$ and $\mathcal{D}_i$ are sequents.

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L, X, Y \longrightarrow \mathbf{S}_R \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L, X \wedge Y \longrightarrow \mathbf{S}_R \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, X \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k \qquad \mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, Y \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, X \wedge Y \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

We want a proof system for **S5**. Since this extends **S4**, besides the classical rules we need the **S4** modal rules, from the end of Section 7.2, in hypersequent form of course. There are four such **S4** rules. First there are the **K4** rules, in which $S^\sharp = \{\Box X, X \mid \Box X \in S\}$ and $S^\flat = \{\Diamond X, X \mid \Diamond X \in S\}$.

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L^\sharp, X \longrightarrow \mathbf{S}_R^\flat \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L, \Diamond X \longrightarrow \mathbf{S}_R \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L^\sharp \longrightarrow \mathbf{S}_R^\flat, X \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, \Box X \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

And here are the hypersequent **T** rules.

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L, X \longrightarrow \mathbf{S}_R \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L, \Box X \longrightarrow \mathbf{S}_R \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, X \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{S}_L \longrightarrow \mathbf{S}_R, \Diamond X \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

So far the rules have made no special use of the hypersequent mechanism; they have all been direct counterparts of sequent calculus rules. There is one final rule that turns the system into one for **S5**, and in it the full mechanism comes into play. First some terminology. Call a formula *modal* if it is of the form $\Box X$ or $\Diamond X$. I'll say the pair of sequents $\mathbf{X}_1 \longrightarrow \mathbf{Y}_1$ and $\mathbf{X}_2 \longrightarrow \mathbf{Y}_2$ is a *modal splitting* of the sequent $\mathbf{U} \longrightarrow \mathbf{V}$ if, first, $\mathbf{X}_1 \cup \mathbf{X}_2 = \mathbf{U}$ and $\mathbf{Y}_1 \cup \mathbf{Y}_2 = \mathbf{V}$ and, second, all formulas in $\mathbf{X}_1$ and in $\mathbf{Y}_1$ are modal. (It is not assumed that $\mathbf{X}_1$ and $\mathbf{X}_2$ are disjoint, and similarly for $\mathbf{Y}_1$ and $\mathbf{Y}_2$).

Modal Splitting Rule If the sequents $\mathcal{C}_i^1$ and $\mathcal{C}_i^2$ are a modal splitting of $\mathcal{C}_i$, then:

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_{i-1} \mid \mathcal{C}_i \mid \mathcal{C}_{i+1} \mid \cdots \mid \mathcal{C}_n}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_{i-1} \mid \mathcal{C}_i^1 \mid \mathcal{C}_i^2 \mid \mathcal{C}_{i+1} \mid \cdots \mid \mathcal{C}_n}$$

8.2 Examples

I'll first give some useful derived rules, and then a hypersequent proof that makes use of them. The first derived rule is *weakening*, which allows the introduction of additional formulas into sequents. It says the following.

Weakening Rule

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X} \longrightarrow \mathbf{Y} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \mathbf{U} \longrightarrow \mathbf{Y}, \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

Sometimes weakening is taken as a basic rule in the sequent calculus, but in our case it is built in indirectly. Note that sequent axioms were not of the form $X \longrightarrow X$, but allowed *side formulas*, $\mathbf{S}_L, X \longrightarrow \mathbf{S}_R, X$, and similarly for the other two axiom forms. All the various rules allow us to carry side formulas along, and also the **K** rules allow for the introduction of additional side formulas. Given this, showing that weakening is a derived rule is an easy induction on proof complexity.

The next derived rules are peculiar to hypersequents—there is no underlying sequent version.

Derived ν Rules

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U}, A \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X} \longrightarrow \mathbf{Y}, \Diamond A \mid \mathbf{U} \longrightarrow \mathbf{V}, A \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X} \longrightarrow \mathbf{Y}, \Diamond A \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

Derived π Rules

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid A \longrightarrow \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

$$\frac{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X} \longrightarrow \mathbf{Y}, \Box A \mid \longrightarrow A \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}{\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X} \longrightarrow \mathbf{Y}, \Box A \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k}$$

Here is a hypersequent derivation showing that the first of the ν rules above is a derived rule. The *Repetition* label refers to the fact that for us lists represent sets, and so repeated sequents can be combined.

$$\begin{array}{cl}
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U}, A \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U}, \Box A \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \mathbf{T}\ \text{Rule} \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \Box A \longrightarrow \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \text{Modal Splitting} \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \text{Weakening} \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \text{Repetition}
\end{array}$$

Showing that the π rules are derived ones is simpler, and does not make use of the Modal Splitting rule. Here is the verification for the first one.

$$\begin{array}{cl}
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid A \longrightarrow \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid \Diamond A \longrightarrow \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \mathbf{K4}\ \text{Rule} \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \text{Weakening} \\ \hline
\mathcal{C}_1 \mid \cdots \mid \mathcal{C}_n \mid \mathbf{X}, \Diamond A \longrightarrow \mathbf{Y} \mid \mathcal{D}_1 \mid \cdots \mid \mathcal{D}_k & \text{Repetition}
\end{array}$$

Finally, Figure 10 displays a hypersequent proof of $P \supset \Box\Diamond P$, in which use is made of some of the derived rules. Note that it begins with a hypersequent axiom, since $P \longrightarrow \Box\Diamond P, P$ is a sequent axiom.

$$\begin{array}{cl}
P \longrightarrow \Box\Diamond P, P \mid \longrightarrow \Diamond P & \\ \hline
P \longrightarrow \Box\Diamond P \mid \longrightarrow \Diamond P & \text{Derived } \nu \text{ Rule} \\ \hline
P \longrightarrow \Box\Diamond P & \text{Derived } \pi \text{ Rule} \\ \hline
\longrightarrow P \supset \Box\Diamond P & \text{Implication Rule}
\end{array}$$

Figure 10. A Hypersequent Proof

8.3 Soundness and Completeness

Equations (8) in Section 7.1 define a translation from sequents into formulas. Following [3] this is extended to hypersequents as follows.

$$[\mathcal{C}_1 \mid \mathcal{C}_2 \mid \cdots \mid \mathcal{C}_n]^f = \Box\mathcal{C}_1^f \vee \Box\mathcal{C}_2^f \vee \ldots \vee \Box\mathcal{C}_n^f \tag{10}$$

Suppose we could show all hypersequents that are provable in the **S5** system just presented have translates that are valid in **S5**. If the formula X were provable, there would be a hypersequent proof ending in the single-component hypersequent $\longrightarrow X$, and its hypersequent translate is $\Box(\top \supset X)$, which would be valid. But if $\Box(\top \supset X)$ is **S5** valid, so is X. Consequently, showing soundness for the **S5** hypersequent calculus comes down to showing all provable hypersequents have **S5** valid translates.

It is easy to see that the translation of each hypersequent axiom is **S5** valid. So if we can show that each of the hypersequent rules preserves validity of translation, we have soundness. This is straightforward for most of the hypersequent calculus rules. The only one needing serious work is the modal splitting rule. Let us say that component $\mathcal{C}$ is $\Box\mathbf{X}, \Diamond\mathbf{Y}, \mathbf{Z} \longrightarrow \Box\mathbf{U}, \Diamond\mathbf{V}, \mathbf{W}$, and that $\Box\mathbf{X}, \Diamond\mathbf{Y} \longrightarrow \Box\mathbf{U}, \Diamond\mathbf{V}$ and $\mathbf{Z} \longrightarrow \mathbf{W}$ is a modal splitting of it. (I write $\Box\mathbf{X}$ to denote the list of formulas in $\mathbf{X}$ with $\Box$ prefixed to each, and similarly for $\Diamond\mathbf{Y}$.) It is enough to show the **S5** validity of the following.

$$\Box[\Box\mathbf{X}, \Diamond\mathbf{Y}, \mathbf{Z} \longrightarrow \Box\mathbf{U}, \Diamond\mathbf{V}, \mathbf{W}]^f \supset \{\Box[\Box\mathbf{X}, \Diamond\mathbf{Y} \longrightarrow \Box\mathbf{U}, \Diamond\mathbf{V}]^f \vee \Box[\mathbf{Z} \longrightarrow \mathbf{W}]^f\}$$

Writing this out in full, we get the following formula.

$$\begin{aligned}\Box[(\bigwedge_i \Box X_i \wedge \bigwedge_i \Diamond Y_i \wedge \bigwedge_i Z_i) \supset (\bigvee_i \Box U_i \vee \bigvee_i \Diamond V_i \vee \bigvee_i W_i)] \supset \\ \{\Box[(\bigwedge_i \Box X_i \wedge \bigwedge_i \Diamond Y_i) \supset (\bigvee_i \Box U_i \vee \bigvee_i \Diamond V_i)] \vee \Box[\bigwedge_i Z_i \supset \bigvee_i W_i]\}\end{aligned}$$

Despite the intimidating appearance of this, it has a simple proof using the Simple Tableau System for **S5** given in Section 6.3. I'll leave this to the reader.

A direct proof of completeness can be found in [3], but for us it is easier to show that Simple **S5** Tableau System proofs can be translated into hypersequent proofs, and then rely on tableau completeness. In (9) a mapping from finite sets of signed formulas to sequents was given. Now that is used to define a mapping from finite sets of *prefixed* signed formulas to hypersequents as follows. For a finite set S of prefixed signed formulas (using positive integers as prefixes):

$$S^s = \mathcal{C}_1 \mid \mathcal{C}_2 \mid \cdots \mid \mathcal{C}_n \text{ where } \mathcal{C}_k = \{\mathcal{X} \mid k\,\mathcal{X} \in S\}^s \tag{11}$$

Now a version of Lemma 8 can be proved for the current set-up.

LEMMA 10. *Let S be a finite set of prefixed signed formulas. If there is a closed tableau for S using the Simple* **S5** *Tableau rules of Table 16 then the hypersequent S^s is provable using the rules of this section.*

Proof. As with Lemma 8 the proof is by an induction on the depth of S, where the depth is the smallest number d such that there is a closed Simple **S5** Tableau for S with d tableau rule applications. The argument for the classical connectives is just the hypersequent analog of what we did before. I'll consider one of the modal cases, and leave the others to you.

Suppose S closes with depth d, the result is known for sets that close with depth less than d, the prefixed formula $n\,T\,\Box A \in S$, and there is a d-step closed tableau for S in which the first rule application is to this prefixed formula, adding the formula $k\,T\,A$ to the tableau branch, where k already occurs (so it must be in S). Of course there is a closed tableau for $S \cup \{k\,T\,A\}$ with fewer than d rule applications. From the induction

hypothesis, the hypersequent image of this set must have a hypersequent proof. By definition,

$$[S \cup \{k\,T\,A\}]^s = \cdots \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \cdots \mid \mathbf{U}, A \longrightarrow \mathbf{V} \mid \cdots$$

where $\mathbf{X}, \Box A$ and $\mathbf{Y}$ are the lists of members of $S \cup \{k\,T\,A\}$ with a prefix of n and signs of T and F respectively, and $\mathbf{U}, A$ and $\mathbf{V}$ are the members with a prefix of k and signs of T and F respectively. But then, using one of the Derived ν Rules, the hypersequent

$$\cdots \mid \mathbf{X}, \Box A \longrightarrow \mathbf{Y} \mid \cdots \mid \mathbf{U} \longrightarrow \mathbf{V} \mid \cdots$$

will also be provable, and this is S^s. ❑

PROPOSITION 11. *The* **S5** *hypersequent calculus is complete.*

Proof. If X is **S5** valid, there is a closed Simple **S5** Tableau for $\{1\,F\,X\}$. By the Lemma, there must be a hypersequent proof of the hypersequent whose only component is $\longrightarrow X$, and so X has a hypersequent proof. ❑

In a clear sense, the hypersequent calculus for **S5** (with the derived rules) bears the same relationship to the Simple **S5** Tableau System that the sequent calculi of Section 7 have to destructive modal tableau systems.

9 LOGICS OF KNOWLEDGE

Up to now only mono-modal logics have been considered. Things become more interesting when several modal operators are combined in a single logic. This is the first of several sections in which we examine such multi-modal logics, and is the simplest of these sections. Most proof methods adapt to multi-modal logics with varying degrees of difficulty, but from now on I will concentrate almost exclusively on prefixed tableaus. These generally make the jump to multi-modal logics with a certain grace. One natural multi-modal logic is a logic of knowledge, first investigated in detail in [36]; also see [15] for a more recent account.

9.1 A Basic Logic of Knowledge

In a logic of knowledge there is a set, usually finite, of *knowers* $\{k_1, k_2, \ldots, k_m\}$. Informally I'll use a, b, ... to range over the set of knowers. For each knower a there is a corresponding modal operator, K_a. We read K_aX as "a knows X." Each K_a is like $\Box$ from earlier sections. It is not as common to have dual modal operators, but I will—I'll use $\overline{K}_a$ for the operator dual to K_a, that is, $\neg K_a \neg$. A dual knowledge operator is like $\Diamond$ from earlier sections. Informally, $\overline{K}_aX$ can be read, "X is compatible with what a knows."

Properties of actual knowledge are difficult to specify. We might know X and also $X \supset Y$, but not know Y simply because we never thought about it. What standard logics of knowledge capture is not actual knowledge, but potential knowledge—what one is entitled to know. The switch to potential knowledge means we drop all considerations of complexity—we potentially could know a tautology with 10^{100} symbols, for instance. But the switch to an idealized point of view does simplify the theory. It is rather easy

to see that, under such an assumption, a knowledge modality should be a normal modal operator. But, what else should be required?

Since one cannot know something that is false, we would want $K_aX \supset X$, the T axiom. On the other hand belief (also idealized) is somewhat similar to knowledge, and if it is belief we are trying to examine, we would not want this axiom. Often a certain degree of introspection is assumed—if one knows something, that fact is also known—that is $K_aX \supset K_aK_aX$. Thus we might want knowledge operators to obey the $S4$ conditions. Further, negative introspection is also often assumed—if one does not know something, it is known that it is not known—that is $\neg K_aX \supset K_a\neg K_aX$. All these together make a knowledge operator obey the $S5$ conditions. But keep in mind that lesser, or different, assumptions may be appropriate in particular cases.

The semantics for a logic of knowledge is simple—a frame is a structure $\langle \mathcal{G}, \mathcal{R}_{k_1}, \mathcal{R}_{k_2}, \ldots, \mathcal{R}_{k_m} \rangle$ where $\mathcal{G}$ is the usual set of possible worlds, and we have an accessibility relation for each knower. A model is based on such a frame in the standard way, by specifying which propositional letters are true at which worlds. If $\mathcal{M}$ is such a model, truth at possible worlds is defined in the usual way, but with the modal condition: $\mathcal{M}, w \Vdash K_aX$ if and only if $\mathcal{M}, w' \Vdash X$ for each $w' \in \mathcal{G}$ with $w\mathcal{R}_aw'$. Often each $\mathcal{R}_a$ is taken to be an equivalence relation, corresponding to $S5$, but other assumptions can be made, and they do not need to be the same for each knower.

An axiomatic treatment of a logic of knowledge is quite straightforward. One simply assumes the appropriate modal axioms (and necessitation rule) for each K_a. I will skip further discussion. Various other proof systems can be adapted to logics of knowledge, but prefixed tableau systems are most 'practical,' and quite natural. They are all that will be covered here. We now take a prefix to be a sequence $1.n_1a_1.n_2a_2.\ldots$ where, except for the first item, 1, each term consists of a positive integer, n, and a knower, a. The idea is, $\sigma.na$ is intended to designate a world that is accessible from the world σ designates, via the accessibility relation for knower a. The propositional connective tableau rules are as they were in the mono-modal case. Before stating the new modal rules, the earlier nu/pi notation must be modified, since it does not keep track of which knowledge operator we are dealing with. This is done in Table 17.

ν^a	ν_0^a	π^a	π_0^a
$T\,K_aX$	$T\,X$	$T\,\overline{K}_aX$	$T\,X$
$F\,\overline{K}_aX$	$F\,X$	$F\,K_aX$	$F\,X$

Table 17. Multi-Modal Nu and Pi Formulas

In Table 13, tableau rules for mono-modal **K** were given. In the multi-modal setting these rules are replaced by those in Table 18. Likewise the mono-modal tableau rules of Table 14 must be replaced with those in Table 19.

$$\frac{\sigma\,\nu^a}{\sigma.na\,\nu_0^a} \qquad \frac{\sigma\,\pi^a}{\sigma.na\,\pi_0^a}$$

for $\sigma.na$ used   for $\sigma.na$ new

Table 18. Multi-Modal Tableau Rules for **K**

$$T^a \quad \frac{\sigma\,\nu^a}{\sigma\,\nu_0^a} \qquad\qquad 4r^a \quad \frac{\sigma.na\,\nu^a}{\sigma\,\nu^a}$$

$$4^a \quad \frac{\sigma\,\nu^a}{\sigma.na\,\nu^a} \qquad\qquad D^a \quad \frac{\sigma\,T\,K_aX}{\sigma\,T\,\overline{K}_aX} \quad \frac{\sigma\,F\,\overline{K}_aX}{\sigma\,F\,K_aX}$$

$$B^a \quad \frac{\sigma.na\,\nu^a}{\sigma\,\nu_0^a}$$

For prefixes σ and $\sigma.na$ already occurring on the tableau branch:

Table 19. Multi-Modal Tableau Rules

To illustrate how this works, Figure 11 displays a derivation using these rules. In it we have a logic of knowledge with two knowers, a and b. It is assumed that the T and $4r$ rules apply to K_b while only the K rules apply to K_a. The figure presents a derivation of $K_a\neg K_b(X \supset Y)$ from $K_a\neg K_b\neg K_b\neg Y$ and K_aX. In the tableau, 4 is from 3 by π^a; 5 is from 4 by negation; 6 is from 5 by T; 7 is from 2 and 8 is from 1 by ν^a; 9 is from 8 by negation; 10 is from 9 by π^b; 11 is from 10 by negation; 12 is from 11 by $4r^b$; 13 is from 12 by T; 14 is from 13 by negation; and 15 and 16 are from 6 by β.

I'll omit proofs of soundness and completeness. They are quite straightforward extensions of the mono-modal proofs given earlier. This is so for both the tableau and the axiomatic treatments.

Finally, as formulated above, knowers were independent beings. One might want to consider relationships between them such as, for instance, that b knows everything that a knows, or that if a knows something, b knows that a knows it. The most straightforward way of handling such things is to formulate them as axiom schemes. For instance, the first condition gives us the scheme $K_aX \supset K_bX$ and the second gives us $K_aX \supset K_bK_aX$. These can be added to an axiomatic formulation of a basic logic of knowledge, or can be taken as global assumptions in a tableau treatment. In many cases such assumptions can be reformulated as tableau rules too. For instance, the two conditions just mentioned correspond to the following two tableau rules.

$$\frac{\sigma\,\nu^a}{\sigma.nb\,\nu_0^a} \qquad\qquad \frac{\sigma\,\nu^a}{\sigma.nb\,\nu^a}$$

for $\sigma.nb$ used, corresponding to $K_aX \supset K_bX$ (left rule); for $\sigma.nb$ used, corresponding to $K_aX \supset K_bK_aX$ (right rule).

Conditions relating knowers are infinitely varied. I will not attempt to provide a general theory for them, but leave it to you to deal with them on a case-by-case basis.

9.2 Common Knowledge

A formula X is common knowledge among a group of knowers if X is true, everybody knows X, everybody knows that everybody knows X, and so on. If our knowers are,

$$
\begin{array}{ll}
1 & T\,K_a\neg K_b\neg K_b\neg Y \quad 1.\\
1 & T\,K_a X \quad 2.\\
1 & F\,K_a\neg K_b(X\supset Y) \quad 3.\\
1.1a & F\,\neg K_b(X\supset Y) \quad 4.\\
1.1a & T\,K_b(X\supset Y) \quad 5.\\
1.1a & T\,X\supset Y \quad 6.\\
1.1a & T\,X \quad 7.\\
1.1a & T\,\neg K_b\neg K_b\neg Y \quad 8.\\
1.1a & F\,K_b\neg K_b\neg Y \quad 9.\\
1.1a.1b & F\,\neg K_b\neg Y \quad 10.\\
1.1a.1b & T\,K_b\neg Y \quad 11.\\
1.1a & T\,K_b\neg Y \quad 12.\\
1.1a & T\,\neg Y \quad 13.\\
1.1a & F\,Y \quad 14.
\end{array}
$$

$$
\begin{array}{ccc}
1.1a\,F\,X \quad 15. & \qquad\qquad & 1.1a\,T\,Y \quad 16.
\end{array}
$$

Figure 11. Logic of Knowledge Tableau Example

say, $k_1, \ldots, k_n$, let us abbreviate $K_{k_1}\varphi \wedge \ldots \wedge K_{k_n}\varphi$ by $E\varphi$, and read it "everybody knows φ." Then common knowledge of X is, informally, the infinite conjunction $X \wedge EX \wedge EEX \wedge EEEX \wedge \ldots$, which we can represent as $\mathcal{C}X$. Of course this is not a real formula, though it can serve for motivation. Semantically, we want $\mathcal{C}X$ to be true at a state if X is true at every *reachable* state, where a state is reachable if there is some path to it along which each state is accessible from the previous one using any one of the accessibility relations $\mathcal{R}_{k_i}$. This seems simple enough, but capturing common knowledge axiomatically involves a fixpoint axiom and a rule of inference that is not obvious, [15]. Common knowledge cannot be captured at all by a conventional cut-free tableau system, [1], and it seems unlikely that it can be captured by a prefixed tableau system either. However, common knowledge applications often fall into two categories: how is common knowledge obtained, and how is common knowledge used given that it has been obtained. Many problems and puzzles involve only the latter, and this is relatively simple. In terms of the illegal equivalence $\mathcal{C}X \equiv X \wedge EX \wedge EEX \wedge EEEX \wedge \ldots$, obtaining common knowledge is the right-left implication, which has an infinitary antecedent, but using common knowledge involves the left-right implication, and this can be replaced with the legal, though infinite, list $\mathcal{C}X \supset X$, $\mathcal{C}X \supset EX$, $\mathcal{C}X \supset EEX$ .... In terms of tableaus using, though not obtaining, common knowledge is captured by rules that can deal with occurrences of $\mathcal{C}$ in negative positions in formulas being proved (which become positive positions when the formula is signed with F to begin a tableau proof). The rules are in Table 20. They are sound, but not complete, though they are complete with respect to a generalized version of common knowledge. I do not go into this here—see [2] for an investigation of a related system.

To show how these rules work, I'll make use of the familiar muddy children puzzle. There are, say, three children sitting in a circle, call them a, b, and c. Each can see the

$$\frac{\sigma\, T\, \mathcal{C}X}{\sigma.na\, T\, \mathcal{C}X} \qquad \frac{\sigma\, T\, \mathcal{C}X}{\sigma\, T\, X}$$

for $\sigma.na$ used

Table 20. Common Knowledge Tableau Rules

foreheads of the others, but not their own. Their legal guardian and designated puzzle person puts a spot of mud on each of their foreheads. At this point each child knows that the other two have muddy foreheads, but does not know the status of their own. Then the puzzle person announces, "at least one of you has a muddy forehead." Note that they already knew this—the effect of the announcement is to make the statement common knowledge. Then they are asked if they know whether or not their forehead is muddy. They do not, and say so. They are asked again, with the same result. They are asked a third time, and all know their forehead is muddy. The problem is to account for this.

To formalize this, let A have the intended meaning, the forehead of a is muddy, and similarly for B and C. At the start, each knows the set-up, so it is common knowledge that each knows the status of the others foreheads. That is, we have the following.

$$\mathcal{C}(K_aB \vee K_a\neg B) \tag{12}$$
$$\mathcal{C}(K_aC \vee K_a\neg C) \tag{13}$$
$$\mathcal{C}(K_bA \vee K_b\neg A) \tag{14}$$
$$\mathcal{C}(K_bC \vee K_b\neg C) \tag{15}$$
$$\mathcal{C}(K_cA \vee K_c\neg A) \tag{16}$$
$$\mathcal{C}(K_cB \vee K_c\neg B) \tag{17}$$

Let S be the formula asserting that someone knows the status of their forehead: $K_aA \vee K_a\neg A \vee K_bB \vee K_b\neg B \vee K_cC \vee K_c\neg C$. Also let $P \not\supset Q$ abbreviate $\neg(P \supset Q)$. Now, at the start it is announced that someone has a muddy forehead, $A \vee B \vee C$. Everybody hears the announcement and sees that everyone heard, and so common knowledge is obtained: $\mathcal{C}(A \vee B \vee C)$. Then it is asked if anyone knows the status of their forehead, and they do not, so $\mathcal{C}(A \vee B \vee C) \not\supset S$. Since everyone hears the answers, this is common knowledge for the next round, $\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S)$. But still nobody knows, and so $\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S$, and this is common knowledge for the next round, $\mathcal{C}(\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S)$. This time everybody knows their forehead is, in fact muddy. This is expressed by the following.

$$\mathcal{C}(\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S) \supset (K_aA \wedge K_bB \wedge K_cC) \tag{18}$$

Formally, (18) is a consequence of (12) – (17) as local premises, assuming no more than T knowledge for each knower. A tableau proof can be found in Figure 12 of $\mathcal{C}(\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S) \supset K_aA$. In it some simple derived rules have been used. One is: conclude $\sigma\, T\, X$ and $\sigma\, F\, Y$ from $\sigma\, T\, X \not\supset Y$, which simply omits the step involving the definition of $\not\supset$. The other is: conclude $\sigma\sigma'\, T\, X$ from $\sigma\, T\, \mathcal{C}X$, where $\sigma\sigma'$ is any prefix that extends σ and occurs on the branch. This is a simple combination of the two rules given earlier for $\mathcal{C}$. In the tableau: 2 and 3 are from 1 by α; 4 is from 3 by π^a; 5 is from

2 by the derived $\mathcal{C}$ rule; 6 and 7 are from 5 by the derived $\not\supset$ rule; 8 is from 7 by α and the definition of S; 9 is a premise; 10 is from 9 by the derived $\mathcal{C}$ rule; 11 and 12 are from 10 by β; 13 is from 11 by T^c; 14 is from 8 by π^c; 15 is from 12 by ν^c; 16 is from 15 by negation; 17 is from 6 by the derived $\mathcal{C}$ rule; 18 and 19 are from 17 by the derived $\not\supset$ rule; 20 is from 19 by α and the definition of S; 21 is a premise; 22 is from 21 by the derived $\mathcal{C}$ rule; 23 and 24 are from 22 by β; 25 is from 23 by T^b; 26 is a premise; 27 is from 26 by the derived $\mathcal{C}$ rule; 28 and 29 are from 27 by β; 30 is from 28 by T^b; 31 is from 20 by π^b; 32 is from 24 by ν^b; 33 is from 32 by negation; 34 is from 29 by ν^b; 35 is from 34 by negation; and 32 is from 18 by the derived $\mathcal{C}$ rule. Closure is by 4 and 13; 16 and 25; 14 and 30; and 31, 32, 33, 35 and applications of the β rule.

In the version of the puzzle embodied in (18) the assumption was that everybody had a muddy forehead. If only two do, say a and b, those who have muddy foreheads know this on the second round. Here is an expression of this.

$$\neg C \supset [\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \supset (K_a A \wedge K_b B)] \tag{19}$$

This, too is provable using the tableau rules given above, but now we must assume the **S5** rules for knowers a and b. On the other hand, the two children a and b can see the forehead of c, know it is not muddy, and can see each other and so know that they both know it, and so on. That is, $\neg C$ is not just true, it is common knowledge between a and b. If the antecedent $\neg C$ in (19) is replaced by this relativized common knowledge assumption, whose proper formulation I'll leave to you, **S5** rules are not needed.

The methods extend to n children with k muddy, but you doubtless get the general idea.

10 CONVERSE

Suppose we have a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{V} \rangle$ with a single accessibility relation, but two modal operators, say $\Box$ and $\Box^{-1}$. Let us say $\Box$ has its usual interpretation, $\mathcal{M}, w \Vdash \Box X$ if $\mathcal{M}, w' \Vdash X$ for all $w' \in \mathcal{G}$ with $w\mathcal{R}w'$, but suppose $\Box^{-1}$ is understood via $\mathcal{M}, w \Vdash \Box^{-1} X$ if $\mathcal{M}, w' \Vdash X$ for all $w' \in \mathcal{G}$ with $w'\mathcal{R}w$. The difference is easy to miss: $\Box$ uses $\mathcal{R}$, but $\Box^{-1}$ uses the relation converse to $\mathcal{R}$, often written $\mathcal{R}^{-1}$. This gives us a natural multi-modal logic, but with the modalities intimately connected. One place where such things come up is *temporal logic*—future and past are converse in this sense. Another place is *CPDL*, propositional dynamic logic with converse. I don't want to get into these topics here (see [32, 35]) but if we assume a simple underlying modality, **K**, **T**, or something of this sort, a tableau system capable of dealing with converse is not complicated. I will discuss it briefly in this section—it is based on the treatment in [30]. See [6] for an axiomatic version.

The simplest way to approach the subject is to build on earlier work. Suppose we use a logic of knowledge with two knowers, a and b, and from now on identify K_a with $\Box$ and K_b with $\Box^{-1}$. Then, for starters, we want the tableau rules from Table 18, or perhaps from Table 19 too if more complex assumptions about $\Box$ are being made. Converseness is a relationship between our two knowers, of the sort discussed at the end of Section 9. It can be captured by the following tableau rules.

$$\frac{\sigma.na\ \nu^b}{\sigma\ \nu_0^b} \qquad \frac{\sigma.nb\ \nu^a}{\sigma\ \nu_0^a}$$

$1 \quad F\,\mathcal{C}(\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S) \supset K_a A \quad 1.$
$1 \quad T\,\mathcal{C}(\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S) \quad 2.$
$1 \quad F\,K_a A \quad 3.$
$1.1a\,F\,A \quad 4.$
$1.1a\,T\,\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \not\supset S \quad 5.$
$1.1a\,T\,\mathcal{C}(\mathcal{C}(A \vee B \vee C) \not\supset S) \quad 6.$
$1.1a\,F\,S \quad 7.$
$1.1a\,F\,K_c C \quad 8.$
$1 \quad T\,\mathcal{C}(K_c A \vee K_c \neg A) \quad 9.$
$1.1a\,T\,K_c A \vee K_c \neg A \quad 10.$

$1.1a\,T\,K_c A \quad 11.$
$1.1a\,T\,A \quad 13.$

$1.1a \quad T\,K_c \neg A \quad 12.$
$1.1a.1c\,F\,C \quad 14.$
$1.1a.1c\,T\,\neg A \quad 15.$
$1.1a.1c\,F\,A \quad 16.$
$1.1a.1c\,T\,\mathcal{C}(A \vee B \vee C) \not\supset S \quad 17.$
$1.1a.1c\,T\,\mathcal{C}(A \vee B \vee C) \quad 18.$
$1.1a.1c\,F\,S \quad 19.$
$1.1a.1c\,F\,K_b B \quad 20.$
$1 \quad T\,\mathcal{C}(K_b A \vee K_b \neg A) \quad 21.$
$1.1a.1c\,T\,K_b A \vee K_b \neg A \quad 22.$

$1.1a.1c\,T\,K_b A \quad 23.$
$1.1a.1c\,T\,A \quad 25.$

$1.1a.1c\,T\,K_b \neg A \quad 24.$
$1 \quad T\,\mathcal{C}(K_b C \vee K_b \neg C) \quad 26.$
$1.1a.1c\,T\,K_b C \vee K_b \neg C \quad 27.$

$1.1a.1c\,T\,K_b C \quad 28.$
$1.1a.1c\,T\,C \quad 30.$

$1.1a.1c \quad T\,K_b \neg C \quad 29.$
$1.1a.1c.1b\,F\,B \quad 31.$
$1.1a.1c.1b\,T\,\neg A \quad 32.$
$1.1a.1c.1b\,F\,A \quad 33.$
$1.1a.1c.1b\,T\,\neg C \quad 34.$
$1.1a.1c.1b\,F\,C \quad 35.$
$1.1a.1c.1b\,T\,A \vee B \vee C \quad 32.$

Figure 12. Muddy Children Puzzle

I think we're at a point where I can omit soundness and completeness arguments. Table 21 shows a simple proof in this system, of $P \supset K_b\overline{K}_aP$. In it, 2 and 3 are from 1 by α, 4 is from 3 by π in Table 18; 5 is from 4 by a ν rule above.

$$\begin{array}{ll}
1 & F\,P \supset K_b\overline{K}_aP \quad 1. \\
1 & T\,P \quad 2. \\
1 & F\,K_b\overline{K}_aP \quad 3. \\
1.1b & F\,\overline{K}_aP \quad 4. \\
1 & F\,P \quad 5.
\end{array}$$

Table 21. Converse Modality Tableau Example

11 THE UNIVERSAL MODALITY AND THE DIFFERENCE MODALITY

Logics of knowledge combine many 'ordinary' modal operators, but there has been considerable investigation of the effects of adding special, expressive, modal operators to a standard modal logic. Two of these that are especially powerful and interesting are the *universal* modality, also called the *global* modality in [6], and the *difference* modality. Discussion of, and axiomatization for both can be found in [6].

Suppose we have a multi-modal logic **L** of the kind considered in Section 9, in which the individual modal operators are among those of Table 15, or **K** of course. That is, we have a prefixed tableau system for **L**. The *universal* modal operator, written E, is a kind of possibility operator that can be read "somewhere." That is, EX informally asserts that X holds at some possible world. Note that the accessibility relation plays no role in this. The dual necessity-like operator is written A. In a model $\mathcal{M}$ for **L** with these operators added, we want the following conditions.

$$\mathcal{M}, w \Vdash EX \iff \mathcal{M}, w' \Vdash X \text{ for some } w' \in \mathcal{M}$$
$$\mathcal{M}, w \Vdash AX \iff \mathcal{M}, w' \Vdash X \text{ for every } w' \in \mathcal{M}$$

To provide prefixed tableau rules for these operators, we need a small extension of the system in Section 9. There a prefix was a sequence of the form $1.n_1a_1.n_2a_2.\ldots$, beginning with 1. From now on prefixes can begin with any positive integer. The nu/pi definition is extended in the obvious way, in Table 22.

ν	ν_0
$T\,AX$	$T\,X$
$F\,EX$	$F\,X$

π	π_0
$T\,EX$	$T\,X$
$F\,AX$	$F\,X$

Table 22. Universal Modality Nu and Pi Formulas

The tableau rules for E and A are given in Table 23. These are to be added to the rules for the other modal operators of **L**.

Soundness and completeness proofs are not difficult, and I omit them. I make one observation, however. It is easy to see that models produced by earlier completeness

$$\frac{\sigma\,\nu}{\sigma'\,\nu_0} \qquad\qquad \frac{\sigma\,\pi}{n\,\pi_0}$$

for σ' used for n new

Table 23. Universal Modality Tableau Rules

proofs for prefixed tableau systems all have a tree structure, since that is the syntactical structure of prefixes. This is no longer the case when the universal modality is present. Instead models are more like forests—sets of trees.

The *difference* modality, also read as *elsewhere*, is a possibility-like operator, too. The formula DX informally can be read as asserting that X holds somewhere else. There is, of course, a dual operator, but since the tableau rules take a somewhat more complex form, I won't consider it. Once again, a discussion and axiomatization for this operator can be found in [6]. As to prefixed tableau rules, the addition to **L** given in Table 24 will do.

$$\frac{T\,\sigma\,DX}{T\,n\,X \;\big|\; T\,\sigma_1\,X \;\big|\; T\,\sigma_2\,X \;\big|\; \cdots \;\big|\; T\,\sigma_k\,X} \qquad\qquad \frac{F\,\sigma\,DX}{F\,\sigma'\,X}$$

In the T rule: n is a new integer, and $\sigma_1, \ldots, \sigma_k$ are all prefixes used on the branch other than σ. In the F rule: σ' is any prefix used on the branch other than σ.

Table 24. Difference Modality Tableau Rules

Figure 13 displays a sample proof using these rules, of $DDP \supset (P \vee DP)$, which is one of the axioms for D in [6]. In it, 2 and 3 are from 1 by α; 4 and 5 are from 3 by α; 6 is from 2 by the TD rule (note that at this point there are no prefixes on the branch other than 1, and 2 is new); 7 and 8 are from 6 by the TD rule (3 is new, and 1 is the only prefix on the branch other than 2); 9 is from 5 by the FD rule.

$$\begin{array}{l}
1\,F\,DDP \supset (P \vee DP) \quad 1.\\
1\,T\,DDP \quad 2.\\
1\,F\,P \vee DP \quad 3.\\
1\,F\,P \quad 4.\\
1\,F\,DP \quad 5.\\
2\,T\,DP \quad 6.
\end{array}$$

$$\begin{array}{ll}
3\,T\,P \quad 7. & \qquad 1\,T\,P \quad 8.\\
3\,F\,P \quad 9. &
\end{array}$$

Figure 13. Prefixed Difference Modality Tableau

12 WHAT ARE THE LIMITATIONS

Going beyond the logics we have looked at so far are those using a *fixpoint* construction. That is, in the semantics some modal operator is modeled by a device that involves minimizing (or maximizing) some monotone operator on the set of possible worlds. Such logics are very powerful, and very resistant to tableau methods. It is an area needing further research. Here is a brief rundown of the most common fixpoint logics.

Propositional dynamic logic is, perhaps, the original example, see [35] for a thorough treatment. In this multi-modal logic, modal operators correspond to computer programs. The semantical treatment of the *while* operator requires a fixpoint construction. From early on there was a tableau system for the logic, [51]. It is, however, of a specialized nature that so far has not lent itself well to treatment by the general methodologies of this chapter.

Propositional dynamic logic was extended to the *propositional μ-calculus* in [41], with modal operators in the language corresponding directly to fixpoint constructions. I do not know how to bring tableau methods to bear.

Finally, common knowledge was discussed above, in Section 9.2. It was made clear that the tableau rules given were only for *using* common knowledge, and could not handle its acquisition. Common knowledge is yet another example of a fixpoint modality, and another example of one for which satisfactory tableau rules do not exist.

13 QUANTIFIED MODAL LOGIC

As if propositional modal logic wasn't complicated enough, each one can be extended to a first-order version in a multiplicity of ways [28, 37, 26]. For starters, domains of quantification can be different at different worlds, or the same at all worlds, or related in ways that depend on relative accessibility. When each possible world has its own domain of quantification, one can think of these domains as representing what exists at each world. In this case quantifiers are *actualist*—they quantify over what actually exists. When the domain of quantification is the same for all worlds, one can think of the common domain as the realm of possible existents. Then quantifiers are *possibilist*. These two versions correspond to well-established philosophical positions, but this is not the place to discuss them. As it happens, constant domain, possibilist quantification is the easiest to capture using prefixed tableaus. And, as it happens, varying domain semantics can be embedded into a constant domain version easily and naturally. So, in this section I'll briefly sketch prefixed tableau systems for constant domain, possibilist versions of the propositional modal logics that were treated earlier, and then say a little about other versions of quantified modal logic.

13.1 Syntax and Semantics

We need a first-order language. I'll assume we have relation symbols of arity 1, 2, ... In the interests of simplicity, there will be no constant or function symbols. I'll also assume there is an infinite list of variables. Atomic formulas are expressions of the form $P(v_1, \ldots, v_n)$ where P is a relation symbol of arity n, and $v_1, \ldots, v_n$ are variables. Formulas are built up from atomic formulas in the usual way, using modal operators ($\Box$ and $\Diamond$ only, for the time being), propositional connectives, and quantifiers. I'll take both

$\forall$ and $\exists$ as primitive in this section. I'll assume the notion of free and bound variable is understood, and so the notion of closed formula, or sentence.

A *constant domain model* is a structure $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{D}, \mathcal{I} \rangle$ where: $\langle \mathcal{G}, \mathcal{R} \rangle$ is a frame as before; $\mathcal{D}$ is a non-empty set, the domain of quantification; and $\mathcal{I}$ is an interpretation, assigning to each n-ary relation symbol P and each possible world w an n-place relation $\mathcal{I}(P, w)$ on $\mathcal{D}$. We are primarily interested in the behavior of sentences, but formulas with free variables come into things, so we need one more piece of machinery. A *valuation* in a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{D}, \mathcal{I} \rangle$ is a mapping v from the set of variables to the domain, $\mathcal{D}$, of the model.

The chief semantic notion is symbolized $\mathcal{M}, w \Vdash_v X$ and is read: formula X is true at world w of model $\mathcal{M}$ with respect to valuation v. The definition follows. In it, a valuation v' is an x-variant of a valuation v if the two valuations agree on all variables except possibly x.

Atomic $\mathcal{M}, w \Vdash_v P(x_1, \ldots, x_n)$ if and only if $\langle v(x_1), \ldots, v(x_n) \rangle \in \mathcal{I}(P, w)$

Negation $\mathcal{M}, w \Vdash_v \neg X$ if and only if not-$\mathcal{M}, w \Vdash_v X$

Propositional Connectives $\mathcal{M}, w \Vdash_v X \wedge Y$ if and only if $\mathcal{M}, w \Vdash_v X$ and $\mathcal{M}, w \Vdash_v Y$, and similarly for the other connectives.

Necessity $\mathcal{M}, w \Vdash_v \Box X$ if and only if $\mathcal{M}, w' \Vdash_v X$ for every $w' \in \mathcal{G}$ with $w \mathcal{R} w'$.

Possibility $\mathcal{M}, w \Vdash_v \Diamond X$ if and only if $\mathcal{M}, w' \Vdash_v X$ for some $w' \in \mathcal{G}$ with $w \mathcal{R} w'$.

Universal Quantifier $\mathcal{M}, w \Vdash_v (\forall x)\varphi$ if and only if $\mathcal{M}, w \Vdash_{v'} \varphi$ for every valuation v' that is an x-variant of v.

Existential Quantifier $\mathcal{M}, w \Vdash_v (\exists x)\varphi$ if and only if $\mathcal{M}, w \Vdash_{v'} \varphi$ for some valuation v' that is an x-variant of v.

As might be expected, if X has no free variables, $\mathcal{M}, w \Vdash_v X$ for some valuation v if and only if $\mathcal{M}, w \Vdash_v X$ for every valuation v. Consequently we can speak of the truth or falsity of a sentence at a world in a model without mentioning the valuation. I'll say a sentence X is **L** valid, where **L** is some normal modal logic determined by a class of frames, if X is true at every world of every model $\langle \mathcal{G}, \mathcal{R}, \mathcal{D}, \mathcal{I} \rangle$ such that $\langle \mathcal{G}, \mathcal{R} \rangle$ is an **L** frame, for every non-empty domain $\mathcal{D}$ and every interpretation $\mathcal{I}$.

13.2 Constant Domain Tableaus

The goal is to extend the tableau systems of Section 6 to take constant domain quantification into account. As it happens, this is accomplished easily by a combination of modal rules and standard tableau quantification rules, [22, 57].

Tableau proofs will be of sentences only. As usual in treatments of first-order logic, there will be a version of existential instantiation—if $(\exists x)P(x)$ is true then $P(x)$ is true for some value of x, so we introduce a symbol intended to designate such a value. For this purpose there is a second list of variables, disjoint from the first. These new variables are called *parameters*. Formulas with parameters as free variables play a role in proofs, but they have no part in what we are trying to prove. From now on, by *sentence* I mean a closed formula none of whose variables are parameters.

Let **L** be one of the propositional modal logics for which a prefixed tableau system was given in Section 6. For a constant domain, first-order version of this we use the propositional rules for **L** from before, and add to them rules for quantifiers. To make it easier to state the new rules, two new formula classifications are introduced, following [57]. In giving them, I'll adopt the following convention. If I write $\varphi(x)$ it is intended to represent a formula in which at most x may occur free; then a subsequent occurrence of $\varphi(p)$ represents the result of substituting the parameter p for every free occurrence of x in $\varphi(x)$. Note that since parameters cannot be quantified, we needn't worry about 'accidental' capture of p in such a substitution. Now, Table 25 contains the new formula cases, and Table 26 gives the new tableau rules. The γ rule allows any parameter to be used, while the δ rule requires a parameter that is new to the branch.

γ	$\gamma(p)$
$T\,(\forall x)\varphi(x)$	$T\,\varphi(p)$
$F\,(\exists x)\varphi(x)$	$F\,\varphi(p)$

δ	$\delta(p)$
$T\,(\exists x)\varphi(x)$	$T\,\varphi(p)$
$F\,(\forall x)\varphi(x)$	$F\,\varphi(p)$

Table 25. Gamma and Delta Formulas

$$\frac{\sigma\,\gamma}{\sigma\,\gamma(p)}\ \text{for any } p \qquad\qquad \frac{\sigma\,\delta}{\sigma\,\delta(p)}\ \text{for } p \text{ new}$$

Table 26. Quantifier Rules

Figure 14 displays a proof of $(\forall x)\Box P(x) \supset \Box(\forall x)P(x)$, an instance of the *Barcan formula*, using the propositional **K** rules. In it, 2 and 3 are from 1 by α; 4 is from 3 by π; 5 is from 4 by δ (p is a new parameter); 6 is from 2 by γ; 7 is from 6 by ν.

$$\begin{array}{ll}
1 & F\,(\forall x)\Box P(x) \supset \Box(\forall x)P(x) \quad 1. \\
1 & T\,(\forall x)\Box P(x) \quad 2. \\
1 & F\,\Box(\forall x)P(x) \quad 3. \\
1.1 & F\,(\forall x)P(x) \quad 4. \\
1.1 & F\,P(p) \quad 5. \\
1 & T\,\Box P(p) \quad 6. \\
1.1 & T\,P(p) \quad 7.
\end{array}$$

Figure 14. Prefixed **K** Barcan Formula Proof

13.3 Soundness and Completeness

By now several soundness and completeness arguments for tableau systems have been given. I think we are at the point where we can be somewhat more terse. A set S of quantified formulas is *satisfiable* if there is a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{D}, \mathcal{I} \rangle$, a valuation v, and a mapping n from the prefixes in S to possible worlds in $\mathcal{M}$, such that if $\sigma\,T\,X \in S$ then $\mathcal{M}, n(\sigma) \Vdash_v X$ and if $\sigma\,F\,X \in S$ then $\mathcal{M}, n(\sigma) \not\Vdash_v X$. A tableau branch is satisfiable if

the set of formulas on it is, and a tableau is satisfiable if some branch is. A proof that tableau rule applications preserve satisfiability can be left to you. The new thing here is the quantifier rules, and they are handled exactly as with standard classical tableau arguments. Once this is established, soundness is by the usual argument.

Completeness is a mix of modal and classical techniques. To keep the discussion uncluttered, I'll assume the underlying logic is **K**; adapting the argument to other logics that have prefixed tableau systems is straightforward.

For starters, the Lindenbaum construction of (1) and (6) needs to be 'doubly Henkinized,' to take care of both prefixes and quantifiers. I'll work with formulas that can contain free variables, but they must all be parameters. Call a set S of prefixed signed formulas $\exists$-*complete* provided, if $\sigma\,\delta \in S$ then for some parameter p, $\sigma\,\delta(p) \in S$. The notion of π-completeness was defined in Section 6.2, as was the notion of omitting infinitely many integers. S omits infinitely many parameters if the set of parameters not occurring in formulas of S is infinite. We still say a set S is **K**-consistent if no **K**-tableau for a finite part of S is closed (though now the tableau rules include those for quantifiers). Every **K**-consistent set S of prefixed formulas that omits infinitely many integers and omits infinitely many parameters can be extended to a set that is maximally **K**-consistent, π-complete, and $\exists$-complete. This can be done via the following modification of the earlier construction, (6).

Double Lindenbaum-Henkin Construction Suppose S is a **K**-consistent set of prefixed sentences. Enumerate the prefixed signed formulas of the language, $\sigma_1\,\mathcal{X}_1$, $\sigma_2\,\mathcal{X}_2$, $\ldots$, whose only free variables are parameters, and define the following sequence of sets.

$$S_1 = S$$

$$S_{n+1} = \begin{cases} S_n \cup \{\sigma_n\,\mathcal{X}_n\} & \text{if } \mathbf{K}\text{-consistent and } \mathcal{X}_n \text{ is not } \pi \text{ or } \delta \\ S_n \cup \{\sigma_n\,\pi, \sigma_n.k\,\pi_0\} & \text{if } \mathbf{K}\text{-consistent, } \mathcal{X}_n \text{ is } \pi\text{, and } \sigma_n.k \text{ is new} \\ S_n \cup \{\sigma_n\,\delta, \sigma_n\,\delta(p)\} & \text{if } \mathbf{K}\text{-consistent, } \mathcal{X}_n \text{ is } \delta, \\ & \quad \text{and } p \text{ is a new parameter} \\ S_n & \text{otherwise} \end{cases} \tag{20}$$

I'll leave it to you to check that $\cup_n S_n$ is maximally **K**-consistent, and both π-complete and $\exists$-complete. Now tableau completeness follows easily. Suppose the sentence X is not provable using the constant domain **K**-tableau rules. Then $\{1\,F\,X\}$ is **K**-consistent, omits infinitely many parameters (all of them), and omits infinitely many integers. Extend it to a maximally **K**-consistent, π-complete, $\exists$-complete set S. Define a model $\mathcal{M} = \langle \mathcal{G}, \mathcal{R}, \mathcal{D}, \mathcal{I} \rangle$ as follows. $\mathcal{G}$ is the set of prefixes in S. For σ and τ in $\mathcal{G}$ set $\sigma\mathcal{R}\tau$ if $\tau = \sigma.n$ for some n. This much is exactly as in Section 6.2. Let $\mathcal{D}$ be the set of parameters. For an n-place relation symbol P, $\mathcal{I}(P, \sigma) = \{\langle p_1, \ldots, p_n \rangle \mid \sigma\,T\,P(p_1, \ldots, p_n) \in S\}$.

Now that we have a model, we need a version of the truth lemma, which for propositional prefixed tableaus took the form of (7). The version we need now is the following.

$$\begin{aligned} \sigma\,T\,Z \in S &\Longrightarrow \mathcal{M}, \sigma \Vdash_v Z \text{ for some } v \\ \sigma\,F\,Z \in S &\Longrightarrow \mathcal{M}, \sigma \nVdash_v Z \text{ for some } v \end{aligned} \tag{21}$$

This is proved by induction on Z. I leave the argument to you. But the consequence

is that the unprovable sentence X is falsified in this model, at world 1. Thus we have completeness for quantified **K**. Extending the argument to other logics is an exercise.

13.4 Variations

In the previous section I presented, in some detail, prefixed tableaus for constant domain **K**, and in outline versions for other constant domain logics. The other extreme is to have a semantics with varying domains, with no special conditions imposed on these domains. Thus, domains from different possible worlds might be disjoint, overlap, coincide, whatever. Recall, varying domain semantics is appropriate for *actualist quantification*, while constant domain semantics corresponds to *possibilist quantification*.

One way of developing prefixed tableaus for varying domain semantics is to introduce a different set of parameters for each prefix. This approach is worked out in detail in [26]. There is, however, a much simpler approach, one that builds directly on what has already been done here. Let us introduce a special one-place relation symbol, E, and read $\mathsf{E}(x)$ informally as *x actually exists*. And let us also introduce relativized quantifiers: $(\forall^{\mathsf{E}} x)\varphi$ abbreviates $(\forall x)[\mathsf{E}(x) \supset \varphi]$, and $(\exists^{\mathsf{E}} x)\varphi$ abbreviates $(\exists x)[\mathsf{E}(x) \wedge \varphi]$. If we use these relativized quantifiers, with the prefixed tableau rules given above, the result corresponds exactly to varying domain semantics. Loosely speaking, it is the interpretation of the E predicate, which can change from world to world, that gives us the effect of varying domains.

What was just said is not entirely accurate. One generally takes domains of quantification to be non-empty. The approach outlined above does not impose such a requirement, since the interpretation of E at a world might, in fact, be empty. But there is a simple way around this. Recall how local and global premises were used in propositional prefixed tableaus—see the end of Section 6.1. The same thing works even with quantifier rules added. So, if we want only non-empty domains, we just take $(\exists x)\mathsf{E}(x)$ as a global premise, which means $\sigma\, T\, (\exists x)\mathsf{E}(x)$ can be added to any tableau branch, for any prefix already present.

Other conditions are sometimes imposed on varying domains. *Monotonicity* is a common assumption: if $w\mathcal{R}w'$ then the domain associated with world w is a subset of that associated with world w'. *Anti-monotonicity* is also used occasionally, if $w\mathcal{R}w'$ then the domain associated with w' is a subset of that associated with w. Both can easily be incorporated into the present approach. For monotonicity, take $(\forall x)[\mathsf{E}(x) \supset \Box\mathsf{E}(x)]$ as a global premise. For anti-monotonicity, use $(\forall x)[\Diamond\mathsf{E}(x) \supset \mathsf{E}(x)]$ as a global premise.

As an example, in Figure 14 there is a proof of the Barcan formula, using possibilist quantification. Try and prove the corresponding actualist quantification version, $(\forall^{\mathsf{E}} x)\Box P(x) \supset \Box(\forall^{\mathsf{E}} x)P(x)$. You can't, with or without $(\exists x)\mathsf{E}(x)$ as a global premise. But it is provable if we assume anti-monotonicity, taking $(\forall x)[\Diamond\mathsf{E}(x) \supset \mathsf{E}(x)]$ as a global premise. A proof can be found in Figure 15. In this, 2 and 3 are from 1 by α; 4 is from 3 by π; $4'$ is 4 unabbreviated; 5 is from $4'$ by δ; 6 and 7 are from 5 by α; $2'$ is 2 unabbreviated; 8 is from $2'$ by γ; 9 and 10 are from 8 by β; 11 is a global premise; 12 is from 11 by γ; 13 and 14 are from 12 by β; 15 is from 13 by ν; 16 is from 10 by ν. Closure is by 6 and 15, 9 and 14, 7 and 16.

In the same way that possibilist quantifiers and quantification rules were added to mono-modal logics, they can be added to a multi-modal logic such as one of the logics of knowledge discussed in Section 9. Indeed, one could even introduce an actually exists

predicate for each knower, E_a, and give each modality its own domain of quantification at each world. But I think we have taken things far enough.

$$

14 CONCLUSION

We have reached the end of the chapter, but not the end of the subject. The literature on modal proof theory is vast, and there are many different approaches besides what was covered here. Here is a select list of pointers (for which I thank the reader for this chapter, Heinrich Wansing). There are higher-arity sequent systems, [7]; higher-level sequent systems, [13]; higher-dimensional sequent systems, [45]. There are display sequent systems, [4, 12, 53, 58, 60], which are particularly appropriate for temporal systems. See [61] for the relationship between these and hypersequents. In addition, there are relational proof systems, [49]; and multiple-sequent systems, [38, 39]. And for general treatments, see [59, 62].

Quantified classical logic generally admits constant and function symbols, and equality. Adding these to quantified modal logic requires choices. Are constant and function symbols to be rigid—having the same designation at each world—or non-rigid? If non-rigidity is the choice, a device called *predicate abstraction* can be added to help sort out ambiguities that arise. How does one deal with the contingent equality of the number 9 and the number of the planets, but not their synonymy? Such things can, in fact, be dealt with, and prefixed tableau systems exist that can help sort things out. See [26] for

a thorough discussion, and [23] for an abbreviated one. Also [25] contains a presentation of a rich first-order system along these lines.

After first-order comes second-order, and full type theory. This tends to get enormously complex. Tableau systems for a version of modal type theory can be found in [24].

To a certain extent I have followed my own interests in this chapter. I've tried to keep it in control, but I think my biases show. The reader should keep in mind that this is an enormous subject, and my tastes may not be that of others. Start here, don't finish here.

1 INTRODUCTION

This chapter is a basic introduction to the field of computational complexity in modal logic. We are mostly concerned with the following question: given a formula A and a set of formulas C, does there exists a model in which all of C is true at every world and A is true at some world? In other words, is $C \models \neg A$ or $C \not\models \neg A$ the case? This is the complement of the (global) consequence problem: $C \models A$ (is A true in every model in which all of C is true at every world). The special case of the consequence problem in which C is the empty set is called the validity problem, and its complement is the satisfiability problem. For finite C, the local consequence problem reduces to the validity problem, because of the deduction theorem.

For many modal logics, these problems are decidable. Here we look at the *difficulty* of deciding them. This is the topic of the theory of computational complexity. As Wikipedia has it:

> Computational complexity theory is part of the theory of computation dealing with the resources required during computation to solve a given problem. The most common resources are time (how many steps it takes to solve a problem) and space (how much memory it takes). Complexity theory differs from computability theory, which deals with whether a problem can be solved at all, regardless of the resources required.

Standard references to this field are [27] and [32].

Organization. The current section introduces common decision problems in modal logic and derives three useful properties of modal logics. In Section 2 we discuss the basic methods of establishing decidability and complexity results for the satisfiability problem in modal logic. In Section 3 we review the basic notions of computational complexity theory and after that we reduce several tiling problems to modal satisfiability problems in order to obtain lower complexity bounds. These say roughly that —up to a polynomial— one cannot give a better algorithm for the problem at hand. Throughout the text, we hardly give references. We end with some historical notes.

Links to Wikipedia. This chapter contains a lot of terminology with which the average logician might not be familiar. We have used links to the relevant Wikipedia entries to facilitate the reader. When viewing this document in a PDF reader, clicking on the highlighted terms should open the relevant Wikipedia page in a browser.

1.1 Examples of decision problems in modal logic

This chapter is about solving problems in modal logic. What is a problem? A problem for us is a yes/no question. These problems are typically formalized as set-membership problems. Here are some examples.

Suppose first that a logic L is presented as a set of wffs (well formed formulas), as in Chapter 2 of this handbook. Then membership in L is the same as being valid. Thus the validity problem equals the L membership problem.

Alternatively, we can define a modal logic as a triple $(\mathsf{Wffs},\ \mathsf{Struc},\ \models)$, a set of wffs, a class of models, and a relation between the two. (To be precise, $\models$ is a relation between a model $\mathcal{M}$, a world w and a wff A.) This is essentially the way logics are defined in abstract model theory; see Chapter 1 of this handbook for further discussion.

In this richer setting, more natural decision problems show up:

Model checking

1. Given a finite model $\mathcal{M}$, is $\mathcal{M}$ a member of Struc?
2. Given a finite model $\mathcal{M}$ in Struc, a world w in $\mathcal{M}$ and a formula $A \in \mathsf{Wffs}$, does $\mathcal{M}, w \models A$ hold?

Satisfiability Given a formula $A \in \mathsf{Wffs}$, does there exists a model $\mathcal{M}$ in Struc and a world w in $\mathcal{M}$ such that $\mathcal{M}, w \models A$ hold?

Consequence Given a set of wffs C and a wff A, does $\mathcal{M} \models C$ implies $\mathcal{M} \models A$ for every model $\mathcal{M}$?

Model comparison problems Given two finite models, does there exists a bisimulation between the two?

Definability Given a set of wffs T and a propositional variable p, does T define p? The latter means that in any model of T, the interpretation of p is uniquely determined by the interpretation of the accessibility relations and the other propositional variables in T.

Proof Given a sequence s of wffs ending in A, is s a Hilbert style proof of A in some given axiom system?

Note that all these problems can be casted as set membership problems. There are also other types of problems whose complexity can studied, for example,

- Given that $A \to B$ is a validity, find a Craig interpolant C.
- Given a first order formula $\varphi(x)$ which is invariant for bisimulation, find the equivalent modal formula.

In the next subsection we have a closer look at the satisfiability problem, the model checking problem and the consequence problem. The wish to compute with models and wffs leads to certain desirable properties for logics. We collect three of these and derive some basic results for logics satisfying these properties. We finish this introduction with an example showing how different the satisfiability problem and the consequence problem may behave.

1.2 A simple and a hard problem

Consider a logic L presented as a set of wffs, as in Chapter 2 of this handbook. Then (1) is a natural problem.

(1) Given a string s, is s an element of L?

On close inspection (1) consists of two rather different problems:

(2) Given a string s, is s a wff?

(3) Given a wff s, is s an element of L?

Problem (1) is often called the validity problem, the set L being the set of valid wffs. Usually it is stated as (3). One can blur the distinction between (1) and (3) because logics are designed in a certain way. Namely it is assumed that problem (2) is much simpler than problem (3). In fact it is assumed that problem (2) can be solved in a practically feasible manner. Before we make this last notion precise let us look at an example. The wffs of the basic modal language were given by the grammar:

$$\varphi ::= p_i \mid \neg\varphi \mid (\varphi \wedge \varphi) \mid \Diamond\varphi.$$

We can see this as shorthand for the following recursive definition, given as a Prolog program:

```
wff(p_I)        :-   integer(I).
wff(¬F)         :-   wff(F).
wff((F ∧ G))    :-   wff(F), wff(G).
wff(◇F)         :-   wff(F).
```

The set of wffs computed by this program is the least fixed point of this recursive definition. In other words it is the smallest set of strings `s` such that `wff(s)` succeeds. Now suppose we run a computer with this program and ask it to determine whether `wff(s)` is true, for an arbitrary string `s`. Does it always terminate? And if so, can we estimate beforehand —based solely on the input `s`— when it will terminate? The first question is answered positively, and we can prove it by induction on the length of the input string. From this proof follows also a positive answer to the second question: The number of recursive calls is bounded by the number of symbols in `s`. This number is closely connected to the amount of time. For our purposes, it is not really relevant to measure time in seconds. For one thing, computers are getting faster every day, so that would make the results quickly outdated. But however fast a machine, it still has to do a number of "basic computation steps", given a program. Now, depending on the granularity of our analysis, we determine ourselves what a basic computation step is and what not. In the above example for instance, we may assume that for each string `s` it takes one computation step to match `s` with the argument of a head in one of the clauses. Then by induction on the length of `s` (notation $|\mathtt{s}|$), we can show that the machine needs at most $|\mathtt{s}|$ steps to find the answer (exactly $|\mathtt{s}|$ in case `s` happens to be a wff). We say that the time required by the machine is linear in the length of the input, or more informally we say that the program is in linear time. The notation which is often used is $O(|s|)$ (read this as "of the order $|s|$"). The big O notation is a way of stating bounds that ignores multiplicative constants and low order terms. This is an example of a computation which is practically feasible: the amount of time necessary grows proportionally with the length of the input.

Now we look at a program which is not practically feasible. Suppose you are given a propositional formula and the question is whether it is a tautology. This is a typical example of a task that one would like a computer to solve. From a theoretical point of view, the problem is clearly solvable. One can answer the question by writing out the truth table and checking whether the last column contains true in every row. This procedure just tries out all possible truth assignments to the propositional variables and checks whether each of them makes the formula true. The reader should convince him/herself that this check is easy: once a truth assignment is chosen, the check can be done using at most as many steps as the number of subformulas of the input formula. But unfortunately the number of checks grows exponentially with the number of propositional variables in the input. For a formula with n variables, 2^n checks have to be made. With some patience (on our side) a computer can carry this out for us. But each time the input formula contains just one more propositional variable, the time we may have to wait doubles. Very rapidly patience alone is not sufficient anymore: even on the fastest computers now available, we would need to wait longer than the lifetime of the universe for input strings containing as many variables as there are characters in this sentence. Thus the procedure is not practically feasible, as it takes time $2^{O(n)}$, for n the number of variables.

We have seen two examples, a linear and an exponential procedure. The practically feasible algorithms are commonly taken to be the procedures which on any input s terminate in at most $p(|s|)$ steps, where $p(x)$ is a polynomial function in x.

So, returning to the beginning, we wanted to solve problem (1) and showed that it splits into two subproblems (2) and (3). We really want to pay attention to problem (3). (In the case of propositional logic, we just saw that (3) seems much harder to solve than (2).) Now if a logic satisfies the following, we can safely ignore (2).

Desirable property 1. There exists a practically feasible algorithm which decides for any string whether it is a wff of the logic.

One can view the wffs as the *data* of the logician. In case of logics presented as a set of strings, they are the only data he has. The property states that access to the data is easy.

1.3 The model checking problem

As discussed above, a modal logic can also be defined as a triple (Wffs, Struc, $\models$), a set of wffs, a class of models, and a relation between the two. (To be precise, $\models$ is a relation between a model $\mathcal{M}$, a world w and a wff A.) Given these data, there is one obvious problem:

(4) Given a finite model $\mathcal{M}$ in Struc, a world w in $\mathcal{M}$, and a wff A, does $\mathcal{M}, w \models A$ hold?

This is often called the model checking problem. In Chapter 1, two procedures are presented which decide this problem for the basic modal language. It was assumed that wffs and models can be encoded as input to a computer program. But it was also assumed that the encodings were correct! That is, they really encoded models and wffs. But just as in the case of problem (1) deciding this is part of the problem. Let's see in detail how this works. The input of problem (4) consists of three parts

1. a string $s_{\mathcal{M}}$ encoding the model $\mathcal{M}$;
2. a string s_w encoding the world w;
3. a string s_A encoding the wff A.

To count as an admissible input to the problem (4) these strings have to satisfy certain properties:

(5) $s_{\mathcal{M}}$ encodes a model $\mathcal{M}$ and $\mathcal{M}$ is an element of Struc;

(6) s_w is the encoding of a world in $\mathcal{M}$;

(7) s_A is the encoding of a wff.

Problem (7) gave rise to our first desirable property. It sounds reasonable to ask the same for problem (5): thus we ask for a procedure which takes at most $p(|s_{\mathcal{M}}|)$ steps, for some polynomial function p to decide whether 1) the string encodes a model, and 2) whether the model belongs to Struc. The first part is not problematic; if we use reasonable encodings (cf. [1] or [10]) this step is practically feasible. The second part, checking whether the model belongs to Struc, is quite a different matter. Here we do not check a simple property, like whether a string is a wff, or encodes a model. Here we check whether the model belongs to a class of models. This is a problem for which it is not even clear that it is decidable in general. In fact [4] (exercise 6.2.4) asks the reader to create a *logic* for which this problem is undecidable (a simple cardinality argument suffices to show that there must be classes for which membership is undecidable).

In modal logic it is common to define the class of models Struc as the class on which a finite set of modal formulas is valid. That means —if the truth definition is first-order— that the class is defined by a sentence from monadic second-order logic of the following shape:

> block of universal quantifiers ranging over sets followed by a first order formula in the signature of the accessibility relations of the logic.

Intuitively, the language in which we define the class of models influences the complexity of deciding membership in that class: the greater expressivity the language offers, the more difficult it

can be to decide membership. This intuition is made precise in the field of descriptive complexity theory [23]. Starting with Fagin's Theorem [12] it turned out that classes of models which are defined by their complexity in deciding membership correspond exactly to classes defined in certain well-known logical formalisms. Fagin's Theorem states that the following are equivalent, for C a class of finite structures,

- membership in C can be decided in non deterministic polynomial time in the size of the input structure;
- C is definable by a sentence of existential second-order logic.

Problems which can be decided in non-deterministic polynomial time are said to be in NP. Boolean satisfiability is the most prominent example of a problem in NP. As stated above some NP problems are generally believed not to be practically feasible. For more about NP, see Section 3. A class of structures defined by a universal second-order sentence is the complement of a class of structures defined by an existential second-order sentence. The complexity class co-NP consists of all problems whose complement is in the complexity class NP. (In computational complexity theory, the complement of a decision problem is the decision problem resulting from reversing the yes and no answers.) Thus Fagin's Theorem also connects the complexity class Co-NP with universal second-order definability. It is also generally believed that Co-NP hard problems cannot be solved in a practically feasible manner.

Desirable property 2.

- The class of models of a logical system is definable by a universal second-order sentence.
- Equivalently, the class is defined such that checking membership for finite models is in co-NP.

The most natural way of defining classes of structures in modal logic —by giving a number of modal axioms— leads in general to an impractical decision procedure. But of course this is the general case. For instance, it is easily seen that checking whether a model satisfies the axiom $\Diamond\top$ is practically feasible. In fact, it turns out that most well-known modal logics have a practically feasible model recognition problem, for instance all logics axiomatized by Sahlqvist axioms. This is because for first-order definable classes the membership problem is decidable in polynomial time. In fact this even holds for a powerful second-order extension of it [23]:

THEOREM 1 (Immerman–Vardi). *Let C be a class of finite structures. If C is defined by a sentence in first-order logic expanded with a least fixed point operator (in notation FO(LFP)), then checking membership in C can be done in polynomial time in the size of the input structure.*

Compared to Fagin's Theorem, Theorem 1 only states one (the easy) direction, and not an equivalence. In fact it is still an open problem to find the language corresponding to polynomial time. (Though it is solved on *ordered* structures: i.e., models which come with a linear order on their domain. Restricted to classes of *ordered* structures the converse of Theorem 1 holds as well, which is the full Immerman-Vardi Theorem.)

In the rest of this chapter we will only deal with modal systems whose class of models is definable in FO(LFP), which implies that membership is decidable in polynomial time.

The complexity of $\models$.

Having settled the hairy details, we can finally look at the problem (4). What we really ask here is the complexity of the relation $\models$. As models and formulas are the data of logic we must be able to access the data, thus we insist that (4) is decidable. How difficult it is to decide (4) in a particular case is a topic carefully studied in finite model theory and in database theory [1, 10]. Note that in the formulation of (4) the complexity is solely due to the expressive power of the language. There is something particular about the design of many modal languages which cause (4) to be practically feasible. We explain that now. As indicated in Chapter 1, the definition of $\models$ is given in terms of first-order logic. As we can see from the standard translation, the basic modal language corresponds to a fragment of first-order logic which contains only two variables. Obviously this is also true when considering more than one modality, but fails when considering polyoadic modalities; see Chapter 5, Section 1.5. But still the meaning of an n-ary modality is defined there using $n+1$ variables. So each modal similarity type τ which has a bound n on the arity of its operators corresponds to a $n+1$ variable fragment of first-order logic. Note that the definition of modal similarity type is general enough to allow a type with infinitely many modalities, each having a different arity. Such modal languages do not correspond to finite variable fragments. Being a bounded variable fragment seems to be a distinguishing feature of modal languages. There is also a nice complexity theoretic argument for requiring boundedness in terms of variables: the model checking problem for each bounded variable fragment of first order logic is practically feasible, while it is not for full first order logic [38].

THEOREM 2 (Immerman–Vardi). *Given a first-order formula $\varphi(\bar{x})$ in a fixed bounded variable fragment, a first-order model $\mathcal{M}$ and a sequence $\bar{a}$ of elements from the domain of $\mathcal{M}$, it is decidable in polynomial time in $|\varphi(\bar{x})|$ and $|\mathcal{M}|$ whether $\mathcal{M} \models \varphi(\bar{a})$.*

This gives us the third desirable property: the definition of $\models$ must be given in terms of a bounded variable fragment of first-order logic. Note that $\models$ could alternatively be defined as the standard translation.

Desirable property 3. The definition of $\models$ is given as a polynomial time computable function from the set of wffs to a bounded variable fragment of first order logic.

We immediately obtain that in favorable cases the model checking problem is practically feasible.

THEOREM 3. *Let L be a logical system satisfying the desirable properties 1 and 3. Let its class of models be defined by a FO(LFP) sentence. Then the model checking problem is decidable in polynomial time.*

1.4 The consequence problem

The consequence problem $C \models A$ is the central problem in logic. Here we restrict to finite C and study its complement:

(8) Given wffs C and A, can A be satisfied on a model $\mathcal{M} \in \mathsf{Struc}$ which globally satisfies C?

Recall that $\mathcal{M}$ globally satisfies C if $\mathcal{M}, w \models C$ holds for *all* worlds w in $\mathcal{M}$. We call this problem *satisfiability under constraints*. Without C we call it simply the *satisfiability* or *local satisfiability* problem.

There is no reason to believe a priori that this problem is decidable for a given modal system, even if it satisfies all design criteria. However there exists a sufficient condition which yields decidability in a straightforward manner.

DEFINITION 4. Let f be some computable function. A logical system $(\mathsf{Wff}, \mathsf{Struc}, \models)$ is said to have the f–bounded model property if for all wffs C, A, it holds that whenever A is satisfiable in a C model (in Struc) it is satisfiable in a C model (in Struc) whose size is bounded by $f(|C|, |A|)$.

THEOREM 5. *For any logical system having all three desirable properties, and having the f–bounded model property, problem (8) is decidable.*

Proof. Consider arbitrary wffs C and A. Then by the bounded model property the answer to (8) is yes if and only if there exists a model $\mathcal{M}$ in Struc whose size is bounded by $f(|C|, |A|)$ which globally satisfies C and locally satisfies A. Up to isomorphism there are finitely many structures of that size, so we can write a procedure which lists all of them (using some representation). By property 2 we can decide whether a structure is in Struc. By Theorem 2 we can check in polynomial time in $f(|C|, |A|)$, $|C|$ and $|A|$ whether a structure globally satisfies C and locally satisfies A. So we have to make a finite number of such checks, which yields the theorem. ❑

The procedure sketched in the last proof highlights a particular feature of algorithms designed to solve a problem in which one asks for the existence of a certain object. Note that this is the distinguishing feature between problems (4) and (8). In problem (4) we are given three objects, a model, a world and a wff and we have to determine whether they stand in the $\models$ relation. In problem (8) we are just given the constraint C and the wff A and we asked for the existence of a model. The algorithm for problem (8) uses the algorithm for problems (4) and (5) every time it “tries” a model from its long list of candidates. So the algorithm for (8) naturally divides into two parts:

- a (difficult) *search* for the right candidate model;
- an (easy) *check* that the candidate is correct (i.e., the model is in Struc, it globally satisfies C, and locally satisfies A).

For these kind of problems a special computational model has been designed which reflects the sketched division of labor. These are called non-deterministic computations. For a non-deterministic computation, the search for the right candidate takes no more time than required to write it down plus the time it takes to check whether a potential candidate is a real candidate. This discussion is captured in the next theorem:

THEOREM 6. *Let the logical system* $(\mathsf{Wff}, \mathsf{Struc}, \models)$ *satisfy all desirable properties. If* Struc *is defined by an FO(LFP) sentence and the system has the f–bounded model property, then there is some polynomial p such that (8) is decidable by a non-deterministic algorithm taking time* $p(f(|C|, |A|), |C|, |A|)$.

The proof of Theorem 18 in Chapter 1 can be extended to show that the basic modal logic has the $2^{(|C|+|A|)}$ bounded model property; see Proposition 10 below. Thus (8) can be decided by a non-deterministic algorithm which takes exponential time in the length of the input. Later on we see that we can do better, the non-determinism is not necessary. We finish the introduction by giving an example of a logic for which (8) is undecidable in general but decidable in non-deterministic polynomial time in the special case when the set of constraints is empty.

1.5 A tiling logic

We present an undecidable problem which is particularly well-suited for modal logics. Moreover finite variants of it exist which are useful in proving complexity results as we will see later on. These are the *tiling problems*. A tile is a one-by-one square which has a 'color' on each of its sides; these colors are given by four functions 'right', 'left', 'up' and 'down'. Given a set T of tiles containing one special tile T_0, a *tiling* of the grid $\mathbb{N} \times \mathbb{N}$ by T is a map t from $\mathbb{N} \times \mathbb{N}$ to T satisfying, for all $n, m \in \mathbb{N}$:

$$\begin{array}{lcl} t(0,0) & = & T_0, \\ \text{right}(t(n,m)) & = & \text{left}(t(n+1,m)), \\ \text{up}(t(n,m)) & = & \text{down}(t(n,m+1)). \end{array}$$

Tiles are assumed to be fixed in orientation, so the above conditions say that colors of adjacent tiles match. (We note that it is not required to use all tiles of T in a tiling of $\mathbb{N} \times \mathbb{N}$.) If such a tiling exist, we say that T *can tile* $\mathbb{N} \times \mathbb{N}$.

The following problem is undecidable.

$\mathbb{N} \times \mathbb{N}$ **tiling**: Given a finite set T of tiles, can T tile $\mathbb{N} \times \mathbb{N}$?

We will now define a modal system Tile which is tailored to encode the above tiling problem. The language of Tile contains two unary modalities $\langle \mathsf{right} \rangle$ and $\langle \mathsf{up} \rangle$. In a model of the form (W, R_r, R_u, V), these modalities receive their meaning in the usual way:

$$\begin{array}{lcl} \mathcal{M}, s \models \langle \mathsf{right} \rangle \varphi & \iff & \mathcal{M}, t \models \varphi \text{ for some } t \text{ with } R_r st, \\ \mathcal{M}, s \models \langle \mathsf{up} \rangle \varphi & \iff & \mathcal{M}, t \models \varphi \text{ for some } t \text{ with } R_u st. \end{array}$$

The class Struc of models of Tile consists of all models (W, R_r, R_u, V) in which R_r and R_u are (the graphs of) two commuting total functions. In particular, grid models satisfy the following condition:

(9) $\forall xyz((R_r xy \wedge R_u xz) \rightarrow \exists w(R_r zw \wedge R_u yw))$.

THEOREM 7. *Problem (8) is undecidable for the logic* Tile.

Proof. We reduce the $\mathbb{N} \times \mathbb{N}$–tiling problem to the satisfiability problem for Tile. We present a procedure that outputs for every instance T of the tiling problem, wffs C_T and A_T such that the following are equivalent

- T can tile $\mathbb{N} \times \mathbb{N}$;
- there exists a model $\mathcal{M}$ in Struc which globally satisfies C_T and locally satisfies A_T.

Take for any set $T = \{T_0, T_1, \ldots, T_k\}$ of tiles a corresponding set $\{t_0, t_1, \ldots, t_k\}$ of propositional variables. Let A_T be t_0. Define C_T as the conjunction of the following formulas (where i ranges over $0,\ldots,k$):

$$\begin{array}{lll} A1 & \bigvee_{0 \le i \le k} t_i & \\ A2 & \bigwedge_{0 \le i \le k} & \left[t_i \rightarrow \bigwedge_{i \ne j} \neg t_j \right] \\ A3 & \bigwedge_{0 \le i \le k} & [t_i \rightarrow \langle \mathsf{right} \rangle \bigvee \{ t_j \mid \text{right}(T_i) = \text{left}(T_j) \}] \\ A4 & \bigwedge_{0 \le i \le k} & [t_i \rightarrow \langle \mathsf{up} \rangle \bigvee \{ t_j \mid \text{up}(T_i) = \text{down}(T_j) \}] \,. \end{array}$$

It is almost immediate that T tiles $\mathbb{N} \times \mathbb{N}$ if and only if there exists a Tile model where C_T holds throughout and t_0 is satisfied at some world. (The reader should verify that in hard direction of the proof property (9) of grid models is crucial.) Thus we have reduced the undecidable tiling problem to problem (8) for the logic Tile. ❑

We hasten to remark that the undecidability of this system has nothing to do with the fact that we are dealing with more than one modality here; one can easily transform this example into an undecidable modal system in the *basic modal language*.

It is interesting to note that *without* constraints which hold globally these grid logics become quite harmless. In fact, the grid–like nature of their models ensures that every locally satisfiable formula A is satisfiable in a model whose size is at most $(|A|+1)^2+1$.

THEOREM 8. *Every locally* Tile *satisfiable formula A is satisfiable in a* Tile *model of size at most* $(|A|+1)^2+1$. *As a corollary,* Tile *has a local satisfiability problem which is decidable in non-deterministic polynomial time.*

Proof. Let $\mathcal{M}$ satisfy A at s. Let k be the modal depth of A. Thus $k \leq |A|$. Let $\mathcal{M}'$ be the smallest substructure of $\mathcal{M}$ which contains s together with all states reachable in at most k (R_r- or R_u-) steps from s and which satisfies property 9. By Lemma 21 in Chapter 1, A is still satisfied in the model $\mathcal{M}'$. The size of the universe of $\mathcal{M}'$ is at most $(k+1)^2$. Unfortunately $\mathcal{M}'$ is not yet a Tile model, because not every state has a R_r and R_u successor. In order to mend this, add one dummy state x to the universe of $\mathcal{M}'$ and put a link from w to x for all states w (including x itself) that do not have a successor yet. That is, define $W^+ = W' \cup \{x\}$, $R_r^+ = R_r' \cup \{(w,x) \mid R_r'wy$ for no y in $\mathcal{M}'\}$, and likewise for R_u^+. Let the valuation stay the same, i.e., define $V^+(p) = V'(p)$ for all p.

The resulting model $\mathcal{M}^+$ is a Tile model. Clearly A is still satisfied at s in this new model, since x is 'too far away' to have any effect on the truth of A. (The k-bisimulation between $\mathcal{M}$ and $\mathcal{M}'$ is also a k-bisimulation between $\mathcal{M}$ and $\mathcal{M}^+$.) This proves the first part of the theorem. The complexity result follows from Theorem 6. ❑

2 DECISION ALGORITHMS

We have seen some very general results and some very basic desirable properties. Now we look at actual algorithms for deciding the satisfiability problem under constraints and the local satisfiability problem for a number of typical cases.

All presented decision algorithms are based on the following idea: show that for each wff A, the following are equivalent:

(10) A is satisfiable on a Struc model.

(11) There exists a finite structure $\mathcal{M}_A$ satisfying

- a finite number of decidable properties, and
- the size of $\mathcal{M}_A$ is bounded by some function $f(|A|)$.

From the discussion in the previous section it should be clear that decidability of the local satisfiability and the validity problems follow from this. A similar reduction will be given for the satisfiability problem under constraints. Note that an upper bound on the time used by the algorithm follows from 1) the function f and 2) the difficulty of checking the properties on $\mathcal{M}_A$.

First let's look at the kind of structures $\mathcal{M}_A$ we are after and what kind of properties we can expect. In the simplest case we just ask that $\mathcal{M}_A$ belongs to Struc and $\mathcal{M}_A, w \models A$ for some world w. Often this is either not possible (for instance, if the logic does not have the finite model property) or $\mathcal{M}_A$ gets unnecessarily large.

For the first case, consider the basic modal language interpreted on models $(\omega, \mathsf{succ}, V)$, hence

$$n \models \Diamond A \iff n+1 \models A.$$

Obviously this logic does not have the finite model property as Struc consists of infinite models only. Still using the technique from the proof of Theorem 8 we can show that each satisfiable A is satisfiable at world 0 in a model $(\{0, 1, \ldots, \mathrm{modal\_depth}(A), \mathsf{dummy}\}, \mathsf{succ}', V)$, which is linear in $|A|$. Here succ' is the set $\{(n, n+1) \mid n < \mathrm{modal\_depth}(A)\} \cup \{(\mathrm{modal\_depth}(A), \mathsf{dummy}), (\mathsf{dummy}, \mathsf{dummy})\}$.

For the second case consider the same language but interpreted on finite binary trees. Let $\Diamond$ be interpreted by the first_child relation. By the same reasoning as above any satisfiable A can be satisfied at the root of a tree of depth $\mathrm{modal\_depth}(A)$. But a binary tree of this depth contains $2^{\mathrm{modal\_depth}(A)}$ many leaves! This model contains a lot of useless information. The only important part for the satisfiability of A at the root is its left most branch.

So in both cases we could do with a *pseudo-model* and that is what $\mathcal{M}_A$ is in general. The relation with some real model can be the identity, it can be a $\mathrm{modal\_depth}(A)$ bounded bisimulation or a more intricate or ad hoc relationship. In principle everything is fine as long as the equivalence between (10) and (11) holds.

We will now review the most popular techniques to create structures $\mathcal{M}_A$. We interleave the analysis with examples of formulas enforcing large models.

2.1 Selection of points

Let A be a satisfiable basic modal wff. Then, by Theorem 22 in Chapter 1, A is satisfiable at the root of a tree of depth at most $\mathrm{modal\_depth}(A)$. This looks like a good candidate for a finite model, the only problem is that it can be infinitely branching. Here selection of points comes in. We first need an important concept: the set of A relevant formulas.

All relevant formulas will be subformulas of A; we need a bit extra though. Given a formula B, let $\sim B$ denote the formula C if B is of the form $\neg C$; otherwise, $\sim B$ is the formula $\neg B$; we say that a set Σ of formulas is closed under taking single negations if $\sim B \in \Sigma$ whenever $B \in \Sigma$. This notion enables us to pretend that a finite set is closed under taking negations by treating $\sim B$ as if it were the real negation of B. Now given a set of formulas Σ, let $Cl(\Sigma)$ be the smallest set of formulas that extends Σ and is closed under taking subformulas and single negations. When A is a formula, we denote the set $Cl(\{A\})$ of relevant A formulas by $Cl(A)$; it is easy to see that the cardinality of $Cl(A)$ is linear in the length of A. We call $Cl(A)$ the *closure* of A.

Now let $\mathcal{M}$ be the chopped tree of finite depth which satisfies A at the root. For any world w in $\mathcal{M}$ define the A theory of w (notation: $\theta^A_{\mathcal{M}}(w)$) as the set $\{B \in Cl(A) \mid \mathcal{M}, w \models B\}$. Now if we can create a model $\mathcal{M}_A \subseteq \mathcal{M}$ such that

root the root of $\mathcal{M}$ is still in $\mathcal{M}_A$, and

succ for each w in $\mathcal{M}_A$, $\theta^A_{\mathcal{M}}(w) = \theta^A_{\mathcal{M}_A}(w)$,

then A is still satisfied at the root of $\mathcal{M}_A$. We create $\mathcal{M}_A$ by selecting for each world w just enough successors in order to ensure that $\theta^A_{\mathcal{M}}(w) = \theta^A_{\mathcal{M}_A}(w)$. Starting at the root, choose, for every subformula of A of the form $\Diamond\varphi$, a successor of the root at which φ is true (if such a successor exists at all). Obviously, at most b successors need to be chosen, where b is the number of diamond subformulas of A. Hence, by deleting all successors that were not chosen and their descendants from the model, we obtain a tree model whose branching degree at the root is at

most b. A simple verification shows that A still holds at the root. Now repeat this process at each of the chosen successors of the root and continue until the leaves of the tree are reached. Obviously A is still satisfied at the root. The result is our desired $\mathcal{M}_A$. Clearly conditions **root** and **succ** are satisfied and we have shown

PROPOSITION 9. *Any satisfiable modal formula A can be satisfied at a the root of a finite tree model with the following properties:*

- *the depth is bounded by the modal depth of A, and*
- *the branching degree is bounded by the number of diamond subformulas of A.*

The number of worlds in this model is exponential in the modal depth of the formula A. It seems that in the worst case such a size is unavoidable. We now show a formula which exemplifies this worst case behavior. We define, for each natural number n, a satisfiable formula $A(n)$ with the following two properties

- the size of $A(n)$ is quadratic in n, and
- when $A(n)$ is satisfied in any model $\mathcal{M}$ at state s, then $\mathcal{M}$ contains as a substructure an isomorphic copy of the binary tree of depth n whose root is s.

Thus the size of the smallest model satisfying $A(n)$ is exponential in $|A(n)|$. The idea underlying the definition of $A(n)$ is very simple: take n propositional variables $p_0, \ldots, p_{n-1}$ and write a formula which when satisfied forces a binary branching tree in which every possible valuation on $\{p_0, \ldots, p_{n-1}\}$ occurs at some leaf. Thus the model certainly contains 2^n different states. The formula is constructed using two macros: $\mathit{branch}(p_i)$ and $\mathit{store}(p_i)$ defined as follows:

$$\begin{array}{lcl} \mathit{branch}(p_i) & := & \Diamond p_i \wedge \Diamond \neg p_i \\ \mathit{store}(p_i) & := & (p_i \rightarrow \Box p_i) \wedge (\neg p_i \rightarrow \Box \neg p_i). \end{array}$$

The formula $A(n)$ then is given as

$$(12)\quad \mathit{branch}(p_0) \wedge \bigwedge_{1 \leq i < n} \Box^i \left[\mathit{branch}(p_i) \wedge \bigwedge_{0 \leq j < i} \mathit{store}(p_j) \right],$$

in which $\Box^i$ abbreviates a sequence of i many boxes. The formula works as follows. Suppose $\mathcal{M}, s \models A(n)$. Then the branch part of $A(n)$ states that every node t reachable in i R–steps from s has two different successors, one forcing p_i and another forcing $\neg p_i$. The store part of the formula states that successors of t created by the branch part satisfy precisely the same proposition letters $p_0, \ldots, p_{i-1}$ as does t. We leave it to the reader to verify that the interplay of the branch and store macros forces a binary tree of depth n, as desired.

2.2 Filtration

Let C, A be wffs. Assume that there exists a model $\mathcal{M}$ and a world w_0 such that $\mathcal{M} \models C$ and $\mathcal{M}, w_0 \models A$. Now if C contains for instance the formula $\Diamond\top$, then $\mathcal{M}$ cannot be a finite tree. So the selection of points method does not work in the presence of global constraints. Instead we will choose enough worlds from the model $\mathcal{M}$ to create a new small model.

We will show that there exists a model $\mathcal{M}'$ containing $2^{O(|C|+|A|)}$ many worlds such that $\mathcal{M}' \models C$ and $\mathcal{M}', w \models A$. The model $\mathcal{M}'$ is defined from the theories $\theta^{A,C}_{\mathcal{M}}(w)$, for worlds w in $\mathcal{M}$. Thus the domain of $\mathcal{M}'$ is the set

$$\{\theta^{A,C}_{\mathcal{M}}(w) \mid w \text{ in } \mathcal{M}\}.$$

Note that the worlds in $\mathcal{M}'$ are sets of formulas. We want to create a model such that each world describes which relevant wffs are true in it. I.e., we want a

Truth Lemma For all wffs $B \in Cl(A, C)$, for all worlds $\theta^{A,C}_{\mathcal{M}}(w)$,

$$B \in \theta^{A,C}_{\mathcal{M}}(w) \text{ if and only if } \mathcal{M}', \theta^{A,C}_{\mathcal{M}}(w) \models B.$$

The desire to have this truth lemma puts three constraints on the model $\mathcal{M}'$:

valuation V' is defined such that for all propositional variables p_i,

$$p_i \in \theta^{A,C}_{\mathcal{M}}(w) \text{ if and only if } \theta^{A,C}_{\mathcal{M}}(w) \in V'(p_i).$$

Relation R' is defined such that

- **min** For all worlds x, if $\Diamond B \in x$, then there exists a world y such that $R'(x, y)$ and $B \in y$.
- **max** For all worlds x, y in $\mathcal{M}'$, for all $\Diamond B \in Cl(A, C)$ if $R'(x, y)$ then $B \in y$ only if $\Diamond B \in x$.

The truth lemma can be shown by induction on the length of the wff. It holds for every model $\mathcal{M}'$ satisfying these three constraints. The first constraint determines the definition of V'. For R', we have more freedom. Any relation satisfying both **min** and **max** will do. For instance, R' can be defined as follows: $R'(x, y)$ if and only if for all $\Diamond B \in Cl(A, C)$, $B \in y$ only if $\Diamond B \in x$. Note that when proving the truth lemma we use two properties of the sets $\theta^{A,C}_{\mathcal{M}}(w)$ which together state that these sets of formulas do not contain blatant propositional inconsistencies:

and For $B \wedge D \in Cl(A, C)$, $B \wedge D \in \theta^{A,C}_{\mathcal{M}}(w) \iff B \in \theta^{A,C}_{\mathcal{M}}(w)$ and $D \in \theta^{A,C}_{\mathcal{M}}(w)$.

not For $B \in Cl(A, C)$, $\sim B \in \theta^{A,C}_{\mathcal{M}}(w) \iff B \notin \theta^{A,C}_{\mathcal{M}}(w)$.

The model $\mathcal{M}'$ thus obtained is called the *filtration* of the model $\mathcal{M}$ through the set of formulas $Cl(A, C)$. Note that —by the truth lemma— $\mathcal{M}' \models C$, and —because $\theta^{A,C}_{\mathcal{M}}(w_0)$ is a world in $\mathcal{M}'$— $\mathcal{M}', \theta^{A,C}_{\mathcal{M}}(w_0) \models A$. Thus we have shown

PROPOSITION 10. *If A is satisfiable in a model which globally satisfies C, then A is satisfiable in a model which globally satisfies C and whose set of worlds is bounded by $2^{O(|C|+|A|)}$.*

2.3 Hintikka set elimination

We now give an algorithm which *constructs* the model whose existence was just shown. The idea comes straight from the proof of the truth lemma. That inductive proof shows that if we can find a set G of subsets of $Cl(A, C)$ such that

HS1 every element of G contains C;

HS2 there is an element of G which contains A;

HS3 every element of G satisfies the properties **and** and **not**

HS4 for every element X of G, for every formula $\Diamond B \in Cl(A, C)$, if $\Diamond B \in X$, then there exists a $Y \in G$ such that

1. $B \in Y$, and
2. for all $\Diamond D \in Cl(A, C)$ if $D \in Y$ then $\Diamond D \in X$.

then, we can prove the truth lemma, and A is satisfiable in a model which globally satisfies C. The filtration described above shows the other direction: if A is satisfiable in a model which globally satisfies C, then a set G satisfying HS1–HS4 exists. So we describe a procedure which tries to create that set G.

Let S_0 consists of all sets $\Delta \subseteq Cl(A, C)$ which contain C and which satisfy properties **and** and **not**. Thus conditions HS1 and HS3 hold for S_0. Clearly S_0 can be effectively computed and $|S_0| \leq 2^{O(|A|+|C|)}$. We now inductively construct a sequence of sets of sets of formulas $S_0 \supsetneq S_1 \supsetneq S_2 \supsetneq S_3 \cdots$. During this construction we try to find witnesses for diamond formulas. We say that a set $X \in S_i$ is *ready* if only for the set X, condition HS4 holds with G replaced by S_i. In other words, the set S_i contains witnesses for all diamond formulas in X. If every set in S_i is ready and S_i satisfies HS2, then return 'A is satisfiable in a global C model'. If there is no set in S_i containing A, then return the negation of the last statement. Otherwise, let S_{i+1} consists of all ready sets in S_i and continue the construction. Since $S_i \supsetneq S_{i+1}$, the construction is guaranteed to terminate in at most $2^{O(|A|+|C|)}$ stages.

Why is this algorithm correct? If the algorithm answers 'satisfiable', then it has found a set of subsets of $Cl(A, C)$ satisfying the four HS conditions. But then we can create a model out of them, just as we did in the filtration. For instance, we can define R to be minimal. Now we use the conditions to show that the truth lemma holds. Conversely, suppose that A is locally satisfiable in a C model $\mathcal{M}$. Let G be the set $\{\theta^{A,C}_{\mathcal{M}}(w) \mid w \text{ in } \mathcal{M}\}$. It is easy to show that G satisfies the four HS conditions, and that the algorithm will never delete any element in G in any of its stages. Thus it will return 'satisfiable'.

How many computation steps does this procedure take? It lasts at most $2^{O(|A|+|C|)}$ stages. At every stage we check whether S_i satisfies properties HS2 and HS4. How can we find out how long each check takes? The simplest way is to formalize the whole procedure in terms of first-order logic and use the results about first-order model checking. We can view the power set of $Cl(A, C)$ as the domain of a first order model, which has unary predicates for each formula in $Cl(A, C)$. Then the conditions HS1–HS4 become just first-order conditions on that model. For instance, we have

$$\forall x(P_{\sim B}(x) \leftrightarrow \neg P_B(x)).$$

with P_B the unary predicate corresponding to the modal formula B. We have to write as many of such first-order conditions as there are subformulas of A and C. Also note that they can all be written using just two first-order variables. But we know that given a model and a first-order formula in a fixed number of variables, checking whether that formula is true in that model can be done in time polynomial in the size of the model and the formula. But the size of each model corresponding to a set S_i is bounded by $2^{O(|A|+|C|)}$. So each check can be done in a polynomial number of steps in $2^{O(|A|+|C|)}$, which is just $2^{O(|A|+|C|)}$ many steps. We must make at most $2^{O(|A|+|C|)}$ many such checks, so the whole algorithm takes $2^{O(|A|+|C|)}$ many steps.

Subsets of $Cl(A, C)$ satisfying HS3 are called Hintikka Sets after Jaakko Hintikka who first employed them.

2.4 Hintikka set elimination without constraints

The last algorithm is very impractical: it takes exponentially many steps for every input. This is because in the first step it already creates all possible candidates for worlds in the model. When the set of constraints is empty we can do better using a non-deterministic algorithm. The idea is the following. Let A be the formula for which we want to decide whether it is locally satisfiable. Guess a set $X \subseteq Cl(A)$ and check whether it satisfies HS2 and HS3. Suppose it does. Then it is a candidate for the root of a model for A. Now we must check HS4 for X. Instead of finding the witnesses Y in some set of candidates, we create them on the fly. Now the important point is what the structure of these Y should be. As the Y will be placed in a model one step away from the root, it is wasteful to prove the truth lemma for Y for all formulas in $Cl(A)$. In order to prove the truth lemma at the root X, we only need that it holds at Y for the set of formulas $Cl\{B|\Diamond B \in Cl(A)\}$. And so forth for every next level. (We urge the reader to verify this.) This is the idea behind the next algorithm: the further we are away from the root, the less diamond formulas we have to find witnesses for. In fact, the recursion depth of the algorithm is bounded by exactly the modal depth of the input formula A. What the algorithm is really doing is searching for the tree model that we constructed in the selection of points proof given above.

The algorithm presented in Figure 1 implements this search for a tree model. We claim that for sets of formulas Δ and Σ such that Σ is closed under taking subformulas and single negations, *K–World*(Δ, Σ) will be true iff there exists a tree model $\mathcal{M}$ such that at the root s, for all $B \in \Sigma$, $(\mathcal{M}, s \models B \iff B \in \Delta)$. This function can be used to solve satisfiability for the basic modal system, since A is satisfiable iff there exists a set $\Delta \subseteq Cl(A)$ such that $A \in \Delta$ and *K–World*$(\Delta, Cl(A))$ is true.

Note that with each recursive call of *K-World*, the size of the set Σ decreases, since we include formulas of smaller modal depth only. Thus the recursion depth is bounded by the modal depth of the input formula A. That the function is correct can be shown by induction on the size of Σ; we leave this to the reader. Now what about the complexity of this algorithm? Obviously, if we feed it the binary-branching tree formula given below Proposition 9 it needs as many steps as there are nodes in the tree, 2^n, for n the number of propositional variables in the formula. But besides the number of steps, we also measure the amount of memory space a machine needs for a specific algorithm. In the Hintikka set elimination algorithm the space used was exponential in the input formula, as the set of all candidates had to be stored. At first sight, the K–World algorithm needs just as much space, as it will create a complete tree model, if it can. But K–World can be implemented in such a way that it only needs to store at most one complete branch of the tree model plus a little storage for administration. The idea is that once it has checked that it can create certain desired witnesses, it can remove those witnesses from memory. It just needs to remember not to do that check again, which is easily implemented. As the length of each branch is bounded by the modal depth of A, the whole algorithm needs a polynomial amount in $|A|$ of memory space. This argument is made precise in Chapter 4.

2.5 Forcing exponentially deep paths

Now we will see that global constraints destroy the polynomially bounded depth of paths of the satisfying models for the basic modal system. In particular, we create a globally satisfiable constraint which, when satisfied, forces a branch in the model containing an exponential number of different Hintikka sets. The algorithm sketched in the previous subsection used only polynomial space because the paths in the satisfying model could be kept “short”.

Assume that Δ and Σ are finite sets of formulas such that $\Delta \subseteq \Sigma$ and Σ is closed under taking subformulas and single negations.

K–World(Δ, Σ) if and only if

- Δ satisfies properties **and** and **not** with respect to Σ, that is,

  not For $B \in \Sigma$, either $\sim B \in \Delta$ or $B \in \Delta$.

  and For $B \wedge D \in \Sigma$, $B \wedge D \in \Delta \iff B \in \Delta$ and $D \in \Delta$.

- for each formula $\Diamond B \in \Delta$ there is a set $\Delta_B \subseteq \Sigma$ such that
  - $B \in \Delta_B$,
  - $(\forall \Diamond D \in \Sigma) : D \in \Delta_B \Rightarrow \Diamond D \in \Delta$, and
  - *K–World*$(\Delta_B, \mathit{Cl}(\{D \mid \Diamond D \in \Sigma\}))$.

Figure 1. The function *K-World* decides **K** satisfiability.

A simple way of forcing the existence of exponentially deep R-paths is to employ binary counters. By a binary counter we will understand a device that can have natural numbers as values, represented as binary strings of 0s and 1s; one should also be able to increment this value by one. We will use a set $\{p_0, \ldots, p_{n-1}\}$ of propositional variables to implement an n-ary binary counter (n-ary means that the counter is reset to zero after reaching $2^n - 1$). We use these variables to encode the n bits of the counter, with p_0 encoding the least significant and p_{n-1} the most significant bit. The variable p_i being true in a given state, encodes the fact that the ith bit of the counter is 1 in that state. The key idea to an encoding into the modal language lies in the following characterization of adding 1 to a binary counter. If $a = a_{n-1} \ldots a_0$ and $b = b_{n-1} \ldots b_0$ are two n–bit counters, then $b = a + 1 \pmod{2^n}$ precisely when the following holds: either $b_i = 0$ and $a_i = 1$ for all i (this is when we start counting at 0 again), or, for some $k \leq n - 1$ we have that

(1) $a_k = 0$, and $b_k = 1$,

(2) $a_j = 1$ and $b_j = 0$ for all $j < k$, and

(3) $a_i = b_i$ for all $i > k$.

In a picture:

$$\begin{array}{llll} 10110 & 0 & 1111 & \mathbf{a} \\ 00000 & 0 & 0001 & \\ \hline 10110 & 1 & 0000 & \mathbf{b = a + 1}. \\ & \mathbf{k} & & \end{array}$$

We want to write wffs $A(n)$ and $C(n)$ which force a counter to take on all values from 0 to $2^n - 1$, in consecutive states. In particular, we want that if $\mathcal{M} \models C(n)$ and $\mathcal{M}, s_0 \models A(n)$, then $\mathcal{M}$ contains an R-path of length $2^n - 1$ starting at s_0. Moreover all sets $\theta_{\mathcal{M}}^{\{p_0,\ldots,p_{n-1}\}}(s_i)$, for s_i lying on this path, are different. We take care that the formulas have length only $O(n^2)$. The formula $A(n)$expresses the fact that the counter is initially set to 0:

$$\neg p_0 \wedge \ldots \wedge \neg p_{n-1}.$$

The formula $C(n)$ will be a conjunction of three wffs which should hold globally in a model. The first conjunct expresses that every state has a successor:

$$\Diamond\top.$$

The next two conjuncts take care of addition. They express that whenever an R–transition is made in the model the binary counter is increased by one. First the simple case of resetting the counter:

$$(p_0 \wedge \ldots \wedge p_{n-1}) \rightarrow \Box(\neg p_0 \wedge \ldots \wedge \neg p_{n-1}).$$

Finally, the last conjunct of $C(n)$ covers the case when we have to 'carry one'. This conjunct will itself be a conjunction, having a conjunct of the following form for every k such that $0 \leq k < n$:

$$(\neg p_k \wedge \bigwedge_{j<k} p_j) \rightarrow \Box(p_k \wedge \bigwedge_{j<k} \neg p_j) \wedge \bigwedge_{i>k} \mathit{store}(p_i),$$

with $\mathit{store}(p_i)$ as defined above and the empty conjunction set to true.

We leave it to the reader to check the correctness of this formula. Note that Proposition 9 states that a wff in the basic modal language can only force models with R–paths at most its modal depth. Now the modal depth of $C(n)$ is just two *for every* n, while the minimal R–depth of models satisfying $C(n)$ is $2^n - 1$. The difference is that $C(n)$ is a constraint which should hold globally.

2.6 Tree automata

The simplest way to see if a formula is satisfiable is to try to construct a model for it. This is what the K-World algorithm does. In fact it constructs a tree model if it can. Having constraints, constructing a tree model has to be done with care as it can become infinite (e.g., if the constraint is $\Diamond\top$). In effect one has to detect looping. Looping will occur as the tree is labeled with sets of relevant wffs (the Hintikka Sets) and there are just finitely many of them. We can see the Hintikka Set elimination algorithm as a particular way to implement this. Tree automata (in particular Büchi tree automata) are yet another way of dealing with infinite models. We describe those here and relate them to the other approaches. But before we go into them, we briefly look at a related problem: satisfiability on finite trees. Suppose we ask, given A and C, is A locally satisfiable in a *finite* tree that globally satisfies C? It seems not easy to adjust the Hintikka set elimination algorithm. We can use a tableaux approach (because we can compute a bound on the depth of the trees) but the complexity of it seems horrendous. As it turns out, a tree automaton approach has the right level of abstraction to deal with both infinite and finite trees in a unified manner. Chapter 17 describes the automata-theoretic approach to temporal reasoning.

A finite state automaton is a device to recognize (finite or infinite) strings in a given finite alphabet. Every automaton defines a language (a set of strings). The key result about these automata is a characterization theorem: a language L can be defined by a finite state automaton if and only if it can be defined by a regular expression. Recall the model $(\omega, \mathsf{succ}, V)$ of the logical system from the introduction of this section. Let V be restricted to Σ, a finite set of propositional variables. Then we can view this model as an infinite string in the alphabet $\mathcal{P}(\Sigma)$, indicating which variables are true at which worlds. The idea of model checking by automata is that for every formula A one creates an automaton A_A which accepts exactly those "models as strings" in which A is true at the origin.

But we can do more with A_A. We could try to check if A_A can accept any string at all. In other words, if A is locally satisfiable. This is called the emptiness problem of an automaton and for Büchi automata this problem is practically feasible.

Now finite state automata are fine for linear models, but in general models in modal logic are graphs. A number of interesting modal systems though have the tree model property. Tree automata generalize sequential automata in that they recognize ranked trees. So we can use the same idea as sketched above to decide satisfiability for the basic modal system using tree automata. In fact, tree automata might be used in any situation in which the models have a tree like property. Arguably the most powerful complexity results in modal logic –in particular for systems in which $\models$ has a second-order definition– have been obtained by employing tree automata.

We sketch the idea in a simple situation, satisfiability under constraints for the basic modal system. First come the technical notions. Let $[n]$ denote the set $\{1, \ldots, n\}$. An n-ary Σ-tree T is a labeling of the set $[n]^*$ by letters from an alphabet Σ. That is, $T : [n]^* \longrightarrow \Sigma$. The empty sequence ϵ is called the root of the tree.

A (non-deterministic) *Büchi automaton* on n-ary trees is a tuple $A = (\Sigma, S, \rho, S_o, F)$ where

- Σ is a finite alphabet.
- S is a finite set of states.
- $\rho : S \times \Sigma \longrightarrow \mathcal{P}(S^n)$ is the transition function. For each state $s \in S$ and letter $\sigma \in \Sigma$, it yields the set of possible S labellings of the n successors of state s.
- $S_0 \subseteq S$ is the set of initial states.
- $F \subseteq S$ is the set of final states.

A *run* of an automaton A on a tree T is a labeling of the nodes of T (notation $r : T \longrightarrow S$) by states S such that

- the root is labeled by an initial state (that is $r(\epsilon) \in S_0$), and
- the transitions obey the transition function ρ. That is, for each node x we have $\langle r(x \cdot 1), \ldots, r(x \cdot n)\rangle \in \rho(r(x), T(x))$.

A run $r : T \longrightarrow S$ is *accepting* if every branch of r visits F infinitely often. That is, for every branch $root, x_1, x_2, \ldots$ of T there are infinitely many i's such that $r(x_i) \in F$.

We will now show how Büchi automata relate to our earlier notions and how they are used to decide satisfiability. Let A, C be basic modal wffs. We have seen the following equivalences:

1. A is locally satisfiable in a model which globally satisfies C.
2. There exists a set $G \subseteq \mathcal{P}(Cl(A, C))$ satisfying conditions HS1–HS4.
3. A is satisfiable at the root of an n-ary tree which globally satisfies C. Here n is determined by the number of $\Diamond$ subformulas in A and C.

We can think of the tree in the last item as being labeled by elements of G (telling us immediately which subformulas of A and C are true in which worlds, without having to apply the truth definition). We call this tree model with the extra labels a *Hintikka tree* for A, C, if the root is labeled with a Hintikka set containing A. So we can add a fourth equivalent statement:

(iv) There exists a Hintikka tree for A, C.

Now our strategy must be clear. Given A and C we must build an automaton $A_{A,C}$ which takes n-ary trees labeled by subsets of $Cl(A, C)$ as input and accepts if and only if the input is a Hintikka tree for A, C. Then we have a fifth equivalent statement:

(v) The set of trees accepted by $A_{A,C}$ is not empty.

As checking emptiness can be done in polynomial time (in the size of the automaton), the complexity of the algorithm based on (v) depends on the complexity of the function creating $A_{A,C}$ from A and C. As we will see this takes time bounded by an exponential in $|A|$ and $|C|$. Thus the size of $A_{A,C}$ is similarly bounded and we obtain an exponential time decision algorithm.

We create $A_{A,C}$ as follows. Let G^- be the set of subsets of $Cl(A, C)$ satisfying HS1 and HS3. For simplicity we assume that C implies $\Diamond\top$, so that every model is infinite. This is easily lifted. Let the number of $\Diamond$ subformulas in A and C be n. $A_{A,C}$ is a Büchi automaton $(\Sigma, S, \rho, S_o, F)$ on n-ary trees with

- $\Sigma = S = F = G^-$.
- $S_0 = \{x \in G^- \mid A \in x\}$.
- ρ is defined as follows. $\rho(X, X)$ is the set of all sequences $\langle X_1, \ldots, X_n\rangle$ such that
  1. for all $\Diamond B \in X$, there is an X_i such that $B \in X_i$, and
  2. for all $\Diamond D \in Cl(A, C)$, for all X_i, if $D \in X_i$, then $\Diamond D \in X$.

  On all other inputs, ρ returns the empty set.

With all machinery developed so far it is straightforward to show that

$$A_{A,C} \text{ accepts a tree } T \text{ if and only if } T \text{ is a Hintikka tree for } A, C.$$

Thus the decision algorithm based on checking emptiness of $A_{A,C}$ is correct.

Now we show how we can check for finite tree satisfiability. Clearly we do not assume that C implies $\Diamond\top$ otherwise the problem is already solved. But we do add $\Diamond\top$ to the set $Cl(A, C)$. Then we create $A_{A,C}$ as follows:

- $\Sigma = S = G^-$.
- S_0 is as before.
- $F = \{x \in G^- \mid \Diamond\top \notin x\}$.
- ρ is defined for X containing $\Diamond\top$ as before and for $X \in F$ as $\rho(X, X) = \langle X, \ldots, X\rangle$. That is, the automaton gets into a self-loop once it reaches a state which should not have successors.

Now, this automaton accepts a tree if and only if T is a Hintikka tree for A, C and every node has a descendant which is the root of a subtree all of its nodes are labeled by one and the same set from F. In a real model we just cut off these subtrees leaving only their roots (which after all say that they do *not* have successors).

Vardi [39] has argued that the tree model property of modal logic is the reason for its robust decidability. Robust means here that expansions of the basic modal language with powerful possibly second-order operators does not destroy decidability. One way to show this is to show that the language is a fragment of the monadic second-order logic of trees, and use the decidability of the latter, which is proved using automata.

2.7 Pseudo-models

The models we constructed so far were not really pseudo-models, in fact they could all be considered as ordinary models. Now we look at two examples in which we shall be working with structures which look very much different from the intended models of the logics.

Two dimensional modal logic

The first logic that we consider here is —just as the tiling logic— also based on grid-like structures, but here we only require that the models are two-dimensional in nature, there will be no functions around. The language has two diamonds, $\Diamond_0$ and $\Diamond_1$, with the standard truth definition. The models are of the form $\mathcal{M} = (W, \equiv_0, \equiv_1, V)$, where we require that $(W, \equiv_0, \equiv_1)$ is in fact a *square* over some set U. That is, W consists of the set $U \times U$ of all *pairs* over U, while $s \equiv_i t$ holds if $s_i = t_i$: the i-th coordinate of s and the i-th coordinate of t should be the same. Denote the resulting system as $\mathbf{S5^2}$.

As a modal system, $\mathbf{S5^2}$ might look rather obscure, but as a logic it is well-known. In fact it is the exact modal counterpart of a restricted fragment of first-order logic with two variables in a signature having a binary relation symbol R for every propositional variable r. This is seen as follows. First observe that the $\mathbf{S5^2}$ model $\mathcal{M} = (W, \equiv_0, \equiv_1, V)$ with $W = U \times U$ is uniquely determined by the set U and the valuation V. Note that for any propositional variable r, $V(r) \subseteq U \times U$, i.e., a binary relation. Thus V can also be seen as an interpretation of the set of binary relation symbols R corresponding to each propositional variable, and we can view (U, V) as an ordinary first-order model. Also observe that we may identify assignments s mapping the two variables x_0 and x_1 to U with pairs $(s(x_1), s(x_0)) \in W$. Thus viewing the states of the modal models as assignments, we may read the statement 'φ holds in (U, V) under assignment s' modally as 'in model $(U \times U, \equiv_0, \equiv_1, V)$, φ is true at state s'. Because $\mathbf{S5^2}$ models are squares, the truth definition of the diamonds can be rewritten exactly as the definition of the first-order existential quantifiers:

$$\mathcal{M}, (a, b) \models \Diamond_0 \varphi \iff \text{there exists } a' \text{ such that } \mathcal{M}, (a', b) \models \varphi.$$

Thus $\Diamond_i$ is another way of writing $\exists x_i$. In a related way, one can define modal systems $\mathbf{S5^n}$ corresponding to first-order logic with n variables for any n. This is done in the field of cylindric modal logic, see [42, 29, 15].

Note that in this modal system, the local satisfiability and the satisfiability problem under constraints collapse. This is because A is locally satisfiable in a C model if and only iff $A \wedge \Box_0 \Box_1 C$ is locally satisfiable. Thus we consider the local satisfiability problem only. That problem is decidable, and a proof for this uses some kind of finite model property as well.

Here, instead of defining a finite model for A by *selecting* points out of the old model, we will *identify* points in the big model and define the finite model as a sort of quotient structure which we call –as before– *filtration* of the original model. It will turn out that this filtration will not be a square itself but a square-like structure that we here dub a *pseudo-square*. This is a model with an underlying frame (W, R_0, R_1) in which both R_0 and R_1 are equivalence relations, and their composition should be the universal relation. That is, (W, R_0, R_1) has to validate

(13) R_0 and R_1 are equivalence relations and $\forall xy \exists z (R_0 xz \wedge R_1 zy)$.

For these kind of structures, we can prove the following proposition. (The system also has the bounded finite model property with respect to squares, but this is much harder to establish

[31, 18].) As we saw before, decidability follows immediately, because it is decidable whether a finite structure is a pseudo-square (this is a first-order property).

PROPOSITION 11. *Any* $\mathbf{S5^2}$*-formula* A *is satisfiable in a square iff it is satisfiable in a pseudo-square of size not exceeding* $2^{|A|}$.

Proof. We concentrate on the left to right direction of this proof since we are only interested in explaining the notion of filtration to a pseudomodel at the moment. (For the other direction of the proof, one shows that given a pseudo-square model, one can always find a square that is bisimilar to it — in fact, bisimilar through a *functional* bisimulation, see [29]).

Suppose that A is satisfied somewhere in the square model $\mathcal{M} = (W, \equiv_0, \equiv_1, V)$. From this we will prove that A is true somewhere in a *filtration* $\mathcal{M}^f$ of $\mathcal{M}$. As before, as the domain of $\mathcal{M}^f$ we take the set of theories:

$$W^f = \{\theta_{\mathcal{M}}^{Cl(A)}(w) \mid w \text{ in } \mathcal{M}\}.$$

Again we want to prove a truth lemma, so the valuation is now also fixed. What would be a good definition for the relations R_0 and R_1 on W^f? In general, this is where the filtration method needs some creative input. Now, if the only requirement were that A is to be true somewhere in the resulting model, there is a whole family of definitions that work (in the sense that they ensure that the conditions **min** and **max** are satisfied). But the extra constraint, viz., that the resulting model should be a pseudo-square, puts some extra restrictions. In any case, the following definition works:

$$R_i(\theta_{\mathcal{M}}^{Cl(A)}(s), \theta_{\mathcal{M}}^{Cl(A)}(t)) \text{ if for all } \Diamond_i\varphi \in Cl(A)\text{: } \mathcal{M}, s \models \Diamond_i\varphi \text{ iff } \mathcal{M}, t \models \Diamond_i\varphi.$$

(The reader should check that this is well-defined.)
We can now prove the main claim concerning filtrations, the truth lemma:

(14) for all formulas $\varphi \in Cl(A)$, for all $\theta_{\mathcal{M}}^{Cl(A)}(s)$: $\mathcal{M}^f, \theta_{\mathcal{M}}^{Cl(A)}(s) \models \varphi$ iff $\varphi \in \theta_{\mathcal{M}}^{Cl(A)}(s)$.

This claim is proved by a formula induction as before. For the diamond cases, one should check that **min** and **max** indeed hold for the given definition of the relations. For **min**, use the fact that $\varphi \to \Diamond_i\varphi$ is valid for every φ in this logic (because $\equiv_i$ is a reflexive relation). For **max**, use the fact that $s \equiv_i t$ implies that $\mathcal{M}, s \models \Diamond_i\varphi$ iff $\mathcal{M}, t \models \Diamond_i\varphi$.

This proves (14), so in order to prove the left to right direction of the Proposition we only have to show that $\mathcal{M}^f$ is a pseudo-square. We leave it to the reader to verify that both R_0 and R_1 are equivalence relations. In order to check the other condition, consider sets $\theta_{\mathcal{M}}^{Cl(A)}(s)$ and $\theta_{\mathcal{M}}^{Cl(A)}(t)$. Now the fact that $\mathcal{M}$ is a square and that s and t are pairs comes in handy. Let $z = (s_0, t_1)$. Then $s \equiv_0 z \equiv_1 t$. But then it follows that $R_0(\theta_{\mathcal{M}}^{Cl(A)}(s), \theta_{\mathcal{M}}^{Cl(A)}(z))$ and $R_1(\theta_{\mathcal{M}}^{Cl(A)}(z), \theta_{\mathcal{M}}^{Cl(A)}(t))$, which shows that indeed, the composition of R_0 and R_1 is the universal relation on $\mathcal{M}^f$. ❑

The reader might wonder whether we can construct the pseudosquare by a Hintikka Set elimination procedure as well, just as we did with the basic modal system. The only difference is that we have to end up in a pseudosquare, whereas with the basic modal system any model was allowed. But how to implement the check for the condition $\forall xy \exists z(R_0xz \wedge R_1zy)$? Suppose it fails for some Hintikka sets, x, y. Which one should we remove from the set of candidates? It seems we have to consider both possibilities. But then we get an algorithm which takes far longer than the original Hintikka set elimination procedure. Instead of $2^{|A|}$ many stages we have $2^{2^{|A|}}$ many. In section 3.5 we will show that indeed this is a harder problem than the satisfiability problem under constraints for the basic modal system.

The until operator

We now consider the modal system given by the propositional language expanded with the binary until operator U, the class of all models of the form (W, R, V) and an interpretation of U as in the chapter on temporal logic (recalled below). Note that this is not a modal system in the strict sense of Chapter 5 of this handbook, as U has a dual existential–universal definition: $\mathcal{M}, s \models \mathsf{U}(\varphi, \psi)$ if and only if there exists u such that $R(s, u)$ and $\mathcal{M}, u \models \varphi$ and for all t such that $R(s, t)$ and $R(t, u)$ it holds that $\mathcal{M}, t \models \psi$.

Our previous methods do not work for this language as they were based on reasoning on trees. It is not hard to see that the formula $\mathsf{U}(p, \top) \wedge \neg\mathsf{U}(p, p)$ is satisfiable but not in a tree. Nevertheless, we will show that this system does have a finite pseudo-model property, and we use this property for showing that it has a decidable satisfiability problem.

To start with, let $\mathcal{L}_{\mathsf{U}}$ be the language obtained by expanding the classical propositional language with the binary connective U. It is convenient to use the following notation: for s and u elements of the domain of some model W,

(15) $\mathcal{M}, su \models \psi$ iff for all t satisfying Rst and $Rtu, \mathcal{M}, t \models \psi$,

because we can now rephrase the truth definition of the until operator as follows:

(16) $\mathcal{M}, s \models \mathsf{U}(\varphi, \psi)$ iff for some u such that Rsu $\mathcal{M}, u \models \varphi$ and $\mathcal{M}, su \models \psi$.

Let M denote the class of all models (W, R, V). We call the resulting modal system $(\mathcal{L}_{\mathsf{U}}, \mathsf{M}, \models)$ the *until system*. Note that $\mathcal{L}_{\mathsf{U}}$ is normally interpreted on models in which R is a linear order, but here we disregard this extra complicating factor.

Different from our earlier proofs, we will not use any kind of finite *model* property in order to prove decidability for the until system. This is not because the system does not have the bounded finite model property (it does); our proof method is for didactic purposes. The idea behind the *mosaic method* is that we construct a finite pseudo-model that we will call a linked set of mosaics. One then has to show that a formula is satisfiable if and only if there exists such a linked set of mosaics for it.

What then are mosaics? One could best describe them as little pieces of a model that, if linked together in a nice way, contain sufficient information to *construct* a real model.

Concerning the notion of a mosaic then, the first question is *what information* we are interested in. This question is easy to answer: as in all previous proofs we are only interested in the truth of subformulas of A. The second question then should be: how large should the little pieces of model be? In all previous proofs, the parts we worked with consisted of just one world. The definition of the until operator makes that this is not enough. We need to define a new concept. Call a subset of the domain of a model $\mathcal{M} = (W, R, V)$ *packed* if every two distinct elements s and t of the subset are R-related (that is, we require that Rst or Rts). Our patchwork pieces then will be packed sets of size at most three.

The number three here derives from the fact that the truth definition of $\mathsf{U}(\varphi, \psi)$ employs three variables. In fact, if one would try to devise a standard translation or a bisimulation game for the $\mathcal{L}_{\mathsf{U}}$-language, the number three would show up as the minimal number of variables needed and as the minimal size of the windows that cover the models during the game. During a game one would see that these windows will only be placed on packed sets of the models. Note that in a tree model there are *no* packed sets of size three, only of size two. Also note that in the two dimensional logic the packed sets in a model are exactly the rows and the columns.

Abstracting from the origin of these pieces, we arrive at the following definition. From now on we let A be an arbitrary but fixed $\mathcal{L}_{\mathsf{U}}$ formula. A is the formula whose satisfiability needs

to be decided. As usual, we let $Cl(A)$ denote the closure under single negations of the set of subformulas of A.

DEFINITION 12. An A-type *mosaic* is a quadruple $\mu = (X, R, A_\varphi, B_\varphi)_{\varphi \in Cl(A)}$ such that X is a set of size at most three; R and every B_φ are binary relations on X; and every A_φ is a unary relation on X. When A is clear from the context, we just use "mosaic".

The basic idea underlying this definition is that A_φ holds of a point if we 'want' φ to be true at it, while B_φ holds of a pair of points if we 'want' φ to be true at each point between them. Obviously, not every such structure is part of some model — we need some further constraints for that. Call a mosaic *coherent* if it satisfies the following conditions (phrased in first-order logic and to be read universally):

$(C0)$ $Rxy \vee Ryx \vee x = y$
$(C1)$ $A_{\neg\varphi}x \leftrightarrow \neg A_\varphi x$
$(C2)$ $A_{\varphi\wedge\psi}x \leftrightarrow A_\varphi x \wedge A_\psi x$
$(C3)$ $B_{\varphi\wedge\psi}xy \leftrightarrow B_\varphi xy \wedge B_\psi xy$
$(C4)$ $(Rxy \wedge Ryz \wedge B_\varphi xz) \rightarrow A_\varphi y$
$(C5)$ $(Rxy \wedge A_\varphi y \wedge B_\psi xy) \rightarrow A_{\mathsf{U}(\varphi,\psi)}x$

A few words of explanation: C0 reflects the fact that we only took packed subsets of the model as the domain of our mosaic mini-models. C1–C3 are self-explanatory; note that there is no analog of C1 for the B-predicates since there is a hidden universal quantifier in the meaning of a predicate B_φ, cf. (15). Finally, C4 and C5 are rather obvious consequences of our intuitive meaning of the A- and B-predicates and the truth definition of the until operator.

How difficult is it to check whether an A–type mosaic is coherent, measured as a function of $|A|$? The size of an A–type mosaic is bounded by a polynomial in $|A|$. The length of the first-order formula formalizing coherence is bounded by a polynomial in $|A|$, and is written using just three (again!) variables. So this check can be made using $p(|A|)$ steps for some polynomial p.

The conditions C0–C5 take care of all *universal* constraints on the A- and B-predicates; but of course there are *existential* demands as well which we will call *requirements*. A requirement of a mosaic $\mu = (X, R, A_\varphi, B_\varphi)_{\varphi \in Cl(A)}$ is one of the two following types of object: for $s, t \in X$

(a) $(A_{\mathsf{U}(\varphi,\psi)}, s)$ such that $A_{\mathsf{U}(\varphi,\psi)}s$,
(b) $(notB_\varphi, s, t)$ such that Rst and *not* $B_\varphi st$.

In order to explain requirements of type (a), suppose that we want the formula $\mathsf{U}(\varphi, \psi)$ to be true at a point s; if there is a point t in the mosaic such that Rst, $A_\varphi t$ and $B_\psi st$, then the mosaic itself *directly fulfills* the requirement (by $(C5)$). This will rarely be the case however; the whole point of the mosaic method is that requirements can be fulfilled by *distinct* mosaics as well, as follows. A *link* between two mosaics μ and μ' is simply a partial isomorphism between the two structures. We say that a link $f : \mu \hookrightarrow \mu'$ *fulfills the requirement* $(A_{\mathsf{U}(\varphi,\psi)}, s)$ of μ if there is some t in μ' with $Rf(s)t$, $A_\varphi t$ and $B_\psi f(s)t$. Likewise, a link $f : \mu \hookrightarrow \mu'$ *fulfills the requirement* $(notB_\varphi, s, t)$ if there is some u in μ' with $Rf(s)u$, $Ruf(t)$ and $\neg A_\varphi u$.

A collection L of mosaics is called a *linked set of mosaics* if every requirement of every mosaic $\mu \in L$ is fulfilled via some link $f : \mu \hookrightarrow \mu'$ to some μ' also in L. It is a linked set of mosaics *for* A if it contains a mosaic with non-empty A_A.

Given a collection L of A-type mosaics, how difficult is it to check that it is a linked set of mosaics *for* A? We can view such a collection L as one first-order structure in the same signature as A-type mosaics in which all the mosaics are pairwise disjoint. Then the universe of L is bounded by three times the number of mosaics. Checking coherence of all mosaics can be done using $|L|$ checks each taking $p(|A|)$ computation steps, for a polynomial p. That L is a

linked set of mosaics for A is a simple first-order statement: $\exists x A_A(x)$. But also the existence of partial isomorphisms can be expressed in first-order logic, by a formula in five variables whose length is polynomially bounded by $|A|$. So the check can be made using a polynomial number of steps in $|L|$ and $|A|$.

Now the main result concerning mosaics is the following.

PROPOSITION 13. *An $\mathcal{L}_{\mathsf{U}}$-formula A is satisfiable if and only if there is a linked set of mosaics for A.*

THEOREM 14. *It is decidable in $2^{O(|A|)}$ steps whether an $\mathcal{L}_{\mathsf{U}}$-formula A is satisfiable.*

Proof. We can adjust the Hintikka set elimination algorithm given for the system **K** in order to deal with mosaics. This is done as follows. Let S be the set of all A-type mosaics (up to isomorphism). It is not hard to show that $|S| \leq 2^{O(|A|)}$. Let $S_0 \subseteq S$ be the subset containing all coherent mosaics. Thus S_0 can be computed in polynomial time in $|S| \leq 2^{O(|A|)}$ and $|A|$. We now inductively construct a sequence of sets of mosaics $S_0 \supsetneq S_1 \supsetneq S_2 \supsetneq S_3 \cdots$, just as in the proof for the system $\mathbf{K}^*$. The idea is that we delete mosaics from S_i if they have a requirement which can not be fulfilled inside S_i. We already showed that the checks to be made at each stage of the algorithm take time polynomial in the size of S_i and $|A|$. As $|S| \leq 2^{O(|A|)}$, there are at most $2^{O(|A|)}$ stages, thus the whole algorithm can be performed in $2^{O(|A|)}$ steps. ❑

We end with the rather involved proof of the correctness of the algorithm.

Proof of Proposition 13 The left to right direction of the proof is easy: suppose that $\mathcal{M} = (W, R, V)$ is a model for A. Out of this model we will cut a linked set of mosaics for A, as follows. Let P be the collection of all packed subsets of W of size at most three. Associate with any set $X \in P$ a mosaic μ_X based on the set X, with R as in $\mathcal{M}$ and with every A_φ and B_φ defined as given by the truth of φ in $\mathcal{M}$. We leave it as an exercise for the reader to verify that the collection of all these mosaics forms indeed a linked set of mosaics.

The direction from right to left in the Proposition is the hard one, although the key idea underlying its proof is quite intuitive. We will construct a model for A *step by step*; that is, we will approximate our model via a series of finite structures that we call *networks*. A *network* is a structure $\mathcal{N} = (W, R, A_\varphi, B_\varphi)_{\varphi \in Cl(A)}$ of the same type as a mosaic but not bounded in size. A network is called *coherent* if it satisfies the conditions C1–C5 above. To ask for C0 would be too much; instead we require coherent networks $\mathcal{N}$ to satisfy the following:

(liveness) every packed set X of size at most three *comes from* a mosaic; that is, for each such set $X \subseteq W$ there is a partial isomorphism $f : \mathcal{N} \hookrightarrow \mu$ such that f is defined on X.

Liveness means that — through the mosaics — we are in control of certain small parts of the model: the packed sets of size at most three. Why only these sets? The truth definition of U provides the answer. The meaning of $\mathsf{U}(\varphi, \psi)$ depends only on these small packed sets in the model.

A *defect* of a network is a requirement that is not directly fulfilled in the network itself, and a network is called *saturated* if it has no defects. A network is *perfect* if it is both coherent and saturated.

This name is well-chosen, since perfect networks are the ones that we are after. The reason for this is that with every network $\mathcal{N} = (W, R, A_\varphi, B_\varphi)_{\varphi \in Cl(A)}$ we can associate a modal model in an obvious way: it is defined as the structure $\mathcal{N}^\circ = (W, R, V^\circ)$ with $V^\circ(p) = A_p$ for all variables p occurring in A. But only for perfect networks can we prove the following *truth lemma*.

CLAIM 15. If $\mathcal{N}$ is a perfect network, then for all formulas $\varphi \in Cl(A)$ and all points s, t in $\mathcal{N}$:

1. $s \in A_\varphi$ iff $\mathcal{N}^\circ, s \models \varphi$,
2. if Rst, then $(s,t) \in B_\varphi$ iff $\mathcal{N}^\circ, st \models \varphi$.

PROOF OF CLAIM The proof of this claim is by induction on the complexity of φ. We only consider the case where φ is of the form $\mathsf{U}(\psi, \chi)$, and only prove part (ii) of the Claim (the first part is simpler).

By the induction hypothesis and the truth definition of U, in order to prove (ii) it suffices to show that for all pairs of points s and t such that Rst, we have that $(s,t) \notin B_\varphi$ iff $u \notin A_\varphi$ for some u with Rsu and Rut. The left to right direction immediately follows from the fact that $\mathcal{N}$ is perfect and thus all requirements of type (b) are fulfilled. For the other direction, suppose that s, t and u are points satisfying Rst, Rsu, Rtu and $u \notin A_\varphi$. Observe that $\{s, t, u\}$ is a packed set of size at most three, whence we may use the (liveness) condition. This yields a partial isomorphism f from $\mathcal{N}$ to some mosaic μ such that f is defined for each of s, t and u. It follows that $Rf(s)f(t)$, $Rf(s)f(u)$, $Rf(t)f(u)$ and $f(u) \notin A_\varphi$; but then it follows from condition C4 that $(f(s), f(t)) \notin B_\varphi$. Returning to $\mathcal{N}$ this shows that $(s,t) \notin B_\varphi$, which is what we needed to prove. ❑

From the previous claim it follows that in order to show that A is satisfiable, it suffices to show that there is a perfect network for it, that is, a perfect network such that A_A is not empty.

CLAIM 16. There is a perfect network for A.

PROOF OF CLAIM The proof of this claim consists of three parts. First we show that there is *some* network for A (not necessarily perfect). This is easy, since we are given a linked set of mosaics for A: as our network we simply take any mosaic with non-empty A_A.

The second and main part of the proof consists in showing that any defect of any network can be *repaired*; that is, we can find a bigger network in which the defect no longer occurs. Without going too much into technical detail, let us see how to repair a defect of type (b) (defects of type (a) are repaired in a similar way).

Suppose that s and t are points of the network $\mathcal{N}$ such that Rst and *not* $B_\varphi st$ for some subformula φ of A, while there is no point u between s and t such that $\neg A_\varphi u$. The idea now is simply to *repair* this defect by adding a *new point* to the network. What kind of point? Well, since we have Rst we know that s and t come from a mosaic; that is, there is a partial isomorphism f from $\mathcal{N}$ to some mosaic μ. Obviously, $(notB_\varphi, f(s), f(t))$ is a requirement of this mosaic. But since we are working in a *linked* set of mosaics, there must be some link g between μ and μ' and some u in μ' such that $Rg(f(s))u$, $Rug(f(t))$ and $\neg A_\varphi u$. Now simply add an entirely new point r to the network; make sure that the relations between s, t and r are such that this part of the model is isomorphic to μ'. It is thus obvious that we have *repaired* the defect, and that the new structure is a network. In order to keep the liveness condition it is essential *not* to relate r to any *other* point besides s and t: in this way the only new packed sets are $\{r, s, t\}$ and its subsets.

Finally, these two parts provide the material and the tools for constructing the desired perfect network for A. Starting from the mosaic for A (which is of course a network), we repair defects, one by one, step by step, thus constructing a sequence $\mathcal{N}_0$, $\mathcal{N}_1$, ... of networks. Using some standard combinatorics we can ensure that the *limit* of the chain of networks is a network without defects. In particular, if we always take new points from a fixed set, say ω, we can enumerate the set of all (potential) defects of any network of the chain; if at each step of the construction we

repair the current network's defect with the lowest number in this enumeration, we can create a perfect network. ❑

3 COMPLEXITY

[27] lists the following as the basic questions of computer science: What is an algorithm? What can and what cannot be computed? When should an algorithm be considered practically feasible? In the previous sections we have —sometimes between the lines— used the available answers to these questions. Before we go back to modal logic we catch a brief glimpse of the theories of computability and computational complexity. Readers familar with this can jump immediately to subsection 3.5.

3.1 Computability

What is an algorithm? It is much easier to decide that a certain procedure can be labeled an algorithm than to give a definition. But a definition is needed when we want to prove that *no* algorithm exists to decide a certain problem. Recall that is what we did with the tiling logic in Section 1.3. Such a definition should be very robust. We would not like that later someone comes up with a procedure for deciding satisfiability under constraints for the tiling logic which we have to accept as an algorithm. As it turned out, the first proposal, now called Turing machine, named after its inventor Alan Turing, was immediately right. For a definition of Turing machines see any complexity or finite model theory textbook or Wikipedia. Every other model of computation that has been defined up to now has been shown to be equivalent to the Turing machine model.

The so-called Church Turing thesis, turns these empirical facts into a principle:

Church–Turing Thesis. The Turing machine that terminates on all inputs is the precise formal notion corresponding to the intuitive notion of an algorithm.

More precisely, for Σ a finite alphabet and $S \subset \Sigma^*$ a set of Σ-strings, there exists an algorithm for deciding membership of Σ-strings in S if and only if there exists a Turing machine which terminates on all input strings $s \in \Sigma^*$ and correctly outputs the answer to the question whether $s \in S$.

The reader may substitute his preferred sufficiently powerful programming language for Turing machine in the thesis (as each sufficiently powerful language is equivalent in computation power to the Turing machine model). Note that the thesis speaks about *all inputs*. That is the reason why we had to be so careful in Section 1 when we spoke about the desirable properties of a logic.

Everyone with a limited amount of programming experience has created programs which do not terminate on some inputs. Such programs are not useful for deciding a yes/no problem, simply because for the particular input on which it does not terminate we do not get an answer. This is a good place to discuss the notion of *semi-decision*. A yes/no problem is said to be semi-decidable if a program (a Turing machine) exists which terminates on all yes instances and on all no instances it does not terminate. The set of valid first-order sentences is the prime example of such a set. It is semi-decidable but not decidable. Note that if both the yes and the no instances (that is, both "halves" of the problem) are semi-decidable, we can decide the whole language.

The reason is that on any input we can start *both* programs, one which terminates on the yes, and the other which terminates on the no-instances. Whatever instance we have, one program must terminate, so we have a decision procedure. Thus a problem is decidable iff both halves of it are semi-decidable. See [27] for a detailed argument.

This is all we want to say about computability. The Church-Turing thesis yields an exact measure between the computable and the non computable problems. There is theory about the difficulty of a problem regardless whether it is a computable or a non computable problem. For instance, we just saw that first-order validity is not computable but still semi-decidable. A natural question is whether there exist even harder problems: those that cannot even be semi-decided. Indeed they do exist, and tiling problems have been developed for these cases as well. For instance, add to the tiling problem an extra special tile T^* and ask whether a tiling exists such that T^* occurs infinitely often on the first row. The complement of our original tiling problem is semi-decidable (Why? Because we can formalize it in terms of first-order logic!), but this is not true anymore for this extended version. Cf., [22] for further reading.

As this chapter is about complexity we now take a closer look at the computable problems.

3.2 Computational complexity

In Section 1 we spoke about practically feasible algorithms, and defined them to be those which take at most $p(n)$ computation steps, for p a polynomial function in n with n representing the length of the input. We were rather vague on what constitutes a computation step, but we can now make that precise using the Turing machine model: it is a step taken by a Turing machine. Even inside the practically feasible and inside the not practically feasible algorithms it makes sense to try to distinguish problems of different complexity. As we are mostly concerned with non practically feasible problems we take a closer look there. Let us first give a formal enough definition of the class **P** of problems solvable in polynomial time.

DEFINITION 17. A Turing machine is polynomially time bounded if there is a polynomial $p(n)$ such that the machine always halts after at most $p(n)$ steps, where n is the length of the input. A problem is solvable in polynomial time (a function is computable in polynomial time) if there is a polynomially time bounded Turing machine that solves it (that computes it). The class of all problems solvable in polynomial time is called **P**.

Within the class of non practically feasible algorithms we have those which take exponential time. We define the class **EXPTIME** of problems solvable in exponential time by requiring that there is some polynomial p such that the Turing machine must halt on all inputs after at most $2^{p(n)}$ steps. Similarly we can define the class of **2EXPTIME** problems, solvable in at most $2^{2^{p(n)}}$ steps, and so on. These classes form a hierarchy and it is known that all inclusions are strict. Consider the class **EXPTIME**. Can we find interesting and natural subclasses here? We can look at the amount of working memory a Turing machine needs in its computation. At our level of discussion it is enough to know that in every computation step of a Turing machine, the machine can read and write a symbol of a specified finite alphabet in a cell of a tape. The tape corresponds to the memory of the Turing machine. Clearly machines are conceivable which take a long time before they reach their decision but which use only a limited amount of memory. A good example is the "bad way of doing model checking" described in Chapter 1. We can define space classes similarly to time classes:

DEFINITION 18. A Turing machine is polynomially space bounded if there is a polynomial $p(n)$ such that no computation of the machine scans more than $p(n)$ tape cells. The class of all

problems solvable by a polynomially space bounded Turing machine is called **PSPACE**.

It should be clear that **P** is contained in **PSPACE**. Note that there is no bound on the amount of time for polynomially space bounded computations. Still we have

PSPACE is contained in **EXPTIME**.

To see this, consider the number of ways a tape containing $p(n)$ cells can be written, in an alphabet containing two symbols. That is $2^{p(n)}$. This bounds the number of configurations of a Turing machine. If a **PSPACE** machine takes more than exponential time, then it has repeated some configuration so it must be in an infinite loop. This is not possible because it must terminate on each input.

Non-determinism. The Turing machine model we had in mind was the *deterministic* Turing machine. This is what we typically think of when we think of a computer program: the output state of a computer program is uniquely determined by its input state (that is, by its input). Moreover, for *every intermediate* state there is exactly one state in which the program can be at the next computation step. In essence, a program is a function from input states to output states.

One of the more difficult abstractions made of a Turing machine is a *non-deterministic* Turing machine. Non-deterministic programs are very useful when the problem consists of a (difficult) search for a solution and an (easy) check whether the solution is correct. The prime example of such a problem is boolean satisfiability: given a propositional formula, does there exists a valuation of the proposition letters such that the formula evaluates to true? For a formula with n letters there are 2^n many possible valuations, an enormous search space. To check whether a given valuation evaluates to true is very easy (the number of steps is polynomially bounded by the number of connectives in the formula). We can write a non-deterministic program which scans the formula from left to right, and has the following non-deterministic rule

> if you read p_i for the first time, then either replace all occurrances of p_i by `true` or replace all occurrances of p_i by `false`.

Consider the application of this rule as one computation step. After scanning the complete formula the program can simply check whether the result evaluates to true. Thus if a formula is satisfiable the program can answer fast and correctly. If the formula is not satisfiable, then none of the choices will lead to a state in which the program will answer that it is. So this program decides the satisfiability problem.

We say that a non-deterministic Turing machine decides a problem if

- for every yes instance of the problem, there is *at least one* computation that accepts the input, and
- for every no instance, *every* computation rejects the input.

Note the asymmetry in this definition. Deterministic Turing machines have just one computation on each given input: this is exactly what determinism requires. But the above non-deterministic program has 2^n many different computations on a formula with n variables. Each of them leads to an accepting or rejecting state in $p(n)$ steps, for p a polynomial. This is the time we measure.

DEFINITION 19. **NP** is the class of problems decided by a polynomially time bounded non-deterministic Turing machine. **NEXPTIME** is the class of problems decided by an exponentially time bounded non-deterministic Turing machine.

Still the reader might ask how long a non-deterministic polynomially time bounded computation really takes. Where "really" means implemented on a deterministic Turing machine. This is one of the greatest puzzles in computer science. The answer is simply:

> *At present we can only do it using an exponentially time bounded deterministic Turing machine. We do not know if we can do better, but we consider it unlikely.*

In other words, the question whether **P**≠**NP** is wide open, though it is generally believed that the two classes are different. Thus we have the following inclusions

$$\mathbf{P} \subseteq \mathbf{NP} \subseteq \mathbf{PSPACE} \subseteq \mathbf{EXPTIME} \subseteq \mathbf{NEXPTIME},$$

and all we know at present is that $(\mathbf{N})\mathbf{P} \subsetneq (\mathbf{N})\mathbf{EXPTIME}$.

3.3 The complexity of modal decision problems

In Section 2 we gave several decision algorithms and analyzed their complexity in rather loose terms. In fact these arguments can be made rigorous without too much ado. Thus we can use them to argue that the problems discussed earlier are in certain complexity classes. We briefly list the results:

1. Propositional satisfiability is in **NP**.
2. Local satisfiability of the logical system tile is in **NP**.
3. Local satisfiability of the basic modal system **K** is in **PSPACE**.
4. Satisfiability under constraints of the basic modal system **K** is in **EXPTIME**.
5. Local satisfiability of two dimensional modal logic is in **NEXPTIME**.

These are nice results but they do not tell us very much, except that for none of them we have found a practically feasible algorithm. Surely that does not mean that no such algorithm exists. We would like to have a similar situation as with decidability: either we show a problem is decidable or we show it is undecidable. Thus we would like to be able to show that a problem is *not in* ***P*** , or it is in **PSPACE**, but not in **NP**, etc. Unfortunately, except for some problems in **EXPTIME**, we cannot show that a problem is not in **P**. At present we just do not know how to do that. As a second best to showing that a problem in **NP** is not in **P** we can show that it is a *core problem* in **NP**. A really desirable property of a core problem Q in **NP** would be that

if Q happens to be in **P**, then every problem in **NP** is also in **P**.

In other words, if you are able to find a polynomial time algorithm for Q, you have found one for all problems in **NP**. Even though this property sounds extremely strong, we now have hundreds of core problems in **NP** (cf., [16]). These are called **NP** complete problems and the crucial notion in their definition is that of a polynomial time reduction.

3.4 Reductions

We have used a reduction from an undecidable problem (tiling) to another problem to show that the latter is also undecidable. The reduction used in the proof of Theorem 7 took an instance of the tiling problem and produced two formulas A and C. The crucial point of the reduction was that it was a *computable* function. Computability was all we needed to transfer undecidability.

In the case at hand we want to transfer a similar negative property: most likely not in **P**. But then we should not ask for mere computability, but for computability in polynomial time. Note that the given reduction of the tiling problem is polynomial time computable. It is an example of a *polynomial reduction* of one problem into another. This simple and intuitive notion is very powerful. To recapitulate: if there is a polynomial reduction from problem A to problem B, then B is at least as hard as A. If we can solve B efficiently (that is, if $B \in \mathbf{P}$), then the same holds for A. But if A requires exponential time, then so does B.

DEFINITION 20. A problem Q is said to be **NP** complete if Q is in **NP** and for every problem Q' in **NP** there is a polynomial reduction from Q' to Q.

We invite the reader to show that **NP** complete problems have the desired property of core problems discussed above. We define complete problems for the other complexity classes in exactly the same way, all the time using polynomial reductions.

From the definition it looks very difficult to show that a given problem which is in **NP** is also **NP** complete, because of the universal quantifier. But that is just appearance, as any problem in **NP** can be decided by a non deterministic polynomially time bounded Turing machine. Thus we need to reduce the acceptance problem of such machines. The first problem shown **NP** complete was boolean satisfiability (This is known as Cook's Theorem.) Once you have one **NP** complete problem it is much easier to get more. Because the composition of two polynomial reductions is a polynomial reduction all one needs to do to establish **NP** completeness of a problem Q in **NP** is to reduce a known **NP** complete problem to it. Similarly for the other complexity classes.

Thus when doing a complexity analysis of a problem one should try to establish a matching upper and lower complexity bound: that is, establish that the problem is complete for some complexity class. The upper bound indicates the amount of time and space needed by the best known algorithm. The matching lower bound that —with the present state of knowledge in computer science— one cannot do better. Note that "cannot do better" is a rather relative notion. For one thing, both $10 \cdot n$ and n^{10} are polynomial functions. As none of the problems we look at is solvable by a practically feasible algorithm anyway, it is at this stage of the discussion enough to use the rather broad but robust complexity classes we discussed.

We will now establish those required lower bounds for the problems listed in the beginning of Section 3.3. When we have reduced a known **NP** complete problem to a problem Q we say that Q is **NP** hard, and so on. Such reductions yield good insight in the expressive power and the design of the modal system.

3.5 Tiling

We will establish matching lower bounds by reductions to finite versions of the tiling problem discussed in Section 1.3.

We start with the simplest finite version, square tiling. The problem is as before, we are given a set of tiles T, containing a special tile T_0, and a natural number n. Note that n is part of the input. The problem is whether the $n \times n$ square can be tiled using the tiles T with the constraints

that T_0 is placed at the four borders on the square. Interestingly, the complexity of this problem depends on how the size n is given.

FACT 21.

1. The $n \times n$ tiling problem with n given in unary is NP complete.
2. When n is given in binary it is NEXPTIME complete.

To get in the mood let us show that propositional satisfiability is NP hard, by reducing the tiling problem to it. So consider an instance of the problem consisting of an n and a set of tiles $T = \{T_0, T_1 \ldots, T_k\}$. We want to create a propositional formula A^n_T which is satisfiable iff there exists a T tiling of the $n \times n$ square. Moreover the formula A^n_T must be computable in polynomial time from T and n. A^n_T will be constructed from the set of propositional variables

$$\{p^t_{xy} \mid 0 \leq t \leq k,\ 0 \leq x, y < n\}.$$

The intended meaning of p^t_{xy} is "Tile T_t is placed on position (x, y)". Note that there are $n^2 \cdot (k+1)$ variables p^t_{xy}. A^n_T is a conjunction of clauses. It consists of the following parts:

- At each point in the square, exactly one tile is placed:

$$\begin{array}{ll} \text{(at least one)} & \bigwedge_{0 \leq x,y \leq n-1} (p^0_{xy} \vee \ldots \vee p^k_{xy}) \\ \text{(at most one)} & \bigwedge_{\substack{0 \leq x,y \leq n-1 \\ 0 \leq t \neq t' \leq k}} \neg(p^t_{xy} \wedge p^{t'}_{xy}). \end{array}$$

- The special tile T_0 is placed all along the edges of the square:

$$\text{(border)} \qquad \bigwedge_{0 \leq i \leq n-1} (p^0_{0i} \wedge p^0_{n-1i} \wedge p^0_{i0} \wedge p^0_{in-1}).$$

- Colors must match horizontally and vertically:

$$\begin{array}{ll} \text{(horizontal)} & \bigwedge_{\substack{0 \leq x,y < n-1 \\ 0 \leq t \leq k}} (p^t_{xy} \rightarrow \bigvee_{t' \mid \mathrm{right}(t) = \mathrm{left}(t')} p^{t'}_{x+1y}) \\ \text{(vertical)} & \bigwedge_{\substack{0 \leq x,y < n-1 \\ 0 \leq t \leq k}} (p^t_{xy} \rightarrow \bigvee_{t' \mid \mathrm{up}(t) = \mathrm{down}(t')} p^{t'}_{xy+1}). \end{array}$$

Clearly this formula is computable from the instance. It is also not hard to show that it is a correct reduction: the formula is satisfiable if and only if the instance can tile the given square. But in order to show that we have given a polynomial reduction, we need to argue that the formula is polynomially computable from the given tiling instance. What is the size of the formula? Look at the last conjunct (vertical). It consists of $n^2 \cdot (k+1)$ conjunctions each containing at most $k+2$ variables and $k+1$ connectives. What is the size of a propositional variable? Naively we think of propositional variables as letters $p, q, r \ldots$ so it is tempting to assume that they have size 1. But if we encode variables in some standard way, e.g. as strings of zeroes and ones, then the more we have of them the more bits we need. We always assume that we use a binary encoding, so for our $n^2 \cdot (k+1)$ many variables we need $\log(n)^2 \cdot \log(k+1)$ bits for each variable. Thus the total size of (vertical) is $O(n^2 \cdot \log(n)^2 \cdot k^2 \cdot \log(k))$. We obtain similar bounds for the other conjuncts. Note how lucky we are that n was given in unary. Otherwise, when n had been given in binary, we had already $2^n \cdot 2^n \cdot (k+1)$ many propositional variables, so our reduction would never have been polynomial.

We will use the binary version of square tiling later on. First we look at a variant called corridor tiling.

Corridor tiling. Given a set of tiles T, a special tile T_0 and an integer n in unary. The problem is whether there exists a height m such that the rectangle $n \times m$ can be tiled by T, with all borders tiled by T_0.

FACT 22. Corridor tiling is PSPACE complete.

Corridor tiling is very well-suited to obtain results for linear structures. Consider the logical system succ consisting of the basic modal language, its models are all initial segments of the natural numbers with successor, and $\Diamond$ is interpreted by the successor function.

PROPOSITION 23. *The problem whether A is (locally) satisfiable in a model which globally satisfies C is PSPACE hard for the system* succ.

Proof. Of course we reduce corridor tiling. Let $T = \{T_0, \ldots, T_k\}$ and n determine an instance. We use variables p_x^t for $0 \leq x \leq n-1$ and $0 \leq t \leq k$. We view an initial segment of the natural numbers as the corridor. Then p_x^t gets a familiar meaning: $\mathcal{M}, i \models p_x^t$ means that "Tile T_t is placed at position (x, i).

Having this interpretation it seems straightforward to write down the constraints:

- The side edges are tiled by T_0:

$$p_0^0 \wedge p_{n-1}^0$$

- Every position is tiled by exactly one tile:

$$\bigwedge_{0 \leq x \leq n-1} p_x^0 \vee \ldots \vee p_x^k.$$

$$\bigwedge_{0 \leq x \leq n-1,\ 0 \leq t \neq t' \leq k} \neg(p_x^t \wedge p_x^{t'}).$$

- Colors match horizontally by

$$\bigwedge_{0 \leq x < n-1,\ 0 \leq t, t' \leq k} ((p_x^t \rightarrow \bigvee_{\{t' | \mathrm{right}(T_t) = \mathrm{left}(T_{t'})\}} p_{x+1}^{t'}).$$

- Colors match vertically by

$$\bigwedge_{0 \leq x \leq n-1,\ 0 \leq t, t' \leq k} ((p_x^t \rightarrow \Box \bigvee_{\{t' | \mathrm{up}(T_t) = \mathrm{down}(T_{t'})\}} p_x^{t'}).$$

- Every row either has a successor or it is the last one:

$$\Diamond \top \vee (p_0^0 \wedge \ldots \wedge p_{n-1}^0).$$

These are all the universal constraints. Now we need worlds in which the formula $(p_0^0 \wedge \ldots \wedge p_{n-1}^0)$ is true, one for the bottom row and one for the top. It is natural to use the locally satisfiable formula for the bottom row. Thus let

$$A ::= (p_0^0 \wedge \ldots \wedge p_{n-1}^0) \wedge \Diamond \top.$$

$\Diamond\top$ is there to ensure that the real tiling starts. But how are we to ensure that the corridor ends? It is conceivable that A is satisfiable in an infinite model making all constraints true in which never another world containing $(p_0^0 \wedge \ldots \wedge p_{n-1}^0)$ exists. This encoding seems hopeless but a closer inspection of the problem helps us out.

Suppose an instance is a yes instance. Then there exists some m such that $n \times m$ can be tiled. We have placed no maximum on m but a little combinatorics show that we can. If a yes instance exists, there exists one in which no row is repeated in the corridor. (Because if there is, we can cut the whole intermediate part out and still have a yes instance.) How many rows of length n can we make with $k+1$ tiles? At most $(k+1)^n$. That gives an upper bound on m. If a tiling exists there exists one with at most $1+(k+1)^n$ many rows. Now we can use the counter formula from Section 2.5 to create a binary counter starting at 0 at the world in which A is true and we just add a constraint stating that the world with counter value $(k+1)^n$ is the last but one world in the model. The counter formula has size polynomial in k and n and the complete formula is polynomial in the size of the input. We leave the details of checking correctness to the reader. ❑

Corridor tiling is highly suited for linear structures but it does not seem easy to use it for establishing the PSPACE lower bound for local **K** satisfiability. For one thing we cannot enforce such deep models without constraints. On the other hand, we can enforce models with an exponential number of leaves. Luckily there are also two person game versions of square and corridor tiling, which are PSPACE and EXPTIME complete, respectively. One play of a game is naturally represented by a sequence of game-positions, representing the moves made by the two players. All plays on a specific board can then be represented by a tree, such that each play is a complete branch in the tree. (For instance, think of chess. Each node represents the board at that stage of the game. The root represents the start position. It has exactly as many successors as there are possible opening moves for white. From each successor there is again one successor for each legal move of black, and so on.) When working with games we are often not interested if a player can win *some* play, rather we want to know if she can win *every* play. If so, we say she has a winning strategy.

As modal logic and trees are closely related, it seems a good idea to encode game trees. That is just what we will do. Tiling games are played as follows. There are two players, a male and a female who alternate in placing tiles. She starts at the origin and they work their way up from left to right, and at the end of a row they start again at the left most position of the next row. Players must obey the matching color rules. She wins a play is she can establish a complete tiling. Otherwise he wins. She has a winning strategy is she can win every play. Clearly she can win *some* play iff a tiling exists. But the question whether she can win *every* play seems harder. And indeed

FACT 24.

1. The problem whether she has a winning strategy in the square tiling game (n given in unary) is PSPACE complete.
2. The same problem for corridor tiling is EXPTIME complete.

We use the square tiling game to show PSPACE hardness of local **K** satisfiability. The corridor game can be used to show EXPTIME hardness for the satisfiability problem under constraints. This is a fairly straightforward extension of the square game, using the same type of variables as in corridor tiling and also using a counter formula. Complete proofs are given in [6, 37, 4].

PROPOSITION 25. *The local satisfiability problem for the basic modal system is PSPACE hard.*

Proof. Let $T = \{T_0, \ldots, T_k\}$, n be an instance of the square tiling game. Use the same propositional variables as in square tiling. Use the branch and store macros of Section 2.1 to create an at most $n^2 - 1$ deep tree containing all possible legal plays. (Add the required extra constraints about matching colors and the uniqueness of tiles from square tiling where needed.) It might be convenient to use an extra variable encoding whose turn it is. Let that be she indicating that she is to move. Now there exists a tiling if there is an $n^2 - 1$ deep path in the tree. The female player has a winning strategy if she can win every game. We can formalize this using the notion of a winning position. Let wp be a variable denoting whether a position is winning for the female player. All leaves at depth $n^2 - 1$ are winning, and only those leaves. Now we inductively define winning positions for the intermediate nodes in the tree. If she is to move, then a position is winning iff she can move to a winning position:

$$she \rightarrow (wp \leftrightarrow \Diamond wp).$$

If he is to move, then a position is winning for her iff he can move at all, and all his moves lead to winning positions for her:

$$\neg she \rightarrow (wp \leftrightarrow (\Diamond \top \wedge \Box wp).$$

Of course these formulas must be true everywhere in the game tree. But, because the tree is of depth only $n^2 - 1$, this can be enforced by a formula of polynomial size in n. Now she has a winning strategy iff the root of the game tree is a winning position for her. Further details are left to the reader. ❑

To end this section we give a more involved reduction, based on ideas from Lewis [26]. As it is the most difficult one, we spell it out completely. We show NEXPTIME hardness for a number of modal systems of which the two-dimensional modal logic from Section 2.7 is a special case. All have the same language and the models are of the same shape, with two accessibility relations H and V. Let Grid be the class of models satisfying

(17) $\forall xy(\exists z(xVz \wedge zHy) \leftrightarrow \exists z(xHz \wedge zVy))$

(18) $\forall xyz((xHy \wedge xVz) \rightarrow \exists w(yVw \wedge zHw))$.

These frame conditions make the models have a grid like nature. (17) states that $V - H$ and $H - V$ paths commute, while (18) states a Church–Rosser like condition. They are both Sahlqvist definable by respectively $\Diamond_h \Diamond_v \varphi \leftrightarrow \Diamond_v \Diamond_h \varphi$ and $\Diamond_v \Box_h \varphi \rightarrow \Box_h \Diamond_v \varphi$, respectively. These conditions play an important role in the study of products of modal logic [15]. Note that all two dimensional models are in Grid.

PROPOSITION 26. *Let* Grid$'$ *be any subclass of* Grid *containing all finite two dimensional frames. The local satisfiability problem for the modal system with class of models* Grid$'$ *is NEXPTIME hard.*

Proof. Let Grid$'$ be as in the proposition. We will reduce the square tiling problem with n given in binary to the satisfiability problem of the modal system with class of models Grid$'$. Without loss we may assume that we have to tile the $2^n \times 2^n$ square. Let an instance $(2^n, T)$, with $T = \{T_0, \ldots, T_t\}$ be fixed.

We will define a formula $A_{n,T}$ which describes this instance. In order to obtain the lower bound we show that

(A) $A_{n,T}$ is computable in polynomial time in n and $|T|$.

(B) if T tiles $2^n \times 2^n$, then $A_{n,T}$ is satisfiable in a finite two dimensional model, and

(C) if $A_{n,T}$ is Grid'–satisfiable, then T tiles $2^n \times 2^n$.

Given (A), (B) and (C) we have an effective reduction from the NEXPTIME-complete tiling problem to Grid'-satisfiability, and the result follows.

We first describe how we represent a T-tiling of $2^n \times 2^n$ in an $\mathbf{S5}^2$ model. Let (N, E) be a binary tree of depth $2n$ with nodes N and edges E. The elements of N are $2n$-long strings in the alphabet $\{0, 1, \Box\}$, placed in the tree as in Figure 2. (We use the symbol $\Box$ to make all nodes a string of the same length).

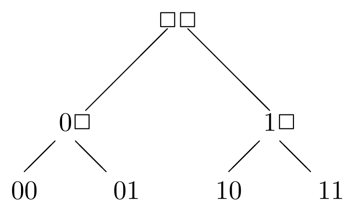

Figure 2. binary tree of depth 2

Let $\mathcal{F} = (N \times N, \equiv_0, \equiv_1)$ be the two dimensional frame with base N. Our formula $A_{n,T}$ will contain the following propositional variables:

d	denotes the nodes in the tree, located on the diagonal
e	denotes the daughter relation in the tree
$p_1, \ldots, p_{2n}$	p_i stands for the i-th bit of the strings encoding the nodes
$t_0, \ldots, t_t$	one variable for each tile,

and variables $p_1^h \ldots p_{2n}^h, t_0^h \ldots t_t^h, p_1^v \ldots p_{2n}^v, t_0^v \ldots t_t^v$, whose meaning will become clear later on.

We now describe a valuation v on $\mathcal{F}$ of these variables. (Because we use V for one of the accessibility relations, we denote the valuation of a model by v in this proof.)

$$\begin{array}{lcl}
\mathsf{v}(d) & = & \{(x, y) \in N^2 \mid x = y\} \\
\mathsf{v}(e) & = & \{(x, y) \in N^2 \mid xEy\} \\
\mathsf{v}(p_i) & = & \{(x, x) \in N^2 \mid x(i) = 1\} \\
\mathsf{v}(p_i^v) & = & \{(x, y) \in N^2 \mid (x, x) \in \mathsf{v}(p_i)\} \\
\mathsf{v}(p_i^h) & = & \{(x, y) \in N^2 \mid (y, y) \in \mathsf{v}(p_i)\}.
\end{array}$$

Let T be a tiling of the $2^n \times 2^n$-grid. A pair $(k, l) \in 2^n \times 2^n$ can be represented by a binary number of length $2n$; the first n places for k and the second n for l. We now make a tile variable t_i true at a leaf x in the tree (N, E) precisely if the tile T_i tiles the pair (k, l) whose representation is x, that is

$$\begin{array}{lcl}
(x, x) \in \mathsf{v}(t_i) & \iff & T_i \text{ tiles } (k, l) \text{ and } (\forall i \leq n) x(i) = k(i) \text{ and} \\
& & \qquad (\forall n < i \leq 2n) x(i) = l(i - n).
\end{array}$$

The t_i^h and t_i^v variables obtain their valuation just as the p_i^h and p_i^v.

We now describe $A_{n,T}$ and show that it is satisfied at the pair (a, a) in $(\mathcal{F}, \mathsf{v})$, where a is the root of the tree (N, E).

We first describe a binary tree of depth $2n$, using the propositional variables $p_1, \ldots p_{2n}$. This will provide us with $(2^n)^2$ leaves each encoding an element in the $2^n \times 2^n$ grid. We use here the "branch and store" formula from Section 2.1 again.

Let $\langle \mathsf{E} \rangle A$ be an abbreviation for $\Diamond_1(e \wedge \Diamond_0(d \wedge A))$, and define $[\mathsf{E}]A = \neg\langle \mathsf{E} \rangle \neg A$. We use $\langle \mathsf{E} \rangle$ as an ordinary **K**-modality. $[\mathsf{E}]^n$ is an abbreviation defined as: $[\mathsf{E}]^0 A = A$ and $[\mathsf{E}]^{n+1} A = [\mathsf{E}][\mathsf{E}]^n A$.

$$d \wedge [\mathsf{E}]^{2n}[\mathsf{E}]\bot \textstyle\bigwedge_{k<2n} [\mathsf{E}]^k \, [\, (\langle \mathsf{E} \rangle p_{k+1} \wedge \langle \mathsf{E} \rangle \neg p_{k+1}) \;\wedge$$

$$\textstyle\bigwedge_{i \le k}((p_i \to [\mathsf{E}]p_i) \wedge (\neg p_i \to [\mathsf{E}]\neg p_i)) \,] \,. \tag{19}$$

Note that the leaves in such a tree make $d \wedge [\mathsf{E}]\bot$ true. Clearly (19) is satisfied at (a, a). The other formulas have a rather redundant formulation if we think about two-dimensional models. Since we want to prove the proposition for a wide class of logics, we have to use this particular formulation. The next two formulas say that on any leaf, precisely one tile variable t holds. Clearly they are satisfied at (a, a).

$$\Box_0^{2n}\Box_1^{2n}[(d \wedge [\mathsf{E}]\bot) \quad \to \quad \bigvee_{1 \le i \le t} t_i] \tag{20}$$

$$\Box_0^{2n}\Box_1^{2n}[\bigwedge_{1 \le i \le t} (t_i \quad \to \quad \bigwedge_{j \ne i} \neg t_j)]. \tag{21}$$

The following formula ensures that the tile T_0 is placed along the edges.

$$\Box_0^{2n}\Box_1^{2n}[d \wedge [\mathsf{E}]\bot \wedge$$

$$((\neg p_1 \wedge \ldots \wedge \neg p_n) \vee (p_1 \wedge \ldots \wedge p_n) \vee (\neg p_{n+1} \wedge \ldots \wedge \neg p_{2n}) \vee \tag{22}$$

$$(p_{n+1} \wedge \ldots \wedge p_{2n})) \to t_0]$$

The next set of formulas capture the behavior of the variables indexed by h and v. First we write formulas which take care of the proper inheritance of information: Let x_i stand for any of $\{p_i, t_i, \neg p_i, \neg t_i\}$

$$\Box_1^{2n}[\Diamond_0^{2n}(x_i) \to x_i^h] \tag{23}$$

$$\Box_0^{2n}[\Diamond_1^{2n}(x_i) \to x_i^v] \tag{24}$$

Then we propagate the new variables in the right direction. Obviously $(\mathcal{F}, \mathsf{v}) \models$ (23)–(26).

$$\Box_1^{2n}[x_i^h \to \Box_0^{2n} x_i^h] \tag{25}$$

$$\Box_0^{2n}[x_i^v \to \Box_1^{2n} x_i^v] \tag{26}$$

Now we can express that colors match:

$$\begin{aligned}\Box_0^{2n}\Box_1^{2n}\, [\, x_h = x_v \wedge y_h = y_v + 1 \wedge t_i^v \wedge \bigvee\{t_j^h \mid 1 \le j \le t\} \to \\ \bigvee\{t_j^h \mid \text{up}(T_i) = \text{down}(T_j)\}\,]\end{aligned} \tag{27}$$

$$\begin{aligned}\Box_0^{2n}\Box_1^{2n}\, [\, y_h = y_v \wedge x_h = x_v + 1 \wedge t_i^v \wedge \bigvee\{t_j^h \mid 1 \le j \le t\} \to \\ \bigvee\{t_j^h \mid \text{right}(T_i) = \text{left}(T_j)\}\,]\,.\end{aligned} \tag{28}$$

Here we use the following abbreviations:

$x_h = x_v$	abbreviates	$\bigwedge_{i \le n}(p_i^h \leftrightarrow p_i^v)$
$x_h = x_v + 1$	abbreviates	$\bigvee_{i \le n}\, [\bigwedge_{l<i}(p_l^h \leftrightarrow p_l^v) \wedge p_i^h \wedge \neg p_i^v \wedge \bigwedge_{i<l \le n}(\neg p_l^h \wedge p_l^v)],$

and similar for the y coordinates where we use the p_i's between p_{n+1} and p_{2n}.

We show that (27) holds everywhere in the model $(\mathcal{F}, \mathsf{v})$. Let $(k,l) \models x_h = x_v \wedge y_h = y_v{+}1 \wedge t_i^v \wedge \bigvee\{t_j^h \mid 1 \leq j \leq t\}$. Then both k and l are leaves in (N,E) by the valuation of the t_i. Then k encodes a pair (x,y) and l a pair $(x,y{+}1)$ in the grid. Because $(k,l) \models t_i^v$, $(k,k) \models t_i$, and T_i tiles (x,y). But since colors match $(x,y{+}1)$ must be tiled by a T_j such that $top(T_i) = down(T_j)$. Then $(l,l) \models t_j$ and indeed $(k,l) \models t_j^h$, as desired.

So we have provided the formula $A_{n,T}$ and shown (B). Clearly the length of this formula is polynomial in $|T|$ and n, and it can effectively be obtained given n and T. This proves (A). Finally we show that the given formula is indeed powerful enough to describe a tiling. So let $A_{n,T}$ be Grid' satisfiable. Then $A_{n,T}$ is satisfied in a model $\mathcal{M} = (W,H,V,\mathsf{v})$ which satisfies (17) and (18). Now suppose that $\mathcal{M}, w \models A_{n,T}$. Then formula (19) forces a binary tree of depth $2n$ starting at w, in which the leaves encode all possible valuations of the p_i-variables. By (17), every leaf in that tree can be reached from w by making $2n$ horizontal, followed by $2n$ vertical steps. So (20) and (21) ensure that at each leaf precisely one tile variable holds. Choose such a tree starting at w and define a tiling of the grid, using the encoding given above. By (20) and (21) this is a well-defined tiling. By (22), the tile T_0 is placed along the edges. Now we check that colors match. Suppose that T_i tiles (x,y) and T_j tiles $(x,y+1)$. Then by (17) we have the following situation in our model:

$wV^{2n}aH^{2n}l$ and $wH^{2n}bV^{2n}k$ for some worlds a and b,

where k is a leaf encoding (x,y) and $\mathcal{M},k \models t_i$ and l a leaf encoding $(x,y{+}1)$ and $\mathcal{M},l \models t_j$. By the inheritance formulas (23) and (24) we have $\mathcal{M},a \models (x,y{+}1)^h \wedge t_j^h$ and $\mathcal{M},b \models (x,y)^v \wedge t_i^v$, where $(x,y{+}1)^h$ abbreviates the conjunction of p_i^h and $\neg p_i^h$ such that p_i and $\neg p_i$ are true at l, etcetera. Now by (18) we have a world c such that $aH^{2n}c$ and $bV^{2n}c$, so $\mathcal{M},c \models (x,y+1)^h \wedge t_j^h \wedge (x,y)^v \wedge t_i^v$ by the propagation formulas (25) and (26). But then by (27) the colors must indeed match. The same argument with (28) shows that colors match horizontally. This proves (C), hence the proposition. ❑

3.6 Language design and complexity

We briefly look at the effect of the design of the modal language on the complexity of the satisfiability problem. We restrict ourselves to the basic modal language. Modal languages all come with an infinite number of propositional variables. What happens if we fix them to some arbitrary finite number n? That is, all formulas are build from propositional variables $p_1, \ldots, p_n$ only. Let us first look at propositional logic. For the full language the satisfiability problem is NP hard. Note that we crucially used the fact that we have an unbounded number of proposition letters in the lower bound proof. If we restrict the number of variables to some fixed n, the problem becomes solvable in linear time: write out the truth table, it contains at most 2^n rows, and make all (at most 2^n) checks. Each check can be done using linear time in the length of the input wff. Of course we must still make a lot of checks but the number is fixed by the design of the language, and not dependent on the input.

Does this also hold for the satisfiability problem of the basic modal system? Halpern [19] showed that it does not. With one propositional variable the satisfiability problem is still PSPACE hard. Here we will explain the idea and give a more efficient encoding as well. What we need is a polynomial time computable translation from arbitrary modal formulas to modal formulas in just one propositional variable, say q, which preserves satisfiability. Then PSPACE hardness of

the full modal language is inherited by the small language. This is Halpern's translation:

$$(p_i)^t \quad = \quad \Diamond(\neg q \wedge \Diamond^i q)$$
$(\cdot)^t$ commutes with all connectives

Again $\Diamond^i$ abbreviates a string of i diamonds, thus the translation is only linear if the i in p_i is given in unary. If i is given in binary, the translation is exponential. We now show that for each wff A, A is satisfiable iff A^t is satisfiable. The right to left direction is easy and left to the reader. For the other direction, let $\mathcal{M} = (W, R, V)$ and let $\mathcal{M}, w_0 \models A$. Create a new model $\mathcal{M}' = (W', R', V')$ such that W' consists of W plus a suitable supply of new worlds, $R'_{\upharpoonright W} = R$, $W \subseteq V'(q)$ and for all $w \in W$ add a path $wRw_1R \ldots Rw_j$ to $\mathcal{M}'$ iff $\mathcal{M}, w \models p_j$. The w_i are all different and not yet in W. Of these new worlds only set $w_j \in V'(q)$. Use new worlds for every $w \in W$ and every propositional variable p_j. An induction on the length of the formula shows that for all $w \in W$, for all subformulas B of A, $\mathcal{M}, w \models B$ iff $\mathcal{M}', w \models B^t$. As $\mathcal{M}, w \models A$ that means that A^t is satisfied in $\mathcal{M}$.

This idea can be used to get a linear translation if the indices of the p's are given in binary. Instead of coding p_i by an i long string of worlds, we encode it by a string of worlds which mimicks the binary encoding of i. For instance, the encoding of p_{101} would be

$$\Diamond(\neg q \wedge \Diamond(q \wedge \Diamond(\neg q \wedge \Diamond q))),$$

in which the leading $\neg q$ is as before to separate "coding" worlds from "real" worlds and the rest of the world sequence is a replica of the string 101. The length of the string of worlds is fixed for all p_i and depends only on the number of variables in the input formula to be translated. Clearly the translation is linear. Details are left to the reader.

Note that we need formulas of unbounded modal depth to encode as many propositional variables as we like. What if we fix the modal depth of our formulas? Then the problem becomes NP complete which is an immediate consequence of the tree model property. Recall that each satisfiable formula A is satisfiable in a tree of depth d the modal depth of A and branching factor b bounded by the number of diamond formulas in A, hence by $|A|$. The number of worlds in such a tree is bounded by b^{d+1}, which —since d is now considered fixed— is simply linear in $|A|$.

If we fix both the number of propositional variables and the modal depth we are rapidly leaving the realm of logic, as then there are only a finite number of wffs up to logical equivalence. A straightforward argument shows that the satisfiability problem then can be decided in linear time. See [19] for further details.

4 HISTORICAL NOTES

We give pointers to further literature and try to sketch a little of the historical development by mentioning some of the milestones. This is not intended to be exhaustive. The chapters 4, 13 and 17 on computational modal logic, description logic and automata for temporal logic, respectively contain useful pointers as well. A detailed set of historical notes together with references to the relavant literature can be found in the notes ending Chapter 6 of [4].

For background, one can consult textbooks on computational complexity [27, 32] and finite model theory [10, 28]. The chapter on computability and complexity in [4] contains detailed arguments of most proofs which are just sketched here and an extended annotated bibliography.

One might say that Cook's Theorem bootstrapped the field of complexity of modal logics [9]. Ladner [25] established the first completeness results for the best known modal logics, focusing on local satisfiability: NP–completeness for S5 and PSPACE–completeness for K,T and S4. The K-World algorithm is from that paper, but using the abstract tableaux developed by Hemaspaandra [36]. The branch and store formula from section 2.1 originates also from [25]. The field took off with Fisher–Ladner [14] and Pratt [33], showing the EXPTIME lower and upper bound for Propositional Dynamic Logic PDL, respectively. This was a large generalization from earlier work: PDL is a multi modal language and the definition of $\models$ is second-order. Moreover within PDL the satisfiability problem under constraints can be reduced to the local satisfiability problem. Pratt introduced the technique of elimination of Hintikka Sets.

In the eighties the field exploded: results for ever more complex modal systems were obtained. Halpern and Moses [20] (the original is from 1985) researched epistemic logic with multiple modalities and transitive closure operators in the tradition of Ladner and Pratt. PSPACE completeness of linear temporal logic with until was settled by Sistla and Clarke [35]. Vardi and Wolper [41] showed how Büchi tree automata can be used for powerful modal logics. A little later, the complexity of the satisfiability problem of one of the most expressive modal logics — the modal μ-calculus— was settled (still EXPTIME–complete) by Emerson and Jutla [11]. More recently, Vardi and co-authors have shown that this result is robust under a number of expansions of the language [40, 34, 24].

There are a number of motivations for studying the complexity of modal satisfiability problems. Description logic is concerned with building knowledge bases and the main computational question is whether a knowledge base is consistent. This field contains a wealth of complexity results, for an enormous variety of modal systems, cf., the handbook [3]. Temporal logic model checking is used in automated program verification, see [7, 8]. Epistemic logic and combinations of epistemic and temporal logics play a role in the analysis of distributed computer programs. Cf., [13] and numerous articles by the authors of that book.

Several attempts have been made to explain why so many modal logics are decidable and why so often their satisfiability problem under constraints is complete for EXPTIME. Vardi [39] emphasizes the tree model property, Andréka, van Benthem, Németi [2] the fact that $\models$ is defined in a guarded fragment of first (or second) order logic, which are really two sides of the same coin, as shown by Grädel [17]. This explanation focuses on the definition of $\models$ and works if the class of structures of a modal system is large enough to allow tree models. Hemaspaandra [36] looks at the frame conditions and their influence, and also at the effect of joining several modal systems. Marx, Venema [30] indicate the importance of "locality" principles (like being in a fixed variable fragment) and the "looseness" principle given by the tree model property. The use of tiling to establish lower bounds has a number of —usually very enthusiastic— advocates, cf., for instance [37, 27, 5, 21].

ACKNOWLEDGEMENT

Some of the material in this chapter has been taken from [30]. The author thanks Martin Otto for very helpful comments.

1 INTRODUCTION

As we have seen in preceding chapters, the worst case complexity of basic reasoning tasks, such as deciding the satisfiability of a modal formula, is at least NP-complete for almost all modal logics. Moreover, for logics extended with features that are useful in practice, the worst case complexity can be much higher, e.g., ExpTime-complete for $\mathbf{K}_n$ extended with non-logical

axioms (background theories), and NExpTime-complete for $\mathbf{K}_n$ extended with converse modalities, graded modalities and nominals.

Some may regard these results as discouraging and the question arises whether automated computation with such logics can be feasible in practice. Fortunately, the kinds of pathological formulae/theories that give rise to these worst case results seem to be rarely encountered in realistic applications, and this has allowed for the successful development and deployment of automated reasoning systems for modal logics and their notational variant, description logics; see Chapter 13 of this handbook. Applications of such systems include, e.g., multi-agent systems [53, 60, 196], configuration [137], conceptual modelling [73], information integration [32], and ontology tools and applications [125, 131, 167, 189, 138, 197].

Even for application derived formulae/theories, however, naive implementations of theoretical proof systems, such as the tableau calculi presented in Chapter 2 of this handbook, are unlikely to be of practical utility. As pointed out in [40], without the use of an analytic cut rule, the minimal length of proofs using these calculi can exceed that of proofs using the truth table method for certain propositional (and modal) formulae. Further, not only is it important that short proofs exist, but also how we go about finding a proof or a counter-model. Much of the work presented in this chapter deals with techniques that reduce the size of the search space or help to traverse the search space more efficiently. Successful modern reasoning systems crucially employ specialised reasoning techniques along with optimisations to dramatically improve typical case performance; cf. for example [85, 90, 97, 115, 116, 158, 159]. In this chapter, we focus on reasoning and optimisation techniques used in tableau-based algorithms and translation-based methods.

Translation-based methods make use of the fact that a wide variety of modal logics can be translated into first-order logic; in fact, they can be considered as characterising certain fragments of first-order logic as explained in Section 2 of Chapter 1 of this handbook. To the translated modal formulae, we can apply first-order reasoning methods, in particular, refinements of resolution [16]. Using this combination of a translation method and resolution has some obvious advantages. Any modal logic which can be embedded into first-order logic can be treated. The translations are straightforward, and can be performed in time $O(n \log n)$, so the engineering effort is minimal. For the resolution part, standard resolution provers can be used, or otherwise they can be used with small adaptations. Modern resolution provers [169, 183, 194] are among the most sophisticated and fastest first-order logic theorem provers currently available. The translation method is generic, it can handle first-order modal logics, undecidable modal logics, and combinations of modal and non-modal logics. In all cases, soundness and completeness of the method is immediate from results showing that the translation is satisfiability equivalence preserving and the soundness and completeness of the resolution calculus for first-order logic. The semi-decidability of first-order logic and the behaviour of first-order resolution on first-order formulae does not give us, however, any immediate insight into the modal fragment of first-order logic, which certainly is decidable, or the behaviour of first-order resolution on translated modal formulae. While termination of a resolution derivation from a translated modal formula is not always guaranteed, there are various ways, using different translations and different refinements of resolution, of obtaining translation-based decision procedures. In Section 3, we discuss some of these approaches and illustrate them using the modal logics $\mathbf{K}_n$, $\mathbf{K4}_n$, $\mathbf{KB}_n$, $\mathbf{K}_n^{\smile}$ ($\mathbf{K}_n$ with converse modalities), and $\mathbf{KB4}_n$. Also, using the modal logic $\mathbf{K}_n$, we want to provide some fundamental understanding of how modern resolution provers work in general, what kind of optimisations are available, and how they can be used to provide effective and practical decision procedures for modal logics.

Tableau-based algorithms are closely related to the prefixed tableau systems presented in Section 6 of Chapter 2 of this handbook. In Section 4, we first explain the exact relationship between the two before describing a tableau algorithm which decides the satisfiability of formulae in the basic multi-modal logic $\mathbf{K}_n$. We then discuss implementation and optimisation techniques which can be used to turn this tableau algorithm into an effective and practical decision procedure for $\mathbf{K}_n$. Following the same structure, we also describe tableau-based algorithms for the modal logics $\mathbf{K4}_n$, $\mathbf{K}_n$ with non-logical axioms, $\mathbf{K}_n^{\smile}$, and their combinations and discuss implementation issues of those algorithms. Whereas the $\mathbf{K}_n$ tableau algorithm terminates "automatically", we use certain cycle detection mechanisms to ensure termination for other modal logics. It can be easily seen that these mechanisms must be chosen carefully to preserve correctness of the algorithm and, at the same time, to enable termination as soon as possible so as to avoid an unnecessarily long search. Interestingly, it has been shown by state of the art description logic reasoners [159, 90, 160] that such tableau algorithms are amenable to optimisation, and that they behave better than their worst-case complexity or that of the corresponding reasoning problem suggest: they implement non-deterministic double exponential decision procedures for logics that are ExpTime-complete.

In Section 5, we give an overview of alternative computational approaches to the satisfiability problem in modal logics. These include automata-based algorithms, direct resolution, the inverse method, and sequent-based approaches. In Section 6, we survey reasoning problems other than satisfiability and provability which are relevant for applications of modal logics, namely, model checking, proof checking, and computing correspondence properties for modal axiom schemata. Finally, we conclude the chapter with a brief review and discussion of current and future research.

2 SYNTAX, SEMANTICS, AND REASONING PROBLEMS OF MODAL LOGICS

Throughout this chapter, we use a notation that is compatible with the one presented in Chapter 1 of this handbook. We will use the symbols $p, q, p_i, q_i, \ldots$ for propositional variables. Here, we will be concerned with extensions and variants of the multi-modal logic $\mathbf{K}_n$. The set of $\mathbf{K}_n$ *formulae* is the smallest set that contains all propositional variables, is closed under Boolean operators, and contains $[i]\psi$ and $\langle i\rangle\psi$ for each $1 \leq i \leq n$ and each $\mathbf{K}_n$ formula ψ. Formulae of the form $[i]\psi$ and $\langle i\rangle\psi$ are called *box formulae* and *diamond formulae*, respectively. In different sections, we will consider different normal forms of $\mathbf{K}_n$ formulae, and thus we are generous here and allow all kinds of Boolean operators and abbreviations, e.g. $\wedge$, $\vee$, $\neg$, $\rightarrow$, $\top$ (for any tautology), $\perp$ (for $\neg\top$), etc.

As usual, the semantics of $\mathbf{K}_n$ is defined in terms of relational, Kripke structures or frames. A *frame* is a tuple $\langle W, R\rangle$ of a non-empty set W (of worlds) and a mapping R from natural numbers i, $1 \leq i \leq n$ to binary relations over W, thus $R(i) \subseteq W \times W$. Here and in the rest of the chapter, we use R_i as an abbreviation of $R(i)$, and we say that w is *i-accessible from v* if $R_i(v, w)$. A *model* is given by a triple $\mathfrak{M} = \langle W, R, V\rangle$, where $\langle W, R\rangle$ is a frame and V is a mapping from propositional variables to subsets of W. The notion of a formula ψ *being true* in a model $\mathfrak{M}$ at a world $w \in W$ is inductively defined as follows (we omit the definition for most Boolean operators).

$$
\begin{array}{llll}
\mathfrak{M}, w & \models & p & \text{iff } w \in V(p) \\
\mathfrak{M}, w & \models & \neg\psi & \text{iff not } \mathfrak{M}, w \models \psi \\
\mathfrak{M}, w & \models & \psi \wedge \phi & \text{iff } \mathfrak{M}, w \models \psi \text{ and } \mathfrak{M}, w \models \phi \\
\mathfrak{M}, w & \models & \psi \vee \phi & \text{iff } \mathfrak{M}, w \models \psi \text{ or } \mathfrak{M}, w \models \phi \\
\mathfrak{M}, w & \models & [i]\psi & \text{iff } \mathfrak{M}, v \models \psi, \text{ for all } v \text{ with } R_i(w, v) \\
\mathfrak{M}, w & \models & \langle i \rangle\psi & \text{iff } \mathfrak{M}, v \models \psi, \text{ for some } v \text{ with } R_i(w, v)
\end{array}
$$

A modal formula ϕ is *satisfiable* in $\mathbf{K}_n$ if there exists some $\mathfrak{M} = \langle W, R, V \rangle$ such that, for some $w \in W$, $\mathfrak{M}, w \models \phi$. In this case, we say that ϕ is *satisfied in* $\mathfrak{M}$. ϕ is *valid* in $\mathbf{K}_n$ if, for every $\mathfrak{M} = \langle W, V \rangle$ and every $w \in W$, $\mathfrak{M}, w \models \phi$; ϕ and ψ are *equivalent* if $\phi \leftrightarrow \psi$ is valid.

As usual, satisfiability and validity are inter-reducible, i.e., ϕ is satisfiable iff $\neg\phi$ is *not* valid, and ϕ is valid iff $\neg\phi$ is *un*satisfiable. Thus, in what follows, we will mostly concentrate on a single inference problem, namely satisfiability testing. It is well-known that the satisfiability problem (and thus validity) in $\mathbf{K}_n$ is PSpace-complete [93, 129] (see also Chapter 3 of this handbook), and there are various decision procedures for this problem [49, 93, 129] and implementations thereof [87, 90, 120, 159]. Many of these procedures exploit the fact that any satisfiable $\mathbf{K}_n$ formula is satisfied in a finite tree model (i.e., one where the relational structure of the frame forms a finite tree) of depth linear in the size of the input formula. In this chapter, we will discuss in depth a resolution-based algorithm (in Section 3) and a tableau-based algorithm (in Section 4) for the satisfiability of $\mathbf{K}_n$, and then explain how these two basic algorithms can be modified to also decide more expressive modal logics.

We will often restrict our attention to formulae in *negation normal form (NNF)*. In formulae in NNF, $\wedge$, $\vee$, and $\neg$ are the only Boolean connectives used, and negation occurs only in front of propositional variables. Each formula of $\mathbf{K}_n$ and all extensions of $\mathbf{K}_n$ discussed in this chapter can be easily transformed into an equivalent formula in NNF in linear time, by pushing negation inwards, using a combination of de Morgan's laws and the duality between box and diamond formulae.

In this chapter we refer to a number of extensions of $\mathbf{K}_n$ which we define in the following.

$\mathbf{K4}_n$, $\mathbf{KB}_n$, and $\mathbf{KB4}_n$. We will discuss decision procedures for $\mathbf{K4}_n$, the multi-modal logic of *transitive frames*, $\mathbf{KB}_n$, the multi-modal logic of *symmetric frames*, and $\mathbf{KB4}_n$, the multi-modal logic of *symmetric and transitive frames*. All these logics share the same language with $\mathbf{K}_n$, but their semantics is based on different classes of frames. As $\mathbf{K4}_n$ models, we only consider those models that are based on frames (W, R) in which each R_i is *transitive*, i.e., where for any $u, v, w \in W$, $R_i(u, v)$ and $R_i(v, w)$ imply $R_i(u, w)$. For example, $\langle i \rangle\langle i \rangle p \wedge [i]\neg p$ is $\mathbf{K}_n$ satisfiable, whereas the same formula is $\mathbf{K4}_n$ unsatisfiable. As $\mathbf{KB}_n$ models, we only consider models that are based on frames (W, R) in which each R_i is *symmetric*, i.e., where for any $u, v \in W$, $R_i(u, v)$ implies $R_i(v, u)$. An example of a formula which is $\mathbf{K}_n$ and $\mathbf{K4}_n$ satisfiable, but $\mathbf{KB}_n$ unsatisfiable, is $\neg p \wedge \langle i \rangle [i] p$. Finally, $\mathbf{KB4}_n$ models are based on frames (W, R) where each R_i is symmetric and transitive. The formula $\langle i \rangle \neg p \wedge \langle i \rangle [i] p$, for example, is $\mathbf{KB4}_n$ unsatisfiable, but satisfiable in $\mathbf{K}_n$, $\mathbf{K4}_n$, and $\mathbf{KB}_n$.

The modal logic $\mathbf{K4}_n$ is axiomatised by the axioms of the modal logic $\mathbf{K}_n$ (see, for example, Chapter 2 of this handbook), plus the axiom schema $\mathbf{4}$ below. Similarly, $\mathbf{KB}_n$ is axiomatised by adding the axiom schema $\mathbf{B}$ to the axiomatisation of $\mathbf{K}_n$. Finally, for $\mathbf{KB4}_n$, we add both axiom schemas $\mathbf{B}$ and $\mathbf{4}$.

Axiom $\mathbf{4}$ $\qquad [i]\phi \to [i][i]\phi$

Axiom $\mathbf{B}$ $\qquad \phi \to [i]\langle i \rangle \phi$

The modal logic $\mathbf{K4}_n$ is of interest since both tableau-based algorithms and translation-based methods require additional techniques to ensure termination. The modal logic $\mathbf{KB}_n$ only requires a rather straightforward modification of the reasoning procedures we present for $\mathbf{K}_n$, but raises some implementation issues for tableau systems. It is also worthwhile to remember that, in classical tableau systems, the treatment of $\mathbf{KB}_n$ requires some form of *cut rule*. Finally, the procedures we present for $\mathbf{KB4}_n$ combine the techniques we introduce for $\mathbf{K4}_n$ and $\mathbf{KB}_n$.

Non-logical axioms. We consider *background theories*, i.e., finite sets $\Gamma = \{\gamma_1, \ldots, \gamma_n\}$ of *non-logical axioms* γ_i. A model $\mathfrak{M}$ *satisfies* a background theory Γ if, for each $w \in W$ and each $\gamma \in \Gamma$, $\mathfrak{M}, w \models \gamma$. As a reasoning problem, we are interested in the satisfiability of a formula ϕ w.r.t. a background theory Γ, i.e., whether there exists a model $\mathfrak{M}$ that satisfies both ϕ and a background theory Γ. Note that, in such a model, ϕ has to be true in at least one world, whereas all formulae in Γ have to be true in all worlds.

Next, we explain why we discuss algorithms that reason w.r.t. background theories. Firstly, considering background theories makes reasoning more difficult, i.e., satisfiability w.r.t. background theories is ExpTime-complete [173], and thus they present a considerable challenge for automated reasoning tools. As with $\mathbf{K4}_n$, tableau algorithms for reasoning w.r.t. background theories no longer terminate on all inputs. However, in contrast to $\mathbf{K4}_n$, background theories allow us to enforce models with paths of exponential length using the standard encoding of incrementation modulo 2^n on n propositional variables representing a binary counter (see, for example, page 14 of [133] for such a formula). The latter can be viewed as a symptom of the increased complexity since we might have to consider and search models with paths of exponential length. Secondly, background theories can be viewed as a weak form of the *universal modality*, i.e., ϕ is satisfiable w.r.t. Γ iff

$$\phi \wedge \bigwedge_{\gamma \in \Gamma} [0]\gamma,$$

is satisfied in a model based on a frame $\langle W, R\rangle$ with $R_0 = W \times W$. In such a model, $[0]$ is called the *universal modality* because it can be used to access all worlds. In [4], it was shown how to reduce satisfiability in $\mathbf{K}_n$ with the universal modality (i.e., where the universal modality might also occur at a deeper modal level) to satisfiability w.r.t. background theories. Thirdly, background theories can be used to "internalise" axioms or "circumscribe" frame conditions. To do this, we first restrict our attention to formulae in negation formal form. As an example, let us consider $\mathbf{K4}_n$ as discussed above and a $\mathbf{K4}_n$ formula ϕ in NNF. It can be shown that ϕ is satisfiable iff ϕ is $\mathbf{K}_n$ satisfiable w.r.t. the background theory

$$\{[i]\psi \rightarrow [i][i]\psi \mid [i]\psi \text{ is a subformula of } \phi \text{ and } 1 \leq i \leq n\}.$$

Finally, background theories are notational variants of description logic *TBoxes* or *terminologies*, which are used in applications to hold the intensional domain knowledge [44, 173]; see also Chapter 13 of this handbook. A TBox is (the description logic variant of) a background theory of the form $\{\phi_i \rightarrow \psi_i \mid 1 \leq i \leq m\}$. Restricting non-logical axioms to implications is (i) not a real restriction: we can transform each background theory Γ into a single implication of the form $\top \rightarrow \bigwedge_{\psi \in \Gamma} \psi$; (ii) quite natural in various application, and (iii) enables the use of efficient optimisation techniques in tableau systems [109], which we will discuss in Section 4.4.

Converse modalities. We discuss modifications of our algorithms to decide satisfiability of $\mathbf{K}_n^{\smile}$ formulae w.r.t. background theories, where $\mathbf{K}_n^{\smile}$ is the extension of $\mathbf{K}_n$ that allows the use of *converse* modal parameters $i^{\smile}$ in modalities. That is, $[i^{\smile}]\phi$ and $\langle i^{\smile}\rangle\phi$ are also well-formed formulae. The mapping R is extended to converse modal parameters as follows: $R_{i^{\smile}} = \{(w, v) \mid$

$R_i(v, w)\}$. Converse modalities are of interest because they occur naturally in applications, e.g., in description logics [105, 171] and temporal logics [163, 187], and because they require reasoning techniques that are able to reason in both directions over relations. For example, to detect the unsatisfiability of the formula $q \wedge \langle i \rangle (p \wedge [i^{\smile}]\neg q)$, one has to reason both ways over R_i. This is similar to the kind of reasoning required for $\mathbf{KB}_n$ but slightly more tricky since, in $\mathbf{K}_n^{\smile}$, reasoning in "both ways" over a relation depends also on the worlds related by R_i. For example, the $\mathbf{KB}_n$ formula $[i]\psi$ is equivalent to the $\mathbf{K}_n^{\smile}$ formula $[i]\psi \wedge [i^{\smile}]\psi$.

Graded/deterministic modalities. We discuss modifications of the tableau algorithm to handle deterministic and graded modalities. The former have (atomic) modal parameters i whose interpretation R_i has to be a functional relation. To understand graded modalities, note that a diamond formula $\langle i \rangle \phi$ can be read as "in at least one i-related world, ϕ is true", and a box formula $[i]\phi$ can be read as "in at most zero i-related worlds, ϕ is not true". *Graded* modalities generalise these formulae: $\mathbf{K}_n^c$ (resp. $\mathbf{K}_n^{\smile,c}$) is the extension of $\mathbf{K}_n$ (resp. $\mathbf{K}_n^{\smile}$) where we also allow for formulae of the form $\langle i \rangle_m \phi$ and $[i]_m \phi$. We read $\langle i \rangle_m \phi$ as "in at least $(m+1)$ i-related worlds, ϕ is true" and $[i]_m \phi$ as "in at most m i-related worlds, ϕ is true". The semantics is extended in the obvious way.

$\mathfrak{M}, w \models \langle i \rangle_m \phi$ iff there are at least $m+1$ worlds $v \in W$ with $R_i(w, v)$ and $\mathfrak{M}, v \models \psi$

$\mathfrak{M}, w \models [i]_m \phi$ iff there are at most m worlds $v \in W$ with $R_i(w, v)$ and $\mathfrak{M}, v \models \psi$

Please note that $\neg[i]_m \phi$ is equivalent to $\langle i \rangle_m \neg\phi$ and that, by adding $\top \rightarrow [i]_1 \top$ to our background theory, we restrict models to those in which R_i is a functional relation. Thus algorithms that can handle both graded modalities and background theories can also handle deterministic modalities. From a complexity point of view, adding graded/deterministic modalities rarely effects the worst case complexity, e.g., $\mathbf{K}_n^c$ and $\mathbf{K}_n^{\smile,c}$ are both PSpace-complete without background theories [93, 186] and ExpTime-complete w.r.t. background theories [173, 184, 186]. From a practical reasoning perspective, graded modalities add quite some difficulty: consider, e.g., the formulae $[i]_3 \top \wedge \langle i \rangle_1 (p \vee q) \wedge \langle i \rangle_1 (\neg p \vee q)$ and $[i]_1 p \wedge [i]_1 \neg p \wedge \langle i \rangle_2 q$. The former is satisfiable, but we have to find that the two diamond formulae can be satisfied via a "common" i-related world. The latter is unsatisfiable, but we have to find that a third i-related world in which neither p nor $\neg p$ holds cannot exist.

Nominals. In their simplest form, nominals [5, 163] are propositional variables that are true in exactly one world; we use $o_1, o_2, \ldots$ for these variables and indicate the availability of nominals in a logic by the superscript $\cdot^o$ as, e.g., in $\mathbf{K}_n^o$. Nominals are of interest for automated reasoning since they destroy the *tree model property (TMP)* (see Chapter 1 of this handbook) of a logic. For example, the formula $o_2 \wedge \langle i \rangle (o_1 \wedge \langle i \rangle o_2)$ has only models with a cycle of length two. We mentioned above that $\mathbf{K}_n$ enjoys this property (and so do its extensions with converse and graded modalities and background theories), and that this property is exploited by tableau- and some resolution-based algorithms. Interestingly, adding nominals to $\mathbf{K}_n^{\smile}$ takes the complexity from PSpace- to ExpTime-completeness [5], and adding nominals to $\mathbf{K}_n^{\smile,c}$ takes the complexity to NExpTime-completeness [186]. Here, we will consider $\mathbf{K}_n^{\smile,o}$ with background theories.

3 TRANSLATION-BASED METHODS

3.1 *Local satisfiability in multi modal* $\mathbf{K}_n$

As outlined in Chapter 1 of this handbook, using the *standard translation* formulae of the basic modal logic $\mathbf{K}$ can be embedded into first-order logic. This translation is also called the *relational translation*, since it is based on the relational Kripke semantics for modal logic. In the following

we denote this translation by π_r and present here its straightforward generalisation to multi-modal $\mathbf{K}_n$.

$$\begin{aligned}
\pi_r(\top, x) &= \top & \pi_r(\bot, x) &= \bot \\
\pi_r(p, x) &= P_p(x) & \pi_r(\neg\varphi, x) &= \neg\pi_r(\varphi, x) \\
\pi_r(\varphi \star \psi, x) &= \pi_r(\varphi, x) \star \pi_r(\psi, x) \quad \text{for } \star \in \{\wedge, \vee, \rightarrow, \leftrightarrow\} \\
\pi_r([i]\varphi, x) &= \forall y\,(R_i(x,y) \rightarrow \pi_r(\varphi, y)) & \pi_r(\langle i\rangle\varphi, x) &= \exists y\,(R_i(x,y) \wedge \pi_r(\varphi, y))
\end{aligned}$$

In the translation, each propositional variable p is uniquely associated with a unary predicate symbol P_p, while each modal parameter i, $1 \leq i \leq n$, is uniquely associated with a binary predicate symbol R_i. In addition, x is an arbitrary first-order variable while y is an arbitrary first-order variable distinct from x.

This translation is *satisfiability equivalence preserving*, that is, for every modal formula φ, φ is $\mathbf{K}_n$ satisfiable iff $\pi_r(\varphi, x)$ is first-order satisfiable. The free variable x is assumed to be existentially quantified.

The currently predominant method for reasoning about first-order formulae is *resolution* [170]. The method requires that a first-order formula or set of first-order formulae φ is first transformed into a satisfiability equivalent set of clauses N_0. This set of clauses is then *saturated* using the *resolution* rule and *factoring* rule shown in Figure 1. That is, given a clause set N_i, $i \geq 0$, these inference rules are applied (top-down) to clauses already in the set and the conclusion C of such an application is added to N_i to give us the clause set N_{i+1}. This process continues until either (i) the current clause set N_i contains the empty clause (i.e. $\bot$) or (ii) no new clauses can be derived, that is, any conclusion of an application of the resolution and factoring rules to clauses in N_i is already contained in N_i. Any clause set containing the empty clause is unsatisfiable. Thus, in the case (i), N_i is unsatisfiable and by the soundness of the resolution calculus, so is N_0. This implies that φ is unsatisfiable, since N_0 is satisfiable iff φ is satisfiable. In the case (ii), if N_i does not contain the empty clause, N_i is satisfiable and it is possible to construct a model for N_i. By the completeness of the resolution calculus, N_0 is satisfiable. It follows that φ is satisfiable. Due to the undecidability of first-order logic, there is in general no guarantee that, after a finite number of steps, we either always encounter case (i) or (ii). If we apply the inference rules of the resolution calculus in a *fair* way, then the completeness of the resolution calculus ensures that, eventually, the empty clause is derived. However, if the formula φ and the clause set N_0 are satisfiable, then the saturation process may continue indefinitely (unless suitable resolution refinements and/or translation methods are used, see below).

The last observation is also true if the formula φ we are considering belongs to a decidable fragment of first-order logic or is the result of translating a formula belonging to a decidable modal logic like $\mathbf{K}_n$. However, starting with [123], a large number of fragments of first-order logic have been shown to be decidable by resolution or refinements of resolution [48, 65, 76, 82, 117, 179].

Resolution: $\dfrac{C \vee A_1 \quad \neg A_2 \vee D}{(C \vee D)\sigma}$
where σ is the most general unifier of atoms A_1 and A_2

Factoring: $\dfrac{C \vee L_1 \vee L_2}{(C \vee L_1)\sigma}$
where σ is the most general unifier of literals L_1 and L_2

Figure 1. The resolution calculus R

Let us start by considering what happens if we apply the basic unrefined resolution calculus to the relational translation of modal formulae. Consider, for example, the modal formula $\varphi_1 = [2](p \to \langle 1 \rangle p)$. Its translation $\pi_r(\varphi_1, x)$ is the first-order formula $\psi_1^r = \forall y\, (R_2(x, y) \to (P_p(y) \to \exists z\, (R_1(y, z) \wedge P_p(z))))$. The corresponding set of clauses N_0^r consists of the two clauses

$$
\begin{array}{ll}
(1) & \neg R_2(a, x) \vee \neg P_p(x) \vee R_1(x, f(x)) \\
(2) & \neg R_2(a, y) \vee \neg P_p(y) \vee P_p(f(y))
\end{array}
$$

where a is a constant introduced during the clause form transformation (for the free variable x in ψ_1^r). We assume that the variables in two clauses to which we want to apply the resolution rule are renamed so that they are variable disjoint, and we consider such *variant clauses* to be equal. There are several possibilities to apply the resolution rule to clauses (1) and (2). For example, we can resolve clause (1) on its second literal, $\neg P_p(x)$, with clause (2) on its third literal, $P_p(f(z))$. The conclusion is

$$
\text{[(1)2,R,(2)3]} \quad (3) \quad \neg R_2(a, f(z)) \vee R_1(f(z), f(f(z))) \vee \neg R_2(a, z) \vee \neg P_p(z)
$$

Clause (3) resolves with clause (2) and yields

$$
\begin{array}{lll}
\text{[(2)3,R,(3)4]} & (4) & \neg R_2(a, f(y)) \vee \neg R_2(a, f(f(y))) \vee R_1(f(f(y)), f(f(f(y)))) \\
& & \qquad \vee \neg R_2(a, y) \vee \neg P_p(y)
\end{array}
$$

This clause also resolves with clause (2), and again, the conclusion resolves with (2), and so forth. Repeatedly resolving the newly derived clauses with (2) yields clauses with increasingly more literals and increasingly more complex terms. All these clauses are new, that is, none is the same as an input clause or a clause derived earlier. As the formula φ_1 and its translation ψ_1^r are satisfiable, we are not able to derive the empty clause. So, the saturation process will continue indefinitely.

There are three approaches that we can take to solve this termination problem:

1. We can develop and use *alternative translations* of modal formulae to first-order (clause) logic, and try to find a translation for which resolution is a decision procedure.

2. We can develop and use *refinements of resolution* which restrict the application of the inference rules of the resolution calculus and use powerful redundancy elimination methods.

3. We can develop and use *alternative inference methods* for first-order logic.

These three approaches are not mutually exclusive, in particular, alternative translations can be combined with both refinements of resolution and alternative calculi.

Investigations following the first approach have resulted in the introduction of the *optimised functional translation* of $\mathbf{K}_n$ to sorted first-order logic, more precisely, to a monadic fragment of sorted first-order logic called *basic path logic* [149, 177]. Basic path logic has a sort S_W for the set of worlds W and a sort S_i for each modal parameter i, $1 \leq i \leq n$, in a modal logic. It has n binary functions $[\_\,\_]_i$ of sort $S_W \times S_i \to S_W$. Also there are special unary predicates def_i of sort S_W representing subsets of W. Each propositional variable p is uniquely associated with a unary predicate symbols P_p of sort S_W. Commonly, the optimised functional translation π_{of} is defined as a two step process: (i) the application of the functional translation to a modal formula which translates it to basic path logic, followed by (ii) the application of a quantifier exchange operation which converts the first-order formula obtained from the functional translation into

prenex normal form and moves all existential quantifiers inwards as far as possible. Since we focus here only on the satisfiability problem, we can give a simplified presentation of the optimised functional translation obtained in just one step.

$$\pi_{of}(\top, s) = \top \qquad \pi_{of}(\bot, s) = \bot$$
$$\pi_{of}(p, s) = P_p(s) \qquad \pi_{of}(\neg\varphi, s) = \neg\pi_{of}(\varphi, s)$$
$$\pi_{of}(\varphi \star \psi, s) = \pi_{of}(\varphi, s) \star \pi_{of}(\psi, s) \quad \text{for } \star \in \{\wedge, \vee, \rightarrow, \leftrightarrow\}$$
$$\pi_{of}([i]\varphi, s) = \forall y{:}S_i(\mathit{def}_i(s) \rightarrow \pi_{of}(\varphi, [s\, y{:}S_i]_i))$$
$$\pi_{of}(\langle i\rangle\varphi, s) = \mathit{def}_i(s) \wedge \pi_{of}(\varphi, [s\, y{:}S_i]_i)$$

where s denotes a *(world) path* and $y{:}S_i$ denotes a variable of sort S_i. The omission of the quantifiers in the definition for $\langle i\rangle\varphi$ is intensional. The optimised functional translation of a modal formula φ in negation normal form is now given by $\pi_{of}(\varphi, x{:}S_W)$, where $x{:}S_W$ is an arbitrary variable of sort S_W, and $x{:}S_W$ as well as the $y{:}S_i$ from $\pi_{of}(\langle i\rangle\varphi, s)$ are free variables which are implicitly existentially quantified.

As an example, consider again the modal formula $\varphi_1 = [2](p \rightarrow \langle 1\rangle p)$. Its optimised functional translation is $\varphi_1^{of} = \pi_{of}(\varphi_1, x{:}S_W) = \forall y{:}S_2\,(\mathit{def}_2(x{:}S_W) \rightarrow (P_p([x{:}S_W\, y{:}S_2]_2) \rightarrow (\mathit{def}_1([x{:}S_W\, y{:}S_2]_2) \wedge P_p([[x{:}S_W\, y{:}S_2]_2\, z{:}S_1]_1))))$.

In the representation of paths we often remove all occurrences of the binary functions $[\_\,\_]_i$ except for the outermost occurrence and also leave out the index of that remaining occurrence, e.g. $[[x{:}S_W\, y{:}S_2]_2\, z{:}S_1]_1$ is written as $[x{:}S_W\, y{:}S_2\, z{:}S_1]$. It is straightforward to restore the original path based on the remaining information. Intuitively, a path term like $[x{:}S_W\, y{:}S_2\, z{:}S_1]$ represents a path from a world x to another, possible identical, world in a Kripke frame via a series of 'steps' along the accessibility relations of the frame. Here an R_2-step is followed by an R_1-step, which is indicated by the sorts S_2 and S_1 associated with the variables y and z, respectively. The def_i predicates express 'definability' for a world in the sense that $\mathit{def}_i(s)$ is true iff the world s has an i-successor.

The standard translation π_r accommodates axiom schemas like $\mathbf{4}$ and $\mathbf{B}$ by adding first-order formulae

$$(R_{\mathbf{B}}) \qquad \forall x\, y\,(R_i(x, y) \rightarrow R_i(y, x))$$
$$(R_{\mathbf{4}}) \qquad \forall x\, y\, z\,((R_i(x, y) \wedge R_i(y, z)) \rightarrow R_i(x, z))$$

representing the *relational frame properties* corresponding to these axiom schemas. By contrast, in the case of the optimised functional translation, we add so-called *functional frame properties* in the form of (conditional) equations between path terms, for example

$$(F_{\mathbf{B}}) \qquad \forall x{:}S_W \forall y{:}S_i \exists z{:}S_i\,(\mathit{def}_i(x{:}S_W) \rightarrow \mathit{def}_i([x{:}S_W\, y{:}S_i]) \wedge \mathit{def}_i(x{:}S_W) \rightarrow x{:}S_W = [[x{:}S_W\, y{:}S_i]\, z{:}S_i])$$
$$(F_{\mathbf{4}}) \qquad \forall x{:}S_W \forall y{:}S_i \forall z{:}S_i \exists u : S_i\,((\mathit{def}_i(x{:}S_W) \wedge \mathit{def}_i([x{:}S_W\, y{:}S_i])) \rightarrow [[x{:}S_W\, y{:}S_i]\, z{:}S_i] = [x{:}S_W\, u : S_i])$$

Functional frame properties corresponding to axiom schemas $\mathbf{5}$, $\mathbf{D}$, $\mathbf{T}$, $\mathbf{G}$, as well as functional frame properties corresponding to weak density, irreflexivity, and McKinsey's axiom can be found in [177].

THEOREM 1 ([149]). *Let $\mathbf{K}_n\Sigma$ be a complete modal logic such that the functional frame properties corresponding to the axiom schemas in Σ are a set of first-order formulae F_Σ. Then φ is satisfiable in $\mathbf{K}_n\Sigma$ iff $F_\Sigma \wedge \pi_{of}(\varphi, x{:}S_W)$ is first-order satisfiable.*

If we are only interested in establishing the satisfiability of formulae in the basic modal logic $\mathbf{K}_n$ or extensions of $\mathbf{K}_n$ by the axiom schema $\mathbf{D}$ for some or all modalities, then the use of sorted first-order logic and binary function symbols can be avoided by using k-ary predicates where the sort information is coded into the predicate names [95, 116]. The k-ary predicate symbols are $P_{p,\sigma}$ and $def_{i,\sigma}$ where p denotes a propositional symbol, σ is a k-sequence of natural numbers and $1 \leq i \leq n$, $n \geq 0$. We use $\overline{x}$ to denote a sequence of variables $x_1, \ldots, x_k$, and we use 'ϵ' and '.' for the empty sequence and the concatenation operation on sequences, respectively.

$$\pi'_{of}(\top, \overline{x}, k, \sigma) = \top \qquad\qquad \pi'_{of}(\bot, \overline{x}, k, \sigma) = \bot$$

$$\pi'_{of}(p, \overline{x}, k, \sigma) = \begin{cases} P_{p,\epsilon} & \text{if } \sigma = \epsilon \text{ and } k = 0 \\ P_{p,\sigma}(x_1, \ldots, x_k) & \text{otherwise} \end{cases}$$

$$\pi'_{of}(\neg\varphi, \overline{x}, k, \sigma) = \neg\pi'_{of}(\varphi, \overline{x}, k, \sigma)$$

$$\pi'_{of}(\varphi \star \psi, \overline{x}, k, \sigma) = \pi'_{of}(\varphi, \overline{x}, k, \sigma) \star \pi'_{of}(\psi, \overline{x}, k, \sigma) \quad \text{for } \star \in \{\wedge, \vee\}$$

$$\pi'_{of}([i]\varphi, \overline{x}, k, \sigma) = \forall x_{n+1}\, (def_{i,\sigma}(\overline{x}) \rightarrow \pi'_{of}(\varphi, \overline{x}.x_{k+1}, k{+}1, \sigma.i))$$

$$\pi'_{of}(\langle i\rangle\varphi, \overline{x}, k, \sigma) = def_{i,\sigma}(\overline{x}) \wedge \pi'_{of}(\varphi, \overline{x}.x_{k+1}, k{+}1, \sigma.i)$$

The translation of a modal formula φ in negation normal form is given by $\pi'_{of}(\varphi, \epsilon, 0, \epsilon)$. In the case of the modal logic $\mathbf{KD}_n$, and in fact for any modal logic where an accessibility relation R_i is serial, all occurrences of $def_{i,\sigma}$ can be replaced with the logical constant $\top$.

The translation π'_{of}, called the polyadic optimised functional translation, takes advantage of two observations:

1. All paths in $\pi_{of}(\varphi, x{:}S_W)$ start with $x{:}S_W$ and since this variable is free, it is implicitly existentially quantified, and is interpreted as a constant. Therefore, removing $x{:}S_W$ from all paths is a satisfiability equivalence preserving transformation.

2. The variables in the paths occurring in $\pi_{of}(\varphi, x{:}S_W)$ are *prefix stable*, that is, for any variable $x_{i+1}{:}S_{j_i}$ there exists a unique prefix $[x{:}S_W\, x_0{:}S_{j_0}\, \ldots\, x_i{:}S_{j_i}]$ such that every path containing $x_{i+1}{:}S_{j_i}$ has the form $[x{:}S_W x_0{:}S_{j_0} \ldots x_i{:}S_{j_i} x_{i+1}{:}S_{j_{i+1}} \ldots x_k{:}S_{j_k}]$. Thus, if a variable occurs at position i in one path, then it occurs at position i in all paths. This property is due to a characteristic ordering of variables in the path terms determined by the structure of modal formulae and is a reflection of the tree model property. Also, since variables do not 'move', the sort information can be associated with the position at which a variable occurs instead of with the variable itself. Thus, we can code the sort information into predicate names. Replacing $P_p([x{:}S_W\, x_0{:}S_{j_0}\, \ldots\, x_k{:}S_{j_k}])$ by $P_{p,S_W S_{j_0} \ldots S_{j_k}}(x, x_0, \ldots, x_k)$ is therefore a satisfiability equivalence preserving transformation.

Taking both observations together, and also taking advantage of the assumption that each sort S_i is uniquely identified by its index i, we see that we can replace $P_p([x{:}S_W\, x_0{:}S_{j_0}\, \ldots\, x_k{:}S_{j_k}])$ with $P_{p,j_0 \ldots j_k}(x_0, \ldots, x_k)$.

For the modal formula $\varphi_1 = [2](p \rightarrow \langle 1\rangle p)$ the translation using π'_{of} is $\psi_1^{of'} = \forall y\, (def_{2,\epsilon} \rightarrow (P_{p,2}(y) \rightarrow (def_{1,2}(y) \wedge P_{p,21}(y, z))))$. The corresponding set $N_0^{of'}$ of clauses again consists of two clauses.

$$\begin{array}{ll} (5) & \neg def_{2,\epsilon} \vee \neg P_{p,2}(y) \vee def_{1,2}(y) \\ (6) & \neg def_{2,\epsilon} \vee \neg P_{p,2}(y) \vee P_{p,21}(y, z) \end{array}$$

Unlike for the clausal form of the relational translation of φ_1, for these two clauses there is no possibility to apply either the resolution rule or the factoring rule. For, we see that $P_{p,21}(y,z)$ in clause (6) is not unifiable with $P_{p,2}(y)$ in clause (5), nor is it unifiable with $P_{p,2}(y)$ in clause (6). So, for this particular example we are able to conclude that $N_0^{of'}$, $\psi_1^{of'}$, and φ_1 are satisfiable without the need to perform a single inference step.

With this translation, is termination of the saturation process guaranteed? Consider the modal formula $\varphi_2 = [2](\neg p \vee [1]q) \vee [2]p$. Its optimised functional translation is

$$\psi_2^{of'} = \forall y(\mathit{def}_{2,\epsilon} \rightarrow (\neg P_{p,2}(y) \vee \forall z(\mathit{def}_{1,2}(y) \rightarrow P_{q,21}(y,z)))) \vee \forall u(\mathit{def}_{2,\epsilon} \rightarrow P_{p,2}(u)).$$

The corresponding set N_0^{of} of clauses consists of just one clause

$$(7) \quad \neg\mathit{def}_{2,\epsilon} \vee \neg P_{p,2}(y) \vee \neg\mathit{def}_{1,2}(y) \vee P_{q,21}(y,z) \vee \neg\mathit{def}_{2,\epsilon} \vee P_{p,2}(u).$$

We consider clauses to be *multisets* of literals, that is, a literal can occur more than once in a clause, as is the case with the literal $\neg\mathit{def}_{2,\epsilon}$ in clause (7). It is sometimes convenient to consider clauses as *sets* of literals. However, this complicates the completeness proof for resolution calculi which commonly proceeds by lifting ground level derivations to the non-ground level. This lifting is easier if clauses are considered to be multisets on both the ground and the non-ground level. Furthermore, multisets make the computational effort explicit which has to go into removing duplicate literals from clauses.

We can resolve clause (7) with itself on the second literal and the last literal. Remember that this means that we first have to generate a variable-disjoint copy of clause (7) to serve as second premise of a resolution step. The conclusion is

$$\begin{aligned}[(7)2,R,(7)6] \quad (8) \quad & \neg\mathit{def}_{2,\epsilon} \vee \neg P_{p,2}(y_1) \vee \neg\mathit{def}_{1,2}(y_1) \vee P_{q,21}(y_1,z_1) \vee \neg\mathit{def}_{1,2}(y_2) \\ & \vee P_{q,21}(y_2,z_2) \vee \neg\mathit{def}_{2,\epsilon} \vee P_{p,2}(u_2) \vee \neg\mathit{def}_{2,\epsilon} \vee \neg\mathit{def}_{2,\epsilon}.\end{aligned}$$

We observe that the number of occurrences of $\neg\mathit{def}_{2,\epsilon}$ has doubled, to four, and also that we now have two subclauses $\neg\mathit{def}_{1,2}(y_1) \vee P_{q,21}(y_1,z_1)$ and $\neg\mathit{def}_{1,2}(y_2) \vee P_{q,21}(y_2,z_2)$ which are variants of each other.[1] Note that these two subclauses are not simply duplicates, so in a clauses-as-sets setting they would still remain, while all the duplicates of $\neg\mathit{def}_{2,\epsilon}$ would not occur. Clause (8) can again be resolved with itself or with clause (7). A possible resolvent is:

$$\begin{aligned}[(7)2,R,(8)8] \quad (9) \quad & \neg\mathit{def}_{2,\epsilon} \vee \neg P_{p,2}(y_3) \vee \neg\mathit{def}_{1,2}(y_3) \vee P_{q,21}(y_3,z_3) \\ & \vee \neg\mathit{def}_{1,2}(y_1) \vee P_{q,21}(y_1,z_1) \vee \neg\mathit{def}_{1,2}(y_2) \vee P_{q,21}(y_2,z_2) \\ & \vee \neg\mathit{def}_{2,\epsilon} \vee P_{p,2}(u_2) \vee \neg\mathit{def}_{2,\epsilon} \vee \neg\mathit{def}_{2,\epsilon} \vee \neg\mathit{def}_{2,\epsilon} \vee \neg\mathit{def}_{2,\epsilon}\end{aligned}$$

We can continue this process indefinitely, producing bigger and bigger clauses. This shows that the saturation process does not terminate.

We observe, however, that resolution is not the only inference rule that can be applied to clause (8): we can also apply the factoring rule. Indeed, there are several possibilities to do so, for example, we can apply the factoring rule to $P_{q,21}(y_1,z_1)$ and $P_{q,21}(y_2,z_2)$. The resulting factor is:

$$\begin{aligned}[(8)4,F,(8)6] \quad (10) \quad & \neg\mathit{def}_{2,\epsilon} \vee \neg P_{p,2}(y_1) \vee \neg\mathit{def}_{1,2}(y_1) \vee \neg\mathit{def}_{1,2}(y_1) \vee P_{q,21}(y_1,z_1) \\ & \vee \neg\mathit{def}_{2,\epsilon} \vee P_{p,2}(u_2) \vee \neg\mathit{def}_{2,\epsilon} \vee \neg\mathit{def}_{2,\epsilon}.\end{aligned}$$

[1] We consider two formulae or clauses to be equal iff they are *variants* of each other, that is, they are syntactically equal modulo variable renaming.

We see that the clause (10) is a subclause of the clause (8) from which it was derived. Clause (10) thus subsumes clause (8). In general, a clause C *subsumes* a clause D iff there is a substitution σ such that $C\sigma$ is a subclause of D. Subsumed clauses are *redundant* and can be removed from a clause set without losing completeness.

Further factoring steps are possible on clause (10), for example, on the two occurrences of $\neg def_{1,2}(y_1)$. It turns out that the final clause that we can derive by a series of factoring steps is a condensation of clause (8). By definition, a *condensation* $\mathrm{Cond}(C)$ of a clause C is a minimal subclause of C which is also an instance of C. A clause C is *condensed* iff there exists no condensation of C which is a strict subclause of C. For any clause C, $\mathrm{Cond}(C)$ subsumes C, and hence C is redundant in the presence of $\mathrm{Cond}(C)$ and can be removed. This justifies that we can systematically replace clauses with their condensation.

The condensation of clauses (7) and (8) are the clauses

$$\begin{array}{ll} (7') & \neg def_{2,\epsilon} \vee \neg P_{p,2}(y) \vee \neg def_{1,2}(y) \vee P_{q,21}(y,z) \vee P_{p,2}(u) \\ (8') & \neg def_{2,\epsilon} \vee \neg P_{p,2}(y_1) \vee \neg def_{1,2}(y_1) \vee P_{q,21}(y_1,z_1) \vee P_{p,2}(u_2). \end{array}$$

These two clauses are variants of each other, that is, we regard them as equal. So, the only clause derivable from (7′) is identical to (7′), which means the saturation process terminates.

It turns out that systematically replacing clauses by their condensation is sufficient to guarantee termination not only for this particular example formula, but for any modal formula in $\mathbf{K}_n$ or $\mathbf{KD}_n$.

THEOREM 2 ([175]). *Let φ be a modal formula and $N_0 = \pi'_{of}(\varphi, \epsilon, 0, \epsilon)$. Then the saturation process from N_0 by the resolution calculus R defined in Figure 1 in which clauses are systematically and eagerly replaced with their condensation always terminates with a clause set N_n, and φ is $\mathbf{K}(\mathbf{D})_n$ unsatisfiable iff N_n contains the empty clause.*

It is important to understand how Theorem 2 is to be interpreted. The theorem says that R plus condensing is a decision procedure for this translation of modal satisfiability problems. It does not stipulate that we must use R plus condensing. Rather, the theorem sets out the minimal requirement or weakest condition we have to impose on a saturation process by R to ensure that it terminates. It states that, as long as we keep clauses condensed, we can use any refinement of the calculus R, we can perform inference steps on any literals in a clause and can perform inference steps in any order, and the saturation process is still guaranteed to terminate. Condensing can be simulated by factoring and subsumption deletion. Consequently, any first-order theorem prover which implements some refinement of R (and subsumption deletion, which is standardly available) can serve as a decision procedure for $\mathbf{K}_n$ and $\mathbf{KD}_n$.

The question as to which particular refinement of resolution to use (determining which inference steps are required for completeness) and which particular strategies and heuristics to use (determining the order in which inference steps are performed) is then subject to both theoretical and empirical investigation. We leave empirical aspects aside for the moment and instead focus on refinements of resolution.

A wide range of refinements of resolution can be formulated in the general resolution calculus of Bachmair and Ganzinger; full details can be found in [16]. In the general resolution calculus, here denoted by $R^{\succ}_{S}$, inference rules are parameterised by an admissible ordering $\succ$ on literals and a selection function S. Essentially, an admissible ordering is a total (well-founded) strict ordering on the ground level such that for literals: $\ldots \succ \neg A_n \succ A_n \succ \ldots \succ \neg A_1 \succ A_1$. This is extended to the non-ground level in a canonical manner. A *selection* function S assigns to each clause a possibly empty set of occurrences of negative literals. If C is a clause, then the

Deduction: $$\frac{N}{N \cup \{\mathrm{Cond}(C)\}}$$
if C is either a resolvent or a factor of clauses in N.

Deletion: $$\frac{N \cup \{C\}}{N}$$
if C is redundant in N.

Splitting: $$\frac{N \cup \{C \vee D\}}{N \cup \{C\} \mid N \cup \{D\}}$$
if C and D are variable-disjoint.

Resolution: $$\frac{C \vee A_1 \qquad \neg A_2 \vee D}{(C \vee D)\sigma}$$
where (i) σ is the most general unifier of atoms A_1 and A_2, (ii) no literal is selected in C, and $A_1\sigma$ is strictly $\succ$-maximal with respect to $C\sigma$, and (iii) $\neg A_2$ is either selected, or $\neg A_2\sigma$ is maximal with respect to $D\sigma$ and no literal is selected in D.

Positive Factoring: $$\frac{C \vee A_1 \vee A_2}{(C \vee A_1)\sigma}$$
where (i) σ is the most general unifier of atoms A_1 and A_2, and (ii) no literal is selected in C and $A_1\sigma$ is $\succ$-maximal with respect to $C\sigma$.

Figure 2. Expansion and inference rules of $R^{\succ}_{S}$

literal occurrences in $S(C)$ are *selected*. No restrictions are imposed on the selection function. The calculus comprises *expansion rules* of the general form

$$\frac{N}{N_1 \mid \cdots \mid N_n}$$

where both the numerator N and the denominators $N_1, \ldots, N_n$ ($n \geq 1$) are finite sets of clauses. Expansion rules are applied top-down. There are three kinds of expansion rules: Deduction, Deletion and Splitting which are defined in Figure 2. The inferences rules consist of the resolution and the factoring rule also defined in Figure 2. The left premise of the resolution rule is called the *positive premise* and the right premise is called the *negative premise*. The implicit assumption is that the premises have no common variables. *Resolvents* are conclusions of resolution steps, while *factors* are conclusions of factoring steps.

A *derivation* in $R^{\succ}_{S}$ from a set of clauses N is a finitely branching, ordered tree T with root N and nodes which are sets of clauses. The tree is constructed by applications of the expansion rules to the leaves. We assume that no resolution or factoring inference (on the same premises) is performed twice on the same branch of the derivation. A branch $N(= N_0), N_1, \ldots$ in a derivation T is called a *closed branch* in T iff the clause set $\bigcup_{j \geq 0} N_j$ contains the empty clause, otherwise it is called an *open branch*. We call a branch B in a derivation tree *complete* (with respect to $R^{\succ}_{S}$) iff no new successor nodes can be added with $R^{\succ}_{S}$ to the endpoint of B, otherwise it is called an *incomplete branch*. A derivation T is a *refutation* iff every path $N(= N_0), N_1, \ldots$ in it is a closed branch, otherwise it is called an *open derivation*.

In general, the calculus $R^{\succ}_{S}$ can be enhanced with standard simplification rules such as tautology deletion and subsumption deletion. In fact, it can be enhanced by all simplification rules which are compatible with a general notion of redundancy [16, 18]. For example, C is redundant in $N \cup \{\mathrm{Cond}(C)\}$. A set N of clauses is *saturated up to redundancy* with respect to a particular refinement of resolution if the conclusion of every inference from non-redundant premises in N is either contained in N, or else is redundant in N. A derivation T from N is called *fair* if, for any path $N(= N_0), N_1, \ldots$ in T with *limit* $N_\infty = \bigcup_{j \geq 0} \bigcap_{k \geq j} N_k$, it is the case that each clause C which can be deduced from non-redundant premises in N_∞ is contained in some N_j. Intuitively, fairness means that no non-redundant inferences are delayed indefinitely. For a finite

complete branch $N(= N_0), N_1, \dots N_n$, the limit N_∞ is equal to N_n.

THEOREM 3 ([18]). *Let T be a fair $\mathcal{R}^{\succ}_{S}$ derivation from a set N of clauses. Then*

1. *if $N(= N_0), N_1, \dots$ is a path with limit N_∞, then N_∞ is saturated (up to redundancy),*
2. *N is satisfiable iff there exists a path in T with limit N_∞ such that N_∞ is satisfiable, and*
3. *N is unsatisfiable iff for every path $N(= N_0), N_1, \dots$ the clause set $\bigcup_{j \geq 0} N_j$ contains the empty clause.*

As an aside, we note that it follows from the decidability result for the optimised functional translation (Theorem 2) that we can use any instance of $\mathcal{R}^{\succ}_{S}$ for the clause sets obtained by applying $\pi_{of'}$ to modal formulae in $\mathbf{K}_n$ or $\mathbf{KD}_n$. In particular, this gives us full flexibility with respect to orderings and selection functions. Furthermore, by Theorem 2, even instances of $\mathcal{R}^{\succ}_{S}$ without splitting will terminate.

The purpose of the ordering $\succ$ and the selection function S is to restrict the set of literals in a clause to which resolution and factoring can be applied. This limits the number of inferences performed and consequently reduces the search space. For example, reconsider the clause set N_0^{of} consisting of just the clause

$$(7) \quad \neg \mathit{def}_{2,\epsilon} \vee \neg P_{p,2}(y) \vee \neg \mathit{def}_{1,2}(y) \vee P_{q,21}(y,z) \vee \neg \mathit{def}_{2,\epsilon} \vee P_{p,2}(u).$$

Using an ordering we could restrict inference steps to the literals $P_{q,21}(y,z)$ and $P_{p,2}(u)$. Now $\neg P_{p,2}(y)$ can no longer be resolved with $P_{p,2}(u)$, since $\neg P_{p,2}(y)$ is neither maximal nor selected. Alternatively, using a selection function we could restrict inference steps to the negative literals $\neg \mathit{def}_{2,\epsilon}$ or $\neg P_{p,2}(y)$. Again, no inference steps are possible.

Let us reconsider our very first example, the set of clauses N_0^r obtained via the relational translation of $\varphi_1 = [2](p \to \langle 1 \rangle p)$:

$$\begin{array}{ll} (1) & \neg R_2(a,x) \vee \neg P_p(x) \vee R_1(x, f(x)) \\ (2) & \neg R_2(a,y) \vee \neg P_p(y) \vee P_p(f(y)) \end{array}$$

If we use an ordering $\succ$ such that $R_1(x, f(x))$ is maximal in clause (1) and $P_p(f(y))$ is maximal in clause (2), then no inference steps are possible on N_0^r. Likewise, if we select the literals $\neg R_2(a,x)$ and $\neg R_2(a,y)$ in their respective clauses, then again no inference steps are possible.

This raises the question whether it is possible to obtain decision procedures for $\mathbf{K}_n$ satisfiability based on the relational translation π_r and the calculus $\mathcal{R}^{\succ}_{S}$ by using particular ordering or selection functions. To simplify matters, we use a technique called structural transformation. The purpose of the structural transformation is to convert the first-order translation into a more manageable form. Before we describe it formally, we need to define some basic notions.

The polarity of (occurrences of) modal or first-order subformulae is defined as usual. Any occurrence of a proper subformula of an equivalence has *zero polarity*. For occurrences of subformulae not below a '$\leftrightarrow$' symbol, an occurrence of a subformula has *positive polarity* if it is inside the scope of an even number of (explicit or implicit) negations, and it has *negative polarity* if it is inside the scope of an odd number of negations. For any first-order formula φ, if λ is the position of a subformula in φ, then $\varphi|_\lambda$ denotes the subformula of φ at position λ and $\varphi[\psi \mapsto \lambda]$ is the result of replacing $\varphi|_\lambda$ at position λ by ψ. The set of all the positions of subformulae of φ is denoted by $\Lambda(\varphi)$.

Structural transformation, also referred to as *renaming*, associates a predicate symbol Q_λ and a literal $Q_\lambda(\overline{x})$ with each element λ of $\Lambda \subseteq \Lambda(\varphi)$, where $\overline{x} = x_1, \dots, x_n$ are the free variables

of $\varphi|_\lambda$, the symbol Q_λ does not occur in φ and two symbols Q_λ and $Q_{\lambda'}$ are equal only if $\varphi|_\lambda$ and $\varphi|_{\lambda'}$ are equivalent formulae. In practice, one may want to use the same symbols for variant subformulae, or subformulae which are obviously equivalent, for example, $\varphi \vee \psi$ and $\psi \vee \varphi$. Let $\mathrm{Def}^+_\lambda(\varphi) = \forall \overline{x}\,(Q_\lambda(\overline{x}) \to \varphi|_\lambda)$ and $\mathrm{Def}^-_\lambda(\varphi) = \forall \overline{x}\,(\varphi|_\lambda \to Q_\lambda(\overline{x}))$. The *definition* of Q_λ is the formula

$$\mathrm{Def}_\lambda(\varphi) = \begin{cases} \mathrm{Def}^+_\lambda(\varphi) & \text{if } \varphi|_\lambda \text{ has positive polarity,} \\ \mathrm{Def}^-_\lambda(\varphi) & \text{if } \varphi|_\lambda \text{ has negative polarity,} \\ \mathrm{Def}^+_\lambda(\varphi) \wedge \mathrm{Def}^-_\lambda(\varphi) & \text{otherwise.} \end{cases}$$

The corresponding clauses are called *definitional clauses*. Now, assume that Λ is a set of positions in a formula φ and that we want to systematically replace subformulae at positions in Λ while adding definitions for the newly introduced predicate symbols. A convenient way to do so, is to start by the renaming innermost subformulae, and then to proceed up towards the root of φ. Formally, define $\mathrm{Def}_\Lambda(\varphi)$ inductively by:

$$\mathrm{Def}_\emptyset(\varphi) = \varphi \quad \text{and} \quad \mathrm{Def}_{\Lambda\cup\{\lambda\}}(\varphi) = \mathrm{Def}_\Lambda(\varphi[Q_\lambda(\overline{x}) \mapsto \lambda]) \wedge \mathrm{Def}_\lambda(\varphi),$$

where λ is maximal in $\Lambda \cup \{\lambda\}$ with respect to the prefix ordering on positions. A *definitional form* of φ is $\mathrm{Def}_\Lambda(\varphi)$, where Λ is a subset of all positions of subformulae of φ (usually, non-atomic or non-literal subformulae).

THEOREM 4 (e.g. [29, 161]). *Let φ be a first-order formula. Then*

1. *φ is satisfiable iff $\mathrm{Def}_\Lambda(\varphi)$ is satisfiable, for any $\Lambda \subseteq \Lambda(\varphi)$, and*
2. *$\mathrm{Def}_\Lambda(\varphi)$ can be computed in polynomial time (or linear time if new symbols are introduced for all formulae occurring in Λ).*

By $\Lambda_m(\varphi)$ we denote the set of positions in $\pi_r(\varphi, x)$ corresponding to non-atomic subexpressions of the modal formula φ.

Structural transformation allows us to keep the structure of the clauses we have to deal with very simple. This in turn simplifies the characterisation of classes of clause sets that can be derived from some initial clause set using $R^{\succ}_S$. For example, assume that, in the relational translation of the modal formula $\varphi_3 = [2]\langle 1\rangle p$, we apply structural transformation to all positions that correspond to non-atomic subexpressions of the original modal formula φ_3. The result is the set of formulae on the left of Figure 3, while the clausal form is given on the right. In general, the formulae we obtain in this way from the relational translation of modal formulae (as well as the corresponding sets of clauses) belong to quite a number of decidable fragments of first-order logic, for example, the two-variable fragment, the guarded fragment [3], Maslov's class K [135], and fluted logic [165, 166]. Resolution decision procedures have been developed for the guarded

$Q_{[2]\langle 1\rangle p}(x)$	$Q_{[2]\langle 1\rangle p}(a)^*$
$\wedge\forall x\,(Q_{[2]\langle 1\rangle p}(x) \to \forall y\,(R_1(x,y) \to Q_{\langle 1\rangle p}(y)))$	$\neg Q_{[2]\langle 1\rangle p}(x) \vee \neg R_2(x,y)^* \vee Q_{\langle 1\rangle p}(y)$
$\wedge\forall x\,(Q_{\langle 1\rangle p}(x) \to \exists y\,(R_1(x,y) \wedge P_p(y)))$	$\neg Q_{\langle 1\rangle p}(x) \vee R_1(x,f(x))^*$
	$\neg Q_{\langle 1\rangle p}(x) \vee P_p(f(x))^*$

Figure 3. The structural transformation and the clausal form of $[2]\langle 1\rangle p$

fragment [48, 76], for Maslov's class K [111, 117], for fluted logic [179] and various other classes related to modal logics, see e.g. [65, 82, 83, 111]. Here we use the results for the clausal class $\mathbf{DL}^*$ defined in [49]. $\mathbf{DL}^*$ is a variation of the class of DL-clauses, that was introduced in [119] for the purpose of deciding expressive description logics.

In order to simplify the definition of $\mathbf{DL}^*$, all clauses are assumed to be maximally split. The components in the variable partition of a clause are called *variable-disjoint* or *split components*, that is, split components do not share variables. If $C_1, \ldots, C_n$ are the split components of C, then we say C can be *decomposed* into $C_1, \ldots, C_n$. A clause which cannot be split further is called a *maximally split clause* or an *indecomposable clause*. Now, a maximally split clause C is a $\mathbf{DL}^*$*-clause* iff the following conditions are satisfied: (i) all literals are unary, or binary; (ii) there is no nesting of function symbols; (iii) every functional term in C contains all the variables of C (this condition implies that, if C contains a functional ground term, then C is ground); (iv) every binary literal (even if it has no functional terms) contains all the variables of C. It can be shown that all clauses in structural form obtained from $\mathrm{Def}_\Lambda(\pi_r(\varphi, x))$ for a modal formula φ belong to $\mathbf{DL}^*$ [49].

In order to decide the class $\mathbf{DL}^*$, we use the following ordering. First we define an order $>_d$ on terms: $s >_d t$ if s is deeper than t, and every variable that occurs in t, occurs deeper in s. Then we define $P(s_1, \ldots, s_n) \succ Q(t_1, \ldots, t_m)$ as $\{s_1, \ldots, s_n\} >_d^{\mathrm{mul}} \{t_1, \ldots, t_m\}$. Here $>_d^{\mathrm{mul}}$ is the multiset extension of $>_d$ [16]. So we have $P(f(x)) \succ P(a), P(x)$ and $P(x, y) \succ Q(x)$, but not $P(f(x)) \succ P(f(a))$. The selection function S is empty. We denote this particular instance of the resolution calculus $\mathsf{R}_S^\succ$ by $\mathsf{R}^{\mathsf{ord}}$.

In the example in Figure 3, the maximal literals (with respect to $\succ$) are marked with *. These are the literals that we may apply resolution or factoring to.

In order to prove that the procedure $\mathsf{R}^{\mathsf{ord}}$ is indeed a decision procedure we have to show that it is complete and terminating. Completeness follows immediately from the completeness of $\mathsf{R}_S^\succ$. Termination follows from the fact, that over a finite signature, there are only finitely many maximally split $\mathbf{DL}^*$-clauses (module variable renaming), and the fact that, from $\mathbf{DL}^*$-clauses, $\mathsf{R}^{\mathsf{ord}}$ produces only clauses that are again in $\mathbf{DL}^*$, or are splittable into components in $\mathbf{DL}^*$ (cf. [111, 119]).

THEOREM 5 ([49, 180]). *Let Σ be an arbitrary set of axiom schemas such that $\mathbf{K}_n\Sigma$ is complete and the clausal form of the relational frame properties F_Σ corresponding to the axiom schemas in Σ are expressible in $\mathbf{DL}^*$. Let φ be a $\mathbf{K}_n$ formula and let N be the clausal form of $F_{\Sigma,\varphi} = F_\Sigma \wedge \mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$. Then*

1. *φ is unsatisfiable in $\mathbf{K}_n\Sigma$ iff $F_{\Sigma,\varphi}$ is first-order unsatisfiable iff there is a refutation of N by $\mathsf{R}^{\mathsf{ord}}$,*
2. *N is a set of $\mathbf{DL}^*$ clauses, and*
3. *any derivation from N in $\mathsf{R}^{\mathsf{ord}}$ (up to redundancy) terminates in double exponential time; if Σ is empty, then any derivation from N in $\mathsf{R}^{\mathsf{ord}}$ (up to redundancy) terminates in exponential time, and*

Here, and in subsequent theorems, we assume that the complexity of redundancy elimination is at most exponential in the size of a clause set. The theorem remains true for $\mathsf{R}^{\mathsf{ord}}$ without the splitting rule, but condensing is key for decidability.

It is usually the case that, when studying modal decidability problems by analysing the decidability of related clausal classes, one comes to realise that stronger results are possible than

initially anticipated. In [49], extensions of $\mathbf{K}_n$ with $\mathbf{PDL}$-like relational operations have been studied. Relational operations expressible in $\mathbf{DL}^*$ include intersection, union, complementation, and converse, as are non-logical axioms.

In R^{ord}, the inferences performed are determined by a refinement based on an ordering and the empty selection function. We now consider results from [49, 119, 121, 180] for a different refinement which is based solely on a selection function and an optional ordering. More precisely, the calculus is based on maximal selection of negative literals. This means the selection function S selects exactly the set of all negative literals in any non-positive clause. When no ordering refinement $\succ$ is used, the resolution rule of $R_S^{\succ}$ can be replaced with the following rule.

Resolution with maximal selection:

$$\frac{C_1 \vee A_1 \quad \cdots \quad C_n \vee A_n \quad \neg A_{n+1} \vee \ldots \vee \neg A_{2n} \vee D}{(C_1 \vee \ldots \vee C_n \vee D)\sigma}$$

provided that for every i, $1 \leq i \leq n$, (i) σ is the most general unifier of A_i and A_{n+i}, (ii) $C_i \vee A_i$ and D are positive clauses, (iii) no A_i occurs in C_i, and (iv) the $\neg A_{n+i}$ are selected. The *negative premise* is $\neg A_{n+1} \vee \ldots \vee \neg A_{2n} \vee D$ and the other premises are the *positive premises*. The literals A_i and A_{n+i} are the *eligible literals*.

Let R^{hyp} be the instance of $R_S^{\succ}$ based on maximal selection and no ordering. This means that the rules are the above resolution rule, positive unordered factoring and splitting. This refinement of resolution is also referred to as *hyperresolution plus splitting*. Condensation is not needed, but could of course be added without losing completeness and will improve the performance of the procedure. Tautology deletion is used as a simplification rule. All derivations in R^{hyp} are generated by strategies in which no application of the resolution or factoring with identical premises and identical consequence may occur twice on the same path in any derivation. In addition, deletion rules, splitting, and the deduction rules are applied in this order, except that splitting is not applied to clauses which contain a selected literal.

All clauses occurring in the clausal form of $\mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$ for a modal formula in $\mathbf{K}_n$ have one of the forms described in Figure 4 [49, 119]. The literals marked with $^+$ are selected in the clauses by the maximal selection function S. The notation $\mathcal{P}(s)$ in the figure represents some literal with a unary predicate symbol and argument term s, and $\mathcal{R}(s,t)$ represents some literal with a binary predicate symbol and argument terms s and t (not necessarily in this order). Two occurrences of $\mathcal{P}(s)$ or $\mathcal{R}(s,t)$ need not be identical, for example, $\neg Q_\psi(x) \vee P_p(x) \vee Q_\chi(x)$ is an instance of $\neg Q_\psi(x) \vee \mathcal{P}(x) \vee \mathcal{P}(x)$, while $\neg Q_\psi(x) \vee \neg R_i(y,x) \vee Q_\chi(y)$ is an instance of $\neg Q_\psi(x) \vee \neg \mathcal{R}(x,y) \vee \mathcal{P}(y)$.

As all non-unit clauses of a typical input set contain a selected literal, all definitional clauses

$\mathcal{P}(a)$	
$\neg Q_\psi(x)^+ \vee \neg P_p(x)^+$	if $\psi = \neg p$
$\neg Q_\psi(x)^+ \vee \mathcal{P}(x)\ [\vee \mathcal{P}(x)]$	if $\psi = \phi_1 \wedge \phi_2$ $[\psi = \phi_1 \vee \phi_2]$
$\neg Q_\psi(x)^+ \vee \neg \mathcal{R}(x,y)^+\ [\vee \mathcal{P}(y)]$	if $\psi = [i]\bot$ $[\psi = [i]\phi]$
$\neg Q_\psi(x)^+\ [\vee \mathcal{P}(f(x))]$	if $\psi = \langle i \rangle \top$ $[\psi = \langle i \rangle \phi]$
$\neg Q_\psi(x)^+ \vee \mathcal{R}(x, f(x))$	

Figure 4. Schematic clausal forms for $\mathbf{K}_n$

can only be used as negative premises of resolution steps. To begin with, there is only one candidate for a positive premise, namely, the ground unit clause $Q_\varphi(a)$ (which representing the input formula φ). Inferences with such ground unary unit clauses produce ground clauses consisting of positive literals only, which are split into ground unit clauses. It can be shown that maximally split (non-empty) inferred clauses have one of two forms: $\mathcal{P}(s)$, or $\mathcal{R}(s, f(s))$, where s is a ground term [119]. In general, s is a nested non-constant functional ground term, which is typically avoided in resolution decision procedures based on an ordering refinement because, in most situations, nesting causes unbounded computations. For the class of clauses under consideration, however, any derived clause is smaller than its positive parent clauses with respect to a well-founded ordering which reflects the structure of the formula.

THEOREM 6 ([119, 121]). *Let φ be a $\mathbf{K}_n$ formula and let N be the clausal form of the formula* $\mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$. *Then*

1. *φ is unsatisfiable in $\mathbf{K}_n$ iff there is a refutation of N by R^{hyp}, and*
2. *any R^{hyp} derivation from N terminates.*

THEOREM 7 ([49]). *Let φ be a $\mathbf{K}_n$ formula. The space complexity for testing the satisfiability of a modal formula φ with R^{hyp} is bounded by $O(nd^m)$, where n is the number of symbols in φ, d is the number of different diamond subformulae in φ, and m is the modal depth of φ.*[2]

Formulae in $\mathbf{K}_n$ translate by the relational translation into the guarded fragment, in particular, into the two-variable guarded fragment $\mathbf{GF}^2$. It is not difficult to see that formulae in $\mathbf{K}_n$ are in fact translated into the subfragment $\mathbf{GF}^-$, introduced in [134]. Under the assumption that either (i) there is a bound on the arity of predicate symbols in $\mathbf{GF}^-$ formulae, or (ii) that each subformula of a $\mathbf{GF}^-$ formula has a bounded number of free variables, the satisfiability problem of $\mathbf{GF}^-$ is PSpace-complete, the same as for the satisfiability problem of $\mathbf{K}_n$. Obviously, there is a bound of two on the arity on predicate symbols occurring in the relational translation of modal formulae in $\mathbf{K}_n$. From these observations a well-known result follows.

THEOREM 8. *The computational complexity of the satisfiability problem of $\mathbf{K}_n$ is PSpace-complete.*

In [81] it is shown that R^{hyp} can be implemented as a modification of the main procedure of a standard (saturation based) first-order theorem prover with splitting (e.g. (M)SPASS [120, 174, 192, 194]) to provide a space optimal decision procedure for $\mathbf{GF}^-$. A direct consequence is the following.

THEOREM 9 ([81, 180]). *R^{hyp} can be turned into a polynomial space resolution decision procedure for $\mathbf{K}_n$.*

A more detailed description of how this can be done is given in Section 3.4.

Another interesting aspect of R^{hyp} is that it can polynomially simulate tableau algorithms [118, 119, 121]. In general, a proof system $\mathcal{A}$ *polynomially simulates* (*p-simulates*) a proof system $\mathcal{B}$ iff there is a function g, computable in polynomial time, mapping proofs of any given formula φ in $\mathcal{B}$ to proofs of φ in $\mathcal{A}$ [38]. To establish a correspondence between tableau proofs and derivations in R^{hyp}, we make use of the fact that each subformula ψ of a given modal formula φ corresponds to a predicate symbol Q_ψ in $\mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$. Every node w occurring in a tableau completion tree corresponds to a term t_w occurring in a R^{hyp} derivation. A formula ψ

[2]The *modal depth* of a formula φ is the maximal nesting of modal operators $\langle i \rangle$ or $[i]$ in φ.

occurring in a set labelling a node w corresponds to a unit clause $Q_\psi(t_w)$ and any edge between nodes w and v with label i in a completion tree corresponds to a unit clause $R_i(t_w, f(t_w))$ in a R^{hyp} derivation, where t_w is the term corresponding to node w and $f(t_w)$ is the term corresponding to node v, for some function symbol f. Given these correspondences, each application of a tableau expansion rule to a completion tree can be simulated by at most two applications of expansion rules in a R^{hyp} derivation.

This p-simulation result extends to tableau algorithms for many extension of $\mathbf{K}_n$, for example extensions by the modal axiom schemas $\mathbf{T}$, $\mathbf{D}$, $\mathbf{B}$, $\mathbf{4}$, and $\mathbf{5}$ [121]. It also extends to other forms of tableau and sequent-style calculi.

The notion of p-simulation leaves open the possibility that an algorithm based on the proof system $\mathcal{A}$ which p-simulates a proof system $\mathcal{B}$ would have to search a much larger search space to find a proof for a given formula than an algorithm based on $\mathcal{B}$. For R^{hyp}, however, it is possible to show that the search space corresponds to that of the tableau algorithm for $\mathbf{K}_n$ presented in Section 4.2 [121]. Related simulation results of tableau procedures for description logics can be found in [118, 119], see also [65]. All these simulation results provide valuable insights into the similarities and difference between tableau methods and resolution. On the one hand, the view presented is that many tableau algorithms are essentially hyperresolution with lazy translation to first-order logic. On the other hand, because of the generality of the setting (first-order logic) it is even possible to exploit the close link with hyperresolution and use it as a basis for systematically developing new tableau procedures. Using this approach, a new tableau decision procedure was essentially ‘read off’ in [49] from a translation-based hyperresolution decision procedure for an expressive PDL-style modal logic.

For the modal logic $\mathbf{K}_n$, an improved version of the relational translation is presented in [9]. In the original presentation, this translation consists of two steps, first mapping a formula from one multi-modal logic into another, and then applying the relational translation to it. Our presentation merges both steps into one. We uniquely associate a unary predicate symbol $P_{p,\sigma}$ with every propositional variable p and sequence σ of modalities. Similarly, we uniquely associate a binary predicate symbol R_σ with every sequence σ of modalities. Then the *tree(-based) relational translation* π_{tr} is defined as follows.

$$
\begin{aligned}
\pi_{tr}(\top, x, \sigma) &= \top & \pi_{tr}(\bot, x, \sigma) &= \bot \\
\pi_{tr}(p, x, \sigma) &= P_{p,\sigma}(x) & \pi_{tr}(\neg\varphi, x, \sigma) &= \neg\pi_{tr}(\varphi, x, \sigma) \\
\pi_{tr}(\varphi \star \psi, x, \sigma) &= \pi_{tr}(\varphi, x, \sigma) \star \pi_{tr}(\psi, x, \sigma) \quad \text{for } \star \in \{\wedge, \vee, \rightarrow, \leftrightarrow\} \\
\pi_{tr}([i]\varphi, x, \sigma) &= \forall y(R_{\sigma.i}(x, y) \rightarrow \pi_{tr}(\varphi, y, \sigma.i)) \\
\pi_{tr}(\langle i\rangle\varphi, x, \sigma) &= \exists y(R_{\sigma.i}(x, y) \wedge \pi_{tr}(\varphi, y, \sigma.i))
\end{aligned}
$$

The translation of a modal formula is given by $\pi_{tr}(\varphi, x, \epsilon)$. The tree relational translation can be viewed as incorporating a feature of the (optimised) functional translation into the relational translation. Whereas the relational translation uses a family of binary predicate symbols R_i, where i is a modal parameter, the tree relational translation uses a larger family of binary predicate symbols R_σ, where σ is a sequence of modal parameters representing a path from the initial world, to encode transitions between worlds. Another difference is that in the tree-based translation the σ are also encoded into the unary predicates.

THEOREM 10. *A modal formula φ is satisfiable in $\mathbf{K}_n$ iff $\pi_{tr}(\varphi, x, \epsilon)$ is first-order satisfiable.*

If we restrict ourselves to $\mathbf{K}$, that is, our logic has only one modality, then the sequence σ in the definition of π_{tr} only serves as a unary coding of the natural numbers. Thus, we can further

simplify the translation by using $\pi_{tr}(\varphi, x, 0)$ as translation of a modal formula and modifying the translation π_{tr} as follows.

$$\pi_{tr}([i]\varphi, x, \sigma) = \forall y(R_{\sigma+1}(x, y) \rightarrow \pi_{tr}(\varphi, y, \sigma{+}1))$$
$$\pi_{tr}(\langle i\rangle\varphi, x, \sigma) = \exists y(R_{\sigma+1}(x, y) \wedge \pi_{tr}(\varphi, y, \sigma{+}1))$$

All other cases in the definition of π_{tr} remain unchanged. In [8] it is shown that we can use the following ordering to ensure that derivations in $R_S^{\succ}$ from the clausal form of $\pi_{tr}(\varphi, x, 0)$ of a $\mathbf{K}$ formula φ terminates: $P_\sigma(s_1, \ldots, s_n) \succ Q_\delta(t_1, \ldots, t_m)$ if either $\sigma < \delta$, or $\sigma = \delta$ and $n > m$. This result can easily be extended to $\mathbf{K}_n$ by defining the ordering $\succ$ as $P_\sigma(s_1, \ldots, s_n) \succ Q_\delta(t_1, \ldots, t_m)$ if either $\mathit{length}(\sigma) < \mathit{length}(\delta)$ or $\mathit{length}(\sigma) = \mathit{length}(\delta)$ and $n > m$. This ordering restriction can be seen to force a kind of top-down approach.

THEOREM 11. *Let φ be a modal formula in $\mathbf{K}_n$ and let N be the clausal form of $\pi_{tr}(\varphi, x, \epsilon)$. Then any derivation from N in R^{ord} (up to redundancy) without splitting terminates.*

One of the interesting aspects of this result is that it does not require the use of structural transformation (nor does it require the use of the splitting rule, but condensing is crucial).

3.2 *Global satisfiability, non-logical axioms, transitive modalities, and* $\mathbf{K4}_n$

So far we have focused on *local satisfiability*, that is, the problem whether for a given modal formula φ, there exists a model $\mathfrak{M} = \langle W, R, V\rangle$ and a world $w \in W$ such that $\mathfrak{M}, w \models \varphi$. Now we turn to the problem of determining whether there is a model $\mathfrak{M}$ such that for all worlds $w \in W$ $\mathfrak{M}, w \models \varphi$, i.e. is φ globally true in some model. The modifications necessary to allows us to determine the *global satisfiability* of a modal formula in $\mathbf{K}_n$ based on the relational translation are minimal: φ is globally satisfiable in $\mathbf{K}_n$ iff $\forall x\, \pi_r(\varphi, x)$ is first-order satisfiable. Is it straightforward to see that the clausal form N of $\mathrm{Def}_{\Lambda_m(\varphi)}(\forall x\, \pi_r(\varphi, x))$ still consists only of $\mathbf{DL}^*$ clauses. Consequently, R^{ord} can decide the satisfiability of the clause set N.

THEOREM 12. *Let Σ be an arbitrary set of axiom schemas such that $\mathbf{K}_n\Sigma$ is complete and the clausal form of the relational frame properties F_Σ corresponding to the axiom schemas in Σ is in $\mathbf{DL}^*$. Let φ be a modal formula in $\mathbf{K}_n$ and let N be the clausal form of $F_{\Sigma,\varphi} = F_\Sigma \wedge \mathrm{Def}_{\Lambda_m(\varphi)}(\forall x\, \pi_r(\varphi, x))$. Then*

1. *φ is not globally satisfiable in $\mathbf{K}_n\Sigma$ iff $F_{\Sigma,\varphi}$ is not first-order satisfiable iff there is a refutation of N by R^{ord},*
2. *N is a set of $\mathbf{DL}^*$ clauses, and*
3. *any derivation from N in R^{ord} (up to redundancy) terminates in double exponential time and in exponential time, if Σ is empty.*

For local and global $\mathbf{K}_n$-satisfiability w.r.t. to a background theory of non-logical axioms the same result is true. Furthermore the complexity of ordered resolution is optimal.

THEOREM 13. *Let $\Gamma = \{\gamma_1, \ldots, \gamma_n\}$ be a finite set of of modal formulae and let φ be a modal formula. Let $F_{\Gamma,\varphi}$ be the first-order formula $\exists x\, \pi_r(\varphi, x) \wedge \bigwedge_{i=1,\ldots,n} \forall x\, \pi_r(\gamma_i, x)$ and let N be the clausal form of $\mathrm{Def}_{\Lambda_{\Gamma,\varphi}}(F_{\Gamma,\varphi})$, where $\Lambda_{\Gamma,\varphi}$ contains all non-atomic positions of $F_{\Gamma,\varphi}$. Then*

1. *φ is unsatisfiable in $\mathbf{K}_n$ w.r.t. Γ iff $F_{\Gamma,\varphi}$ is first-order unsatisfiable iff there is a refutation of N by R^{ord},*

2. *N is a set of $\mathbf{DL}^*$ clauses, and*

3. *any derivation from N in $\mathcal{R}^{\mathrm{ord}}$ (up to redundancy) terminates in exponential time.*

In contrast to $\mathcal{R}^{\mathrm{ord}}$, derivations in $\mathcal{R}^{\mathrm{hyp}}$ from the clausal form of $\mathrm{Def}_{\Lambda_{\Gamma,\varphi}}(F_{\Gamma,\varphi})$, as defined in Theorem 13, are not guaranteed to terminate. Tableau algorithms face the same problem, and the solution typically used is a technique called *blocking*. See Sections 4.3 and 4.4 for details. This technique can be transferred to the context of first-order clausal logic and $\mathcal{R}^{\mathrm{hyp}}$ derivations as described in [118]. It involves the addition of a *blocking rule* which at certain points during a derivation adds equations $t_1 \approx t_2$ between ground terms t_1 and t_2 to the clause set, rendering inferences on literals involving the greater of the two terms redundant. One of the interesting properties of this approach is that completeness follows immediately from the general completeness result for $\mathcal{R}^{\mathrm{hyp}}$ [18], only soundness needs to be established. Another way of combining blocking with $\mathcal{R}^{\mathrm{hyp}}$ is presented in [27]. In addition, optimisations techniques like *lazy unfolding* and *absorption*, which will be discussed in detail in Section 4.4, are in-built and therefore free in $\mathcal{R}^{\mathrm{hyp}}$.

However, for $\mathbf{K}_n$ extended with axiom schemas sometimes quite different approaches are required. For example the formula $\forall xyz\,((R_i(x,y) \wedge R_i(y,z)) \rightarrow R_i(x,z))$ stating the transitivity of R_i is not a formula in any of the relevant decidable first-order fragments. The corresponding clause does not belong to $\mathbf{DL}^*$ either. To handle transitive modal logics one possibility is to use the *ordered chaining calculus* introduced in [15] for binary relations satisfying the general schema $R_i \circ R_j \subseteq R_k$. A decision procedure for a first-order fragment covering the modal logics $\mathbf{K4}$, $\mathbf{KD4}$, and $\mathbf{KT4}$, and their multi-modal variants, which is based on ordered chaining, is presented in [77]. Recent work in [124] presents an extension of $\mathcal{R}^{\succ}_{S}$ which can decide the guarded fragment with transitive guards. This provides a decision procedure for all modal logics translatable into this fragment.

In the following we present another approach, the *axiomatic translation* approach [181], which allows a variety of modal logics with transitive modalities to be embedded in $\mathbf{DL}^*$. Consequently this allows the use of $\mathcal{R}^{\mathrm{ord}}$ to decide these logics. This method is not restricted to transitive modal logics and applies to a large class of modal logics.

Remember that structural transformation introduces for each modal subformula $[i]\psi$ of a modal formula φ a predicate symbol $Q_{[i]\varphi}$ in $\pi_r(\varphi, x)$. The general principle of the axiomatic translation approach for $\mathbf{K4}_n$ is the following. For every transitive modality $[i]$ and every subformula $[i]\psi$ of the formula φ, add the first-order formula

$$(A_{\mathbf{4}}) \qquad \forall xy\,((Q_{[i]\psi}(x) \wedge R_i(x,y)) \rightarrow Q_{[i]\psi}(y)).$$

to the translation. The main technical question with the axiomatic translation principle is to know how many instances of such a ‘schema formula’ need to be added to the translation. In the Hilbert axiomatisation, axioms such as $\mathbf{4}$ are valid for all substitution instances. Since we do not have access to a substitution rule, we need to make sure from the outset that enough instances of the schema formulae are present in the translation of φ. (Of course, this does not preclude a lazy implementation which delays the translation of subformulae and the inclusion of instances of schema formulae until absolutely necessary.) The clausal form of $A_{\mathbf{4}}$ is $\neg Q_{[i]\psi}(x) \vee \neg R_i(x,y) \vee Q_{[i]\psi}(y)$, which is a $\mathbf{DL}^*$ clause (and a guarded clause).

THEOREM 14. *Let φ be a modal formula and Ξ the set of all subformulae of the form $[i]\psi$ of φ. Let $F_{\mathbf{4}}$ be the first-order formula $\bigwedge_{[i]\psi\in\Xi} \forall xy\,((Q_{[i]\psi}(x) \wedge R_i(x,y)) \rightarrow Q_{[i]\psi}(y))$. Let N be the clausal form of $F_{\mathbf{4},\varphi} = F_{\mathbf{4}} \wedge \mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$. Then*

1. *φ is unsatisfiable in $\mathbf{K4}_n$ iff $F_{\mathbf{4},\varphi}$ is first-order unsatisfiable iff there is a refutation of N by R^{ord},*

2. *N is a set of $\mathbf{DL}^*$ clauses, and*

3. *any derivation from N in R^{ord} (up to redundancy) terminates in exponential time.*

The same result is true for global satisfiability in $\mathbf{K4}_n$ and also reasoning with respect to non-logical axioms. Theorem 14 reduces reasoning in $\mathbf{K4}_n$ to reasoning in $\mathbf{K}_n$ with background theories. Consequently, R^{hyp} combined with a blocking rule provides an alternative decision procedure for $\mathbf{K4}_n$.

3.3 *Converse modalities and the modal logics $\mathbf{KB}_n$ and $\mathbf{KB4}_n$*

Extending the results of Section 3.1 to modal logics with *converse modalities* or to the modal logics $\mathbf{KB}_n$ and $\mathbf{KB4}_n$ is straightforward. For converse modalities we have to extend our definition of the relational translation π_r as follows:

$$\pi_r([i^\smile]\varphi, x) = \forall y\,(R_i(y,x) \to \pi_r(\varphi, y)) \qquad \pi_r(\langle i^\smile\rangle\varphi, x) = \exists y\,(R_i(y,x) \wedge \pi_r(\varphi, y))$$

Then, Theorem 13 extends to the following.

THEOREM 15. *Let $\Gamma = \{\gamma_1, \ldots, \gamma_n\}$ be a finite set of of $\mathbf{K}_n^\smile$ formulae and let φ be a $\mathbf{K}_n^\smile$ formula. Let $F_{\Gamma,\varphi}$ be the first-order formula $\exists x\,\pi_r(\varphi, x) \wedge \bigwedge_{i=1,\ldots,n} \forall x\,\pi_r(\gamma_i, x))$. Let N be the clausal form of $\mathrm{Def}_{\Lambda_{\Gamma,\varphi}}(F_{\Gamma,\varphi})$ where $\Lambda_{\Gamma,\varphi}$ contain all non-atomic positions of $F_{\Gamma,\varphi}$. Then*

1. *φ is unsatisfiable in $\mathbf{K}_n^\smile$ w.r.t. Γ iff $F_{\Gamma,\varphi}$ is first-order unsatisfiable iff there is a refutation of N by R^{ord},*

2. *N is a set of $\mathbf{DL}^*$ clauses, and*

3. *any derivation from N in R^{ord} (up to redundancy) terminates in exponential time.*

In the case of the modal logic $\mathbf{KB}_n$ we extend the relational translation (or the axiomatic translation) by adding the relational frame property $R_{\mathbf{B}}$ corresponding to $\mathbf{B}$, namely $\forall xy\,(R_i(x,y) \to R_i(y,x))$, to the translation of φ. Finally, in the case of $\mathbf{KB4}_n$ we restrict ourselves to the axiomatic translation and again add the relational frame property $R_{\mathbf{B}}$ to the translation of φ.

In all these cases, the clausal form N of the translated modal formulae as well as that of $R_{\mathbf{B}}$ consists only of $\mathbf{DL}^*$ clauses. Consequently, R^{ord} provides us with a decision procedure for the satisfiability of N.

THEOREM 16. *Let φ be a $\mathbf{KB}_n$ formula and let N be the clausal form of the first-order formula $F_{\mathbf{B},\varphi} = \forall xy\,(R_i(x,y) \to R_i(y,x)) \wedge \mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi, x))$. Then*

1. *φ is unsatisfiable in $\mathbf{KB}_n$ iff $F_{\mathbf{B},\varphi}$ is first-order unsatisfiable iff there is a refutation of N by R^{ord},*

2. *N is a set of $\mathbf{DL}^*$ clauses, and*

3. *any derivation from N in R^{ord} (up to redundancy) terminates in exponential time.*

The result extends easily to global satisfiability and non-logical axioms. So, the axiomatic translation for $\mathbf{KB}$ is another reduction into $\mathbf{DL}^*$, but also $\mathbf{GF}^2$, and R^{ord} is an exponential time decision procedure [181]. Besides R^{ord} we can also use R^{hyp} to decide the satisfiability of N (this is a consequence of the main results in [82, 83]).

THEOREM 17. *Let φ be a $\mathbf{KB4}_n$ formula and let Ξ be the set of all subformulae of the form $[i]\psi$ of φ. Let $F_{\mathbf{B4}}$ be the first-order formula*

$$\forall xy\,(R_i(x,y) \rightarrow R_i(y,x)) \wedge \bigwedge_{[i]\psi\in\Xi} \forall xy\,((Q_{[i]\psi}(x) \wedge R_i(x,y)) \rightarrow Q_{[i]\psi}(y)).$$

Let N be the clausal form of $F_{\mathbf{B4},\varphi} = F_{\mathbf{B4}} \wedge \mathrm{Def}_{\Lambda_m(\varphi)}(\pi_r(\varphi,x))$. Then

1. *φ is unsatisfiable in $\mathbf{KB4}_n$ iff $F_{\mathbf{B4},\varphi}$ is first-order unsatisfiable iff there is a refutation of N by R^{ord},*
2. *N is a set of $\mathbf{DL}^*$ clauses, and*
3. *any derivation from N in R^{ord} (up to redundancy) terminates in exponential time.*

As described in Section 3.1, in the case of the optimised functional translation, we add so-called *functional frame properties* in the form of (conditional) equations between path terms to accommodate additional axiom schemas like $\mathbf{4}$ and $\mathbf{5}$. Alternatively, one can replace syntactic unification in the inference rules of R with *theory unification* [175, 176]. The resulting calculus is called *theory resolution*. So far, the only decision procedures for modal logics like $\mathbf{K4}_n$ or $\mathbf{KB}_n$ based on theory resolution make use of a term depth bound, that is, any derived clause involving terms of depth greater than a pre-computed bound dependent on the modal formula whose satisfiability is tested will be removed [175, 178].

This section is an incomplete discussion of the different uses of first-order resolution. Due to space restrictions we have only been able to present a few of the translations that are available and have omitted a lot of details. Other translation methods are surveyed in [64, 148]. See also the surveys [65, 49, 122, 180, 182].

3.4 Implementation and optimisation

In this section, we give a brief overview of the implementation of the resolution calculus presented in Section 3.1 and discuss some of the issues involved in using such an implementation for theorem proving in modal logic. For further details on the implementation of first-order theorem provers see e.g. [193, 169, 183].

The procedure ResolutionProver presented in Figure 5 is the main procedure implementing the calculus $R^{\succ}_{S}$. The input is a set N of clauses. The output on termination is a proof of unsatisfiability or a saturated clause set. The procedure operates on two sets of clauses, $\mathcal{US}$ and $\mathcal{WO}$ (the set of *usable clauses* and the set of *worked-off clauses*). The set $\mathcal{WO}$ contains all the clauses that have already been used as premises in inference steps (or can never be used as premises) and the set $\mathcal{US}$ contains all the clauses that still need to be considered as premises. In our particular case, the input set N is the clausal form of the translation of some modal formula.

The procedure proceeds as follows. First, the input set N is simplified by the function ired, that is, all tautologies and strictly subsumed clauses are deleted from N (this is achieved by the two argument ired function). The set N is then divided into two sets: the *usable clauses* $\mathcal{US}$ and the *worked-off clauses* $\mathcal{WO}$. The set $\mathcal{US}$ contains all the clauses which are candidates for

```
Procedure ResolutionProver(N)
local WO, US, NEW, Given;
begin
  WO := ∅;
  US := ired(N,N);
  Stack := emptystack();
  while (US ≠ ∅) and (⊥ ∉ US or not stackempty(Stack))
  do
    if (⊥ ∈ US) then
      (Stack, US, WO) := backtrack(Stack, US,WO);
    else
      begin
        (Given, US) := choose(US);
        if (splittable (Given)) then
          begin
            NEW := firstsplitcase(Given);
            Stack := push(Stack, secondsplitcase(Given))
          end
        else
          begin
            WO := WO ∪ {Given};
            NEW := inf(Given, WO);
          end
      end
      (NEW, WO, US) := ired(NEW, WO, US);
  return(US)
end
```

Figure 5. Standard inference loop in a saturation theorem prover

inferences and the set $\mathcal{WO}$ contains all the clauses that have already been selected for inferences. Initially, the set $\mathcal{WO}$ is the empty set, while $\mathcal{US}$ contains all clauses of N remaining after application of ired. Next the procedure enters the main inference loop in which it remains while the set $\mathcal{US}$ is not empty and the empty clause $\perp$ has not been derived or there are still alternative branches of the derivation tree that need to be considered. Within the main loop it is first checked whether the set $\mathcal{US}$ contains the empty clause. If so, the current branch of the derivation is a closed branch and backtracking takes the computation to a different branch of the derivation. Otherwise the function choose selects a clause from $\mathcal{US}$. This clause is called the *given clause*. If the splitting rule can be applied to the given clause, one of its two split components is taken to be the newly derived clause, which is stored in $\mathcal{NEW}$, and the other split component is pushed onto a stack. Basically, this creates a new branch in the derivation tree that is explored later, if it turns out that the current branch can be closed. This corresponds to a depth-first construction of the derivation tree. If the splitting rule cannot be applied, we add the given clause to the set $\mathcal{WO}$ and compute all conclusions of inferences by resolution and factoring between the given clause and clauses in $\mathcal{WO}$ using the function inf. After removing redundant clauses from the sets $\mathcal{US}$, $\mathcal{WO}$, as well as the newly derived clauses (this is achieved by the three argument ired function), the remaining new clauses are added to the set $\mathcal{US}$, and a new iteration of the main

loop is entered.

Important points to note about the ResolutionProver procedure are the following. First, in the main inference loop, the function inf computes all conclusions derivable from the given clause and clauses in $\mathcal{WO}$. For example, suppose we use the R^{hyp} instance of $R^{\succ}_{S}$. Let the set $\mathcal{US}$ contain the clauses $Q_{\langle 1\rangle\varphi}(t)$, $D_0 = \neg Q_{\langle 1\rangle\varphi}(x) \vee R_1(x, f(x))$, and $D_1 = \neg Q_{\langle 1\rangle\varphi}(x) \vee Q_{\varphi}(f(x))$, as well as n clauses of the form $C_{i+1} = Q_{[1]\psi_i}(t)$ and $D_{i+1} = \neg Q_{[1]\psi_i}(x) \vee \neg R_i(x, y) \vee Q_{\psi_i}(y)$, for $1 \leq i \leq n$. If we first choose each D_i, $0 \leq i \leq n{+}1$ they are simply moved to $\mathcal{WO}$, without any new clause being inferred from them. The same is true if we continue by choosing each C_{i+1} in turn. Finally, when we choose $Q_{\langle 1\rangle\varphi}(t)$, the clauses $R_i(t, f(t))$ and $Q_{\varphi}(f(t))$ is computed by inf and moved to $\mathcal{US}$. When $R_1(t, f(t))$ becomes the given clause, inf computes in one step the clauses $Q_{\psi_i}(f(t))$, for $1 \leq i \leq n$. This corresponds to the application of the tableau inference rule

$$\frac{w : \langle i\rangle\varphi \qquad w : [i]\psi_1 \quad \cdots \quad w : [i]\psi_n}{v : \varphi \qquad v : \psi_1 \quad \cdots \quad v : \psi_n}$$

where v is an i-successor of w. However, if we choose clauses starting with D_0, followed by D_1, and then $Q_{\langle 1\rangle\varphi}(t)$, inf infers $R_1(t, f(t))$ and $Q_{\varphi}(f(t))$, corresponding to an application of the $\Diamond$-rule in the tableau algorithm defined in Figure 8. If we proceed by choosing $R_1(t, f(t))$, then each C_{i+1} directly followed by D_{i+1}, inf infers $Q_{\psi_i}(f(t))$, corresponding to a series of applications of the $\Box$-rule in Figure 8. This shows that the way in which clauses are selected by choose gives us added flexibility in how the search for a refutation is directed.

Second, the ordering $\succ$ and the selection function S only influence the function inf without changing what has just been said. Concerning the selection function S the user is able to select among a fixed set of pre-defined selection functions. The selection function which selects every negative literal in any clause is usually included in that set. Concerning the ordering $\succ$, state-of-the-art first-order theorem provers standardly contain implementations of recursive path orderings, lexicographic path orderings or Knuth Bendix orderings, which are parameterised by an ordering on the signature of the input clause set N, which the user can specify. Refinements of the particular ordering $\succ$ defined in Section 3.1 can be obtained by either recursive path orderings or Knuth Bendix orderings (definitions of orderings and ordering extensions can be found in [52]).

Third, the remaining functions in ResolutionProver are firstsplitcase and secondslitcase which basically determine the order in which branches of a derivation tree are investigated. Again, it is possible to exercise control on this order by using some heuristic.

Fourth, the implementation of backtrack has significant influence on the performance of the prover. On the stack we only store the second split component that may need to be considered at a later point, but not the current state of $\mathcal{WO}$ and $\mathcal{US}$. The information required to return $\mathcal{WO}$ and $\mathcal{US}$ to the correct state on backtracking is stored in each clause, allowing us to remove clauses which are no longer derivable and restoring clauses which are no longer redundant after backtracking. When we derive a contradiction it is not necessary to backtrack to the state associated with the split component currently on top of the stack. Instead more intelligent forms of backtracking are possible. For example, the theorem prover SPASS [194] implements *branch condensing*. Here, on backtracking, all first components not used to derive a contradiction are removed from the set $\mathcal{US}$ as well as all the corresponding second split components on the stack. The prover then backtracks to the second split component which is now on top of the stack, removing clauses which are no longer derivable and restoring clauses which are no longer redundant. For further details see [193]. This form of intelligent backtracking is closely related but not identical to *conflict-directed backjumping* [78, 164]. See also Section 4.2.

An alternative to explicit splitting is *splitting through new propositional variables* [168] implemented in the theorem prover VAMPIRE [169] or the generalisation called *separation* in [179]. In the splitting through propositional variables approach, a clause $C \vee D$ with variable-disjoint components C and D is replaced with two clauses $C \vee p$ and $D \vee \neg p$, where p is a new propositional variable called a *split propositional variable*. The ordering $\succ$ and the selection function S are extended to ensure that p is minimal in $D \vee \neg p$ and $\neg p$ is selected in D. This makes it impossible for the clause $C \vee D$ to be derived from the two new clauses and also blocks $D \vee \neg p$ for inferences until we derive a clause in which p is maximal. The derivation of a contradiction from the split component C in explicit splitting then corresponds to the derivation of a clause $E \vee p$ where E consists solely of split propositional variables. If p is maximal in $E \vee p$ we can derive $E \vee D$ which corresponds to backtracking to the branch of the derivation in which D is true. Note that this again is a form of intelligent backtracking since $E \vee p$ is a representation of all the split components involved in deriving a 'contradiction'. Thus, in backtracking we ignore all other splits not represented by a split propositional variable in $E \vee p$. Unlike branch condensing and (conflict-driven) backjumping, however, those splits are still present. A disadvantage of splitting through new propositional symbols is that subsumption and reductions such as unit propagation are not as effective as for explicit splitting. De Nivelle [47] has suggested modifications of the standard inference and redundancy elimination rules which take account of split propositional variables.

Both explicit splitting and splitting through new propositional variables split a clause $C \vee D$ into split components C and D. The two branches of the derivation do not necessarily investigate disjoint sets of Kripke/first-order models. For variants of splitting we have the option to add the negation of C, $\neg C$, to the branch on which D is true. However, in contrast to propositional logic, the benefit is less obvious. For example, assume that C is $Q_{[i]p}(a)$ and that the clause set to which we add $\neg C = \neg Q_{[i]p}(a)$ contains already the unit clause $Q_{[i](p\wedge q)}(a)$. We can propagate the unit clause $\neg C$ to all clauses in the clause set which removes all occurrences of $Q_{[i]p}(a)$ from those clauses. However, the contradiction between $\neg Q_{[i]p}(a)$ and $Q_{[i](p\wedge q)}(a)$ is not detected. This is true even if the clause set contains the definitional clauses $Q_{[i]p}(x) \vee R(x, f(x))$, $Q_{[i]p}(x) \vee \neg P_p(f(x))$, which we can use to derive $R(a, f(a))$ and $\neg P_p(f(a))$. Only when $R(a, f(a))$ and $Q_{[i](p\wedge q)}(a)$ together with the definition clauses $\neg Q_{[i](p\wedge q)}(x) \vee \neg R(x, y) \vee P_p(y)$ (and $\neg Q_{[i](p\wedge q)}(x) \vee \neg R(x, y) \vee P_q(y)$) are used to derive $P_p(f(a))$, is a contradiction detected. Note also that the clause $R(a, f(a))$ might trigger the derivation of a large number of additional clauses which would not be derived in the absence of $\neg Q_{[i]p}(a)$ or its definitional clauses. In general, the computational effort expended to this point might be great without a guarantee that there is a payoff. Termination is however not compromised.

Used as a procedure to test the satisfiability of a $\mathbf{K}_n$ formula φ with any refinement of $R_S^{\succ}$ and any of the translations presented in this section, ResolutionProver requires exponential space in the size of φ. In [81] we have shown how ResolutionProver can be turned into a space optimal decision procedure for the class $\mathbf{GF}^{\,-}$. This modified procedure provides also a polynomial space decision procedure for the relational translation of $\mathbf{K}_n$ and $\mathbf{KB}_n$ formulae. If we focus on $\mathbf{K}_n$, then a simple modification of ResolutionProver as described in Figure 6 is sufficient. The procedure uses an additional local variable t which stores the term we currently focus on. Initially it is the only ground term in N, and is returned by groundTerm. The procedure choose selects the given clauses in a particular order. It starts by choosing non-ground clauses. This transfers all definitional clauses from $\mathcal{US}$ to $\mathcal{WO}$ without any inference steps being performed. Then it selects ground clauses in an order which ensures that the derivation corresponds to a depth-first exploration of the completion tree in a tableau derivation. Finally, ired is modified so

Procedure ResolutionProver(N)
local $\mathcal{WO}, \mathcal{US}, \mathcal{NEW}$, Given, t;
begin
  t := groundTerm(N);
  ...
  (Given, $\mathcal{US}$, t) := choose($\mathcal{US}$, t);
  ...
  ($\mathcal{NEW}, \mathcal{WO}, \mathcal{US}$) :=
      ired($\mathcal{NEW}, \mathcal{WO}, \mathcal{US}$, t);
  ...
end

Procedure choose($\mathcal{US}$, t)
begin
  if ($C \in \mathcal{US}$ where C is non-ground) **then**
    return($C, \mathcal{US} - \{C\}, t$)
  else if ($Q(t) \vee C \in \mathcal{US}$) **then**
    return($Q(t) \vee C, \mathcal{US} - \{Q(t) \vee C\}, t$)
  else if ($R_i(t, s) \in \mathcal{US}$) **then**
    return($R_i(t, s), \mathcal{US} - \{R_i(t, s)\}, s$)
  else if ($R_i(u, v) \in \mathcal{US}$ with v having greatest depth in $\mathcal{US}$) **then**
    return($R_i(u, v), \mathcal{US} - \{R_i(u, v)\}, v$)
end

Figure 6. Modified procedures for a polynomial space decision procedure for $\mathbf{K}_n$

that it removes from $\mathcal{WO}$ all clauses containing argument terms which are not subterms of the term t. This modification ensures that the information on terms which have been fully explored and does not contribute to a refutation is removed, bringing the space requirements down to polynomial space.

3.5 *Other extensions (counting, nominals)*

The modal logics $\mathbf{K}_n^c$ and $\mathbf{K}_n^{\smile,c}$ with graded modalities and the modal logic $\mathbf{K}_n^o$ with nominals can be translated to first-order logic using a number of different embeddings. The simplest one is an extension of the relational translation as follows (the symbol o_i denotes a nominal).

$$\pi_r(\langle i\rangle_m\varphi, x) = \exists y_1 \ldots y_m\, (R_i(x, y_1) \wedge \ldots \wedge R_i(x, y_m) \wedge y_1 \not\approx y_2 \wedge \ldots \wedge y_{m-1} \not\approx y_m)$$
$$\pi_r([i]_m\varphi, x) = \forall y_1 \ldots y_{m+1}\, ((R_i(x, y_1) \wedge \ldots \wedge R_i(x,y_{m+1})) \rightarrow (y_1 \approx y_2 \vee \ldots \vee y_n \approx y_{m+1}))$$
$$\pi_r(o_i, x) = (x \approx o_i)$$

The superposition calculus [14] and the basic superposition calculus [17] are extensions of $R_S^{\succ}$ with rules for equality reasoning. In [113, 112] it is shown that the basic superposition calculus can be used to decide the satisfiability of knowledge bases in the $\mathcal{SHIQ}$ description logic. It follows that it can also be used to decide the satisfiability of formulae in $\mathbf{K}_n^c$ and $\mathbf{K}_n^{\smile,c}$.

An extension of the optimised functional translation to $\mathbf{K}_n^c$ is presented and shown to be sound and complete in [150].

4 TABLEAU-BASED ALGORITHMS

In this section, we describe tableau-based decision procedures for modal logics and discuss their complexity and implementation issues. First, we discuss various choices for presenting tableau algorithms in general, and then present the basic tableau algorithm for $\mathbf{K}_n$ together with a detailed discussion of implementation and optimisation issues. Next, we modify this algorithm to handle $\mathbf{K4}_n$, background theories, converse modalities, and their combinations, and point out relevant modifications concerning the implementation and optimisation.

Intuitively, a tableau algorithm tries to construct, for an input formula φ, a model of φ; i.e., to decide the validity of a formula ψ, the tableau algorithm is started with $\neg\psi$. Depending on the modal logic, it is often convenient to consider an abstraction of models rather than models, namely a so-called *tableau*.

4.1 Tableau algorithms in general

We start with a description of a tableau algorithm for multi modal $\mathbf{K}_n$. Roughly speaking, this algorithm takes the input formula φ and deduces constraints on the model it is going to build by breaking it down into its sub-formulae. We will first describe different styles in which this attempt at a model construction has been described and relate them to each other.

The "breaking down" is realized through *tableau expansion rules*; quite often, we find one such expansion rule per logical constructor. For example, if we know that $\psi_1 \wedge \psi_2$ should be true in world w of the model we are constructing, then we break the conjunction down and explicitly add the constraints that each ψ_i has to be true in w. Next, we discuss the rules that handle box- and diamond formulae. Intuitively, if we know that $\langle i\rangle\psi$ should be true in world w, then we "generate" a witness world w', which is i-accessible from w and in which ψ is true. This can be formalised in different ways:

- for certain modal logics such as $\mathbf{K}_n$, one can first handle all formulae talking about a single world, then collect *all* constraints concerning another world and process these, and so on [129]. This approach is sometimes called "distructive" [92] (see also Chapter 2) because we can forget the constraints concerning an "old" world once we procede to the next one.

- *labelled* tableaux are closely related to propositional tableaux: they are sets of *labelled* formulae that partially describe a model: each formula is labelled with the world it should be true in (see Chapter 2 of this handbook). For example, the case where $\langle 1\rangle\psi$ is true in world w would translate to finding the labelled formula $w : \langle 1\rangle\psi$ in our tableau, and the $\Diamond$-rule adds labelled formulae $w' : \psi$ and $w1w'$, where the latter encodes that w' is 1-accessible from w. This information is required if we find, additionally, a formula of the form $w : [1]\psi'$: in this case, the $\Box$-rule adds $w' : \psi'$.

  Alternatively, one can store the information that w' is i-accessible from w in the labels by using appropriate sequences instead of atomic "names" w, w'. We start with the empty sequence labelling the input concept, and then append these labels, e.g., as follows: if a world is generated for a labelled formula $s : \langle i\rangle\psi$, we name this world $s(i,\psi)$ and simply introduce the new labelled formula $s(i,\psi) : \psi$. Please note that $si : \psi$ does not suffice because $\langle 1\rangle\psi \wedge \langle 1\rangle\neg\psi$ is satisfiable, but only in a world that has two *distinguished* 1-acccessible worlds.

- other tableau algorithms explicitly store the relational structure of the model (or tableau) they are building. More precisely, they work on labelled graphs (often trees) where nodes represent worlds and labelled edges represent i-accessibility. Moreover, nodes are labelled with the *set of formulae* that should be true in the corresponding world. Thus, instead of finding two labelled formulae $w' : \psi'$ and $w' : \psi''$ in a tableau, we would find both formulae in the label of the node w', written $\{\psi', \psi''\} \subseteq \mathcal{L}(w')$.

  An advantage of this approach is that all information concerning a single world is kept in the same place. For example, it allows for the detection of obvious inconsistencies such as $w : p$ and $w : \neg p$ by a test that is local to $\mathcal{L}(w)$. When considering logics with converse

or graded modalities, the advantages of this "one node per world" approach become even more pronounced. State-of-the-art implementations of modal tableau algorithms adopt this approach [159, 90], which is why we have chosen it for this section.

Similarly, the $\vee$-rule is often formulated using either branching or non-determinism in the model construction. For example, if we know that $\psi_1 \vee \psi_2$ should be true in w, then the $\vee$-rule can be formalised in the following two ways:

- we *branch* our model construction into two, one in which ψ_1 is true in w and one in which ψ_2 is true in w, and then continue with the construction of each branch independently.

  This is how non-deterministic constructors are handled in standard first order and modal logic tableau: the tableau rules expand a tree where each branching represents a non-deterministic choice, and thus where each path stands for a possible model.

- we non-deterministically choose one ψ_i to be true in w. This yields a non-deterministic algorithm which, when implemented, requires back-tracking to be complete.

  From a computational perspective, this approach is preferable since, in contrast to the above "branching" alternative, it preserves the useful "one node per world" property. Additionally, it can easily be adapted to exploit techniques developed for solving SAT problems, such as David-Putnam and related heuristics [41, 87]. State-of-the-art implementations of modal tableau algorithms handle disjunctions (and possibly other non-deterministic operators) in this way, and are combined with intelligent back-tracking (or back-jumping) and heuristics to make the "good" choice first, see Section 4.2.

The algorithms described in this chapter will use the latter, non-deterministic formulation, and will work on a single model/tableau at any world in time, where all information concerning each world is stored in a single node.

Figure 7 shows two example applications of different tableau algorithms to decide the satisfiability of the $\mathbf{K}$ formula $\psi = \langle 1 \rangle p \wedge \langle 1 \rangle q \wedge [1](\neg p \vee \neg q)$. On the left hand side, we show the result of a standard labelled tableau, where we use sequences as labels. First, we have broken down the conjunctions, then generated two new labels $(1, p)$ and $(1, q)$ for the two diamond formulae. Next, we have expanded the box formula for both new worlds, and finally branched for the disjunctions. The resulting tree stands for four different attempts to construct a model, one for each path from a leaf node to the root. Only the one ending in the filled node corresponds to a model since all other branches contain obvious inconsistencies: e.g., the first one contains both $(1, p) : p$ and $(1, p) : \neg p$.

On the right hand side, we show a (successfull) application of the non-deterministic version of a tableau algorithm working on trees. It has generated three nodes w_i with labels that are completely expanded sets of formulae. Here, the edges stand for the accessibility relations, i.e., w_2 and w_3 are 1-accessible from w_1. In contrast, on the left hand side, (the formulae along) one *path* in the tree represents a model, i.e., edges relate formulae that are true in the same model.

4.2 *Local satisfiability for multi modal* $\mathbf{K}_n$

Before we describe the algorithm, we introduce an appropriate data structure in which to represent models (and later tableaux). Firstly, it will be convenient to assume that all formulae descriptions are in *negation normal form* (see Section 2). The tableau algorithms presented in this section work on *completion trees*: a *completion tree* is a finite tree where each node x is

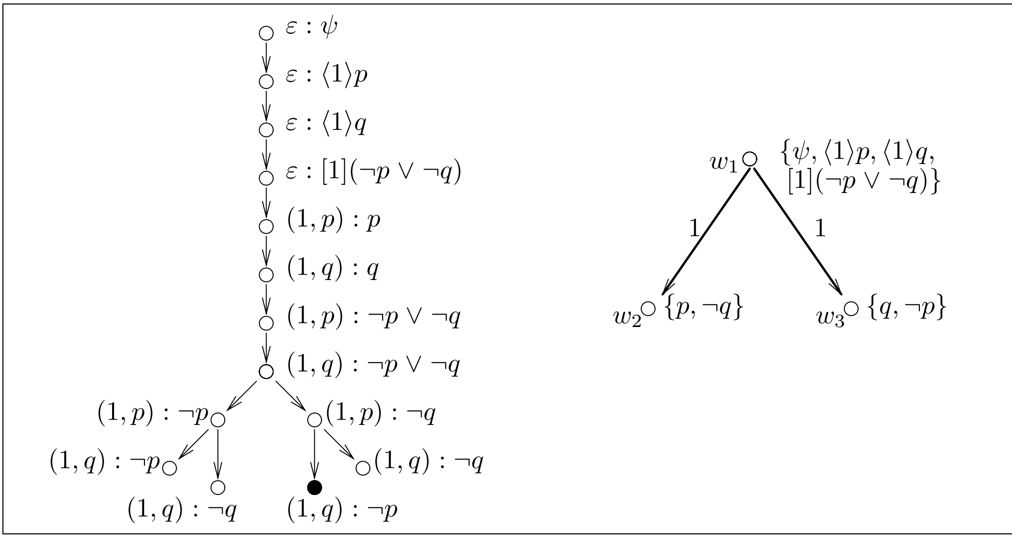

Figure 7. Two application of tableau algorithms to the same formula.

labelled with a *set* $\mathcal{L}(x)$ of formulae, and edges are labelled with modal parameters. A node y is called an *i-successor of* a node x if y is a successor of x and the edge from x to y is labelled with i. A completion tree is said to be *closed* if it contains a node x with $\{p, \neg p\} \subseteq \mathcal{L}(x)$; a completion tree that is not closed is *open*, and it is *complete* if no *expansion rule* applies—the expansion rules are given in Figure 8. Please note that they are formulated in such a way that, if a rule is applicable (i.e., the corresponding condition is satisfied by the current completion tree), then its application indeed changes the tree.

To decide the satisfiability of ϕ (in NNF), the tableau algorithm is started with a completion tree consisting of the root node x_0 only, with $\mathcal{L}(x_0) = \{\phi\}$. It applies the expansion rules until the completion tree becomes closed or complete, and returns "ϕ is satisfiable" if the expansion rules can be applied such that they yield a complete and open tableau, and "ϕ is unsatisfiable" otherwise. The "*can* be applied" formulation is due to the non-deterministic $\vee$-rule, as discussed in Section 4.1. Also, the algorithm does not fix any order in which the rules are to be applied, which means that an implementation has to/can chose a "good" one.

$\wedge$-rule:	*If*	there is a node x with $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_1, \psi_2\}$.
$\vee$-rule:	*If*	there is a node x with $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \cap \mathcal{L}(x) = \emptyset$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_i\}$ for some $i \in \{1, 2\}$.
$\Diamond$-rule:	*If*	there is a node x with $\langle i \rangle \psi \in \mathcal{L}(x)$ and x has no i-successor y with $\psi \in \mathcal{L}(y)$,
	then	create a new i-successor y of x with $\mathcal{L}(y) := \{\psi\}$.
$\Box$-rule:	*If*	there is a node x with $[i]\psi \in \mathcal{L}(x)$ and x has an i-successor y with $\psi \notin \mathcal{L}(y)$,
	then	$\mathcal{L}(y) := \mathcal{L}(y) \cup \{\psi\}$.

Figure 8. The expansion rules for $\mathbf{K}_n$.

Before discussing the properties of this algorithm, we would like to point out that the tableau

rule

$$\frac{w : \langle i \rangle \varphi \qquad w : [i]\psi_1 \quad \cdots \quad w : [i]\psi_n}{v : \varphi \qquad v : \psi_1 \quad \cdots \quad v : \psi_n}$$

mentioned in Section 3.4 of this chapter corresponds, in our notation, to

If there is a node x with $\{\langle i \rangle \varphi, [i]\psi_1, \ldots, [i]\psi_n\} \subseteq \mathcal{L}(x)$,
then create a new i-successor y of x with $\mathcal{L}(y) := \{\varphi, \psi_1, \ldots, \psi_n\}$.

The fact that our algorithm decides satisfiability of $\mathbf{K}_n$ formulae is an immediate consequence of the following lemma, for which we first need to define the semantics of completion trees. Let $\mathbf{T}$ be a completion tree, $\mathfrak{M} = \langle W, R, V \rangle$ a model, and π a (total) mapping from the nodes of $\mathbf{T}$ to W. Then $\mathfrak{M}$ is said to *satisfy* $\mathbf{T}$ *via* π if, for each node x in $\mathbf{T}$,

1. for each $\psi \in \mathcal{L}(x)$, we have $\mathfrak{M}, \pi(x) \models \psi$ and
2. for each i successor y of x, we have $R_i(\pi(x), \pi(y))$.

LEMMA 18. *Let ϕ be a $\mathbf{K}_n$ formula and $\mathbf{T}$ a completion tree generated by the tableau algorithm for ϕ.*

1 *When applied to ϕ, the tableau algorithm terminates.*

2 *If $\mathfrak{M}$ satisfies $\mathbf{T}$ via π and one of the expansion rules is applicable to $\mathbf{T}$, then this rule can be applied in such a way that it yields a $\mathbf{T}'$ satisfied by $\mathfrak{M}$ via π or an extension of π.*

3 *If $\mathbf{T}$ is complete, then there exists a model $\mathfrak{M}$ and a mapping π such that $\mathfrak{M}$ satisfies $\mathbf{T}$ via π iff $\mathbf{T}$ is open.*

Lemma 18.1 is due to the fact that (i) the breadth and depth of the completion tree are bounded linearly by the length of ϕ, (ii) node labels are sets of subformulae of ϕ, and (iii) the completion tree is built in a monotonic way, i.e., each rule strictly increases node labels or adds new nodes. Property (i) is due to the fact that there are at most $|\phi|$ diamond modalities in ϕ and that the maximal modal depth of formulae in node labels strictly decreases from a node to its (i-)successors. Lemma 18.2 is an immediate consequence of the semantics of $\mathbf{K}_n$ and completion trees. For example, let the $\Diamond$-rule be applicable to some $\mathbf{T}$ with $\langle i \rangle \psi \in \mathcal{L}(x)$, and let $\mathfrak{M}$ satisfy $\mathbf{T}$ via π. Hence $\mathfrak{M}, \pi(x) \models \langle i \rangle \psi$, and thus there exists some $w \in W$ with $R_i(\pi(x), w)$ and $\mathfrak{M}, w \models \psi$. As a consequence, we can extend π to $\pi(y) = w$ for y the newly introduced node, and $\mathfrak{M}$ satisfies the result of this rule application via (the extended) π. The “if” direction of Lemma 18.3 is easy since each open completion tree can be viewed as a model with W the set of nodes, $x \in V(p)$ if $p \in \mathcal{L}(x)$, and $R_i(x, y)$ if y is an i-successor of x. The only-if direction of Lemma 18.3 is trivial.

THEOREM 19. *The $\mathbf{K}_n$ tableau algorithm decides $\mathbf{K}_n$ satisfiability and can be implemented in polynomial space.*

As an immediate consequence of Lemma 18 and the fact that each model $\mathfrak{M}$ satisfying ψ is one that satisfies the initial completion tree (and vice versa), we thus have the first point of Theorem 19. The second part follows from the following observations. As a consequence of (i) and (ii) in the proof sketch of Lemma 18.1, we can store each branch of a completion tree in space bounded polynomially in the length of ψ. Next, we observe that we can consider each branch independently, and thus we can build the completion tree in a depth first manner, keeping only a single branch in memory at each point in time. Finally, our $\vee$-rule is non-deterministic, but it is known how to transform a non-deterministic polynomial space algorithm into a deterministic one that also runs in polynomial space [172].

Implementation Issues

Even this “simplest” modal logic $\mathbf{K}_n$ extends propositional logic, and thus the complexity is rather discouraging from an implementational perspective: we may have to consider a number of models (or completion trees) that is exponential in the size of the input formula. Moreover, because the completion tree is usually built in a depth first manner, with the $\wedge$- and $\vee$-rules being exhaustively applied to a given node before creating any modal successors with the $\Diamond$-rule, it is easy to find formulae with unsatisfiability “hidden” in the leaves of the tree for which a naive implementation will always exhibit pathological worst case behaviour. Consider, for example, the formula:

$$\phi = (p_1 \vee q_1) \wedge \ldots \wedge (p_n \vee q_n) \wedge \langle i \rangle \psi \wedge [i]\neg\psi. \tag{11}$$

There are 2^n different ways in which the combination of the $\wedge$-and $\vee$-rules can be applied to a node whose label is initialised with $\{\phi\}$, but in each case subsequent applications of the $\Diamond$- and the $\Box$-rules will eventually lead to a closed completion tree. A naive implementation of the trace technique with “chronological” backtracking search would consider all 2^n possible expansions before concluding that the input formula is unsatisfiable; this kind of unproductive backtracking search in often referred to as *thrashing*.

Fortunately, a wide range of optimisation techniques has been developed in order to improve the efficiency with which the algorithm explores the space of possible models [104, 103]. Although these optimisations may lead to a situation in which the worst case behaviour would actually be much worse than the theoretical worst case, empirical studies have shown that such optimised algorithms are very effective with *typical* formulae, i.e., formulae derived from applications. These techniques include normalisation and simplification, dependency directed backtracking, SAT based search techniques, simplification of node labels, heuristics and caching.

Normalisation and Simplification As usual, our description of the $\mathbf{K}_n$ tableau algorithm assumes that the input formula is in negation normal form (NNF); this simplifies the (description of the) algorithm, but it means that a completion tree will only be closed when a propositional variable and its negation occur in the same node label. For example, when testing the satisfiability of the formula $(p \wedge q) \wedge \neg(p \wedge q)$, the transformation into NNF would give $(p \wedge q) \wedge (\neg p \vee \neg q)$; in practise this means that, in spite of the “obvious” contradiction, backtracking search will be performed in order to determine that the formula is unsatisfiable.

For this reason, practical algorithms do not transform the input concept into NNF, but include a $\neg$-rule that performs a single (negation) normalisation step (e.g., applying the $\neg$-rule to $\neg(p \wedge q) \in \mathcal{L}(x)$ would cause $\neg p \vee \neg q$ to be added to $\mathcal{L}(x)$), and a completion tree is closed if it contains a node x with $\{\psi, \neg\psi\} \subseteq \mathcal{L}(x)$ for an arbitrary formula ψ. Moreover, in order to facilitate the detection of such closure conditions, the input formula is *normalised* and *simplified* so that logically equivalent formulae are more often syntactically equivalent. This is achieved by (recursively) applying a set of rewrite rules to the input formula, and by ordering conjuncts w.r.t. some total ordering. For example, we re-write $\vee$ and $\Diamond$ formulae as negated $\wedge$ and $\Box$ formulae, respectively; we remove redundant parentheses between conjunctions; we order conjuncts; and we simplify formulae using the following equivalences: $(\psi \wedge \psi) \leftrightarrow \psi$, $\neg\neg\psi \leftrightarrow \psi$, $(\psi \wedge \neg\psi \wedge \rho) \leftrightarrow \neg\top$, $(\psi \wedge \top) \leftrightarrow \psi$, $(\psi \wedge \neg\top) \leftrightarrow \neg\top$, and $[i]\top \leftrightarrow \top$.

If the above transformations are applied to the formula ϕ from the above example (11), then $\langle i \rangle\psi$ would be rewritten as $\neg[i]\neg\psi$, $\neg[i]\neg\psi \wedge [i]\neg\psi$ would be rewritten as $\neg\top$ and $(p_1 \vee q_1) \wedge \ldots \wedge (p_n \vee q_n) \wedge \neg\top$ would be rewritten as $\neg\top$, a formula that is trivially unsatisfiable.

If ψ_1 was added to $\mathcal{L}(x)$ by the		
$\wedge$-rule for $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$,	then $\mathsf{dep}(\psi_j, x) := \mathsf{dep}(\psi_1 \wedge \psi_2, x)$ for each $j \in \{1, 2\}$	
$\vee$-rule for $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$,	then $\mathsf{dep}(\psi_j, x) := \mathsf{dep}(\psi_1 \vee \psi_2, x) \cup \{b\}$ for each $j \in \{1, 2\}$	
$\Diamond$-rule for $\langle i \rangle \psi_1 \in \mathcal{L}(x')$,	then $\mathsf{dep}(\psi_1, x) := \mathsf{dep}(\langle i \rangle \psi_1, x')$	
$\Box$-rule for $[i]\psi_1 \in \mathcal{L}(x')$,	then $\mathsf{dep}(\psi_1, x) := \mathsf{dep}([i]\psi_1, x') \cup \mathsf{dep}(\langle i \rangle \psi_2, x')$	
	where x was generated by the $\Diamond$-rule for $\langle i \rangle \psi_2 \in \mathcal{L}(x')$	

Figure 9. Inductive definition of $\mathsf{dep}(\psi, x)$

Dependency Directed Backtracking As we saw in the above example (11), inherent unsatisfiability concealed in sub-formulae can lead to large amounts of unproductive backtracking search known as thrashing. Although the normalisation and simplification technique described above solved the problem for this example, this might not have been the case if the unsatisfiability caused by the modal sub-formulae had been slightly less trivial. Consider, e.g., the following, only slightly modified formula ϕ':

$$\phi' = (p_1 \vee q_1) \wedge \ldots \wedge (p_n \vee q_n) \wedge \langle i \rangle (\psi \wedge \rho) \wedge [i]\neg\psi. \tag{12}$$

To avoid an exponential search in the case of ϕ', a more sophisticated solution is required, and can be found by adapting a form of dependency directed backtracking called *backjumping*, which has also been used, e.g., in solving constraint satisfiability problems [19] and (in a slightly different form) in the HARP theorem prover [153].

Intuitively, backjumping works by labelling each formula ψ in the label of a node x with a dependency set $\mathsf{dep}(\psi, x)$ indicating the *branching points* (i.e., applications of the $\vee$-rule) on which it depends. In case the completion tree is closed because it contains some node x with $\{\psi, \neg\psi\} \in \mathcal{L}(x)$, we use $\mathsf{dep}(\psi, x)$ and $\mathsf{dep}(\neg\psi, x)$ to identify the most recent branching point b on which ψ or $\neg\psi$ depends. The algorithm can then *jump* back to b over intervening branching points *without* exploring any alternative branches (non-deterministic choices), and make a different non-deterministic choice which might not lead to the same closure condition being encountered. In case no such b exists, the closure did not depend on any non-deterministic choice, and the algorithm stops.

To be more precise, a *branching point* is simply a non-negative integer b indicating the b-th $\vee$-rule application in the run of the tableau algorithm. Initially, for x_0 the root node and ϕ the input formula, $\mathsf{dep}(\phi, x_0) := \emptyset$. The sets $\mathsf{dep}(\psi, x)$ are then defined inductively as shown in Figure 9. In this way, each formula in each node label is associated with a dependency set. If the completion tree is closed because it contains some node x with $\{\psi, \neg\psi\} \in \mathcal{L}(x)$, the *closure dependency set* $S := \mathsf{dep}(\psi, x) \cup \mathsf{dep}(\neg\psi, x)$, and the algorithm backtracks to the b-th $\vee$-rule application (or exits if $b = 0$).

The procedure for expanding a completion tree $\mathbf{T}$ is given in Figure 10. For an input formula ϕ, $\mathbf{T}$ is initialised to contain a single node x_0 with $\mathcal{L}(x_0) = \{\phi\}$ and $\mathsf{dep}(\phi, x_0) := \emptyset$; ϕ is satisfiable if Satisfiable($\mathbf{T}$,0) returns $\{-1\}$ and unsatisfiable otherwise. For example, when expanding the formula ϕ' from 12 above, the $\wedge$-rule might first be applied exhaustively via recursive calls to Satisfiable, resulting in $\{p_1 \vee q_1, \ldots, p_n \vee q_n, \langle i \rangle (\psi \wedge \rho), [i]\neg\psi\} \subseteq \mathcal{L}(x_0)$ and $\mathsf{dep}(\psi_j, x_0) = \emptyset$ for each formula $\psi_j \in \mathcal{L}(x_0)$. These dependencies reflect the fact that, so far, no non-deterministic choices have been made. A top-down and "left to right" strategy might then cause Branch to be called n times, with, for the j-th call, $b = j$, $f_1 = p_j$, $f_2 = q_j$ and

```
Procedure Satisfiable(T,b)
local f;
begin
  if for some node x in T, {ψ, ¬ψ} ∈ L(x)
  then
    return(dep(ψ, x) ∪ dep(¬ψ, x))
  else if T is complete then
    return({−1})
  else
    begin
      f := some unexpanded formula in node
      x in T
      if f is of the form ψ1 ∨ ψ2 then
        return(Branch(T,b                    +
        1,x,ψ1,ψ2,dep(f, x)))
      else
        begin
          expand f (as per Fig. 8 and 9)
          return(Satisfiable(T,b))
        end
    end

Figure 10. Procedure for tableau expansion with backjumping

$D = \emptyset$, so that $p_1, \ldots, p_n$ are added to $\mathcal{L}(x_0)$ with $\mathsf{dep}(p_j, x_0) = j$. Next, recursive calls to Satisfiable would expand: $\langle i\rangle(\psi \wedge \rho) \in \mathcal{L}(x_0)$, causing the generation of an i-successor x_1 of x_0 with $\mathcal{L}(x_1) = \{\psi \wedge \rho\}$ and $\mathsf{dep}(\psi \wedge \rho, x_1) = \emptyset$; $[i]\neg\psi \in \mathcal{L}(x_0)$, causing $\neg\psi$ to be added to $\mathcal{L}(x_1)$, with $\mathsf{dep}(\neg\psi, x_1) = \emptyset$; and $\psi \wedge \rho \in \mathcal{L}(x_1)$, causing ψ and ρ to be added to $\mathcal{L}(x_1)$, with $\mathsf{dep}(\psi, x_1) = \mathsf{dep}(\rho, x_1) = \emptyset$. The completion tree would then be closed, as $\{\psi, \neg\psi\} \subseteq \mathcal{L}(x_1)$, and Satisfiable would return $\mathsf{dep}(\psi, x_1) \cup \mathsf{dep}(\neg\psi, x_1) = \emptyset$.

If we were using chronological backtracking, the recursion would return to the n-th branching point, i.e., the one where Branch was called with $b = n$, $f_1 = p_n$ and $f_2 = p_n$. $\mathbf{T}$ would be restored to its state prior to adding p_n to $\mathcal{L}(x_0)$, and the rule would be applied again such that q_n was added to $\mathcal{L}(x_0)$. Using backjumping, however, we return from Branch immediately because $b \notin S$. This is obviously true for all of the preceding branching points, so all calls to Branch will return without expanding the completion trees obtained by adding the various q_j to $\mathcal{L}(x_0)$, and Satisfiable will eventually return $\emptyset$, allowing us to conclude that ϕ' is unsatisfiable.

SAT Based Search Techniques Even with the addition of dependency directed backtracking, a naive implementation of the $\Diamond$-rule is inherently inefficient as it can lead to the repetition of parts of the expansion. For example, given an input formula

$$\phi'' = (\rho \vee \psi_1) \wedge \ldots \wedge (\rho \vee \psi_n), \tag{13}$$

where $\psi_1 \wedge \ldots \wedge \psi_n$ is satisfiable but ρ is not, the procedure described above would lead to the construction of n (possibly large) closed completion trees, each with $\rho \in \mathcal{L}(x_0)$, before a complete and open completion tree is constructed.

This problem can be avoided by using more sophisticated search techniques. One of best

known of these is the Davis-Putnam algorithm, originally designed for solving propositional satisfiability (SAT) problems [42]. The basic idea behind Davis-Putnam is that, instead of branching on unexpanded disjunctions, we branch on a formula ψ such that ψ occurs in an unexpanded disjunction in a node x of the completion tree and $\{\psi, \neg\psi\} \cap \mathcal{L}(x) = \emptyset$; the algorithm then searches the two possible trees obtained by adding ψ or $\neg\psi$ to $\mathcal{L}(x)$. This basic technique is usually enhanced with heuristics and simplification rules (which we will discuss in more detail below); in particular, we usually branch first on formulae that occur in many unexpanded disjunctions and, if $\{\psi \vee \rho, \neg\psi\} \subseteq \mathcal{L}(x)$, then $\psi \vee \rho$ is deterministically expanded by adding ρ to $\mathcal{L}(x)$. It is easy to see that if this strategy is applied to ϕ'' above, we would branch first on ρ (as it occurs in n unexpanded disjunctions), and at most one closed completion tree (if ρ is tried first) would be constructed before finding a complete and open one.

This technique has been shown to be very effective with formulae generated at random using generators adapted from those used to generate SAT problems [87, 114]. Such problems typically include a relatively small number of propositional variables (so there is likely to be significant repetition of the sub-formulae occurring in disjunctions), and have a very low modal depth (so the importance of propositional reasoning is emphasised); this is because large numbers of propositional variables and/or a high modal depth would result in almost all problems of reasonable size being trivially satisfiable. Formulae from applications, however, typically do not exhibit these characteristics, and Davis-Putnam is much less effective—in fact it can even be counter-productive if the negated formulae that Davis-Putnam introduces are large and/or complex [103].

An alternative technique used in [56] is to enhance the standard chronological backtracking method with a *no-good list* for each node, i.e., a set of formulae, each of which has already been shown to lead to a closed completion tree when it is added to the node label by an application of $\vee$-rule. Formulae in the no-good list are not considered when applying the $\vee$-rule. Using this technique with ϕ'' above, ρ would be added to the no-good list after the first application of the $\vee$-rule leads to a closed completion tree. In subsequent applications of the $\vee$-rule, ρ would not be considered, and ψ_j would always be selected. This technique has the advantage that wasted search is avoided without adding negated formulae that could themselves lead to additional (possibly non-deterministic) expansion.

Note that, when using these (and other) optimisations in addition to backjumping, care must be taken to ensure that *all* dependencies are being taken into consideration. For example, when using a no-good list to restrict the possible choices made by the $\vee$-rule, it is important to also consider the dependencies associated with the relevant formulae in the no-good list.

Simplification of Node Labels As well as the standard tableau expansion rules described in Figure 8, additional inference rules can be applied to the formulae occurring in a node label, usually with the objective of simplifying them and reducing the number of $\vee$-rule applications. The most commonly used simplification, often called *Boolean Constraint Propagation* (BCP) [74], is again derived from SAT solvers, where it is usually used in conjunction with the Davis-Putnam procedure. The basic idea is to identify a disjunction $\psi_1 \vee \ldots \vee \psi_n \in \mathcal{L}(x)$ such that the negations of all but one of the ψ_j are already elements of $\mathcal{L}(x)$; when this is the case, the formula can be deterministically expanded by adding the relevant ψ_j to $\mathcal{L}(x)$. This amounts to applying the following inference rule

$$\frac{\neg\psi_1, \ldots, \neg\psi_n, \psi_1 \vee \ldots \vee \psi_n \vee \psi}{\psi}$$

to the formulae in a node label, which is a restricted variant of hyper resolution, see 3.1.

As we have already seen, when $\neg\rho$ is added to $\mathcal{L}(x_0)$ during the expansion of ϕ'' above, the BCP rule can be applied to all the remaining $\phi \vee \psi_j$ formulae, leading to a complete and open completion tree without any further applications of the $\vee$-rule. Note that, as with the more sophisticated search techniques described above, careful consideration needs to be given to the dependencies of formulae added by such inference rules if they are to be used together with backjumping.

Heuristics As mentioned in Section 4.1, one advantage of the non-deterministic formulation of the $\vee$-rule is that an algorithm can try to choose a "good" order in which to try the different possible expansions. In practise, this usually means using heuristics to select the way in which the $\vee$-rule is applied to the disjunctions in a node label, and the order in which the successor nodes created by $\Diamond$-rule applications are expanded; in either case, a heuristic function is used to compute the relative "goodness" of candidate formulae/nodes.

When using the Davis-Putnam technique, the well known MOMS heuristic [74] is often used to select the formulae on which to branch; it tries to select formulae that will maximise the effect of BCP and so minimise the number of non-deterministic choices needed in order to complete the completion tree [103]. There is little evidence, however, that (a suitably adapted form of) this heuristic is effective with modal formulae, and even some evidence to suggest that interference with the backjumping optimisation makes it counter productive [103].

An alternative heuristic, whose design was prompted by this observation, tries to maximise the effect of backjumping by preferentially selecting formulae with low valued dependencies [103, 99]. This heuristic has the added advantage that it can also be used to select the order in which successor nodes are expanded.

Caching When using the top-down construction strategy, all information from predecessors is added to a node label before it is processed. This means that, when a given node has been fully expanded (i.e., the expansion rules have been exhaustively applied to it), a successor node y with $\mathcal{L}(y) = \{\psi_1, \ldots, \psi_n\}$ can be treated as an independent problem, equivalent to testing the satisfiability of $\psi_1 \wedge \ldots \wedge \psi_n$.

A completion tree may contain many such nodes, and the labels of nodes tend to be quite similar, particularly as the labels of i-successors of a node x each contain the same formulae resulting from $\Box$-rule applications to $[i]\psi$-formulae in $\mathcal{L}(x)$. For some formulae, this may result in the same sub-problem being solved again and again. In order to avoid this, it is possible to cache and re-use the results of such sub-problems. The usual technique is to use a hash table to store the satisfiability status of node labels (i.e., sets of formulae treated as a conjunction). Before applying any expansion rules to a new node x, the cache is interrogated to determine if the satisfiability status of $\mathcal{L}(x)$ is already known. If it is known, then the result can be used without further expansion, i.e., $\mathcal{L}(x)$ can be treated as though it were either $\{\bot\}$ (for unsatisfiable) or $\{\top\}$ (for satisfiable). If the satisfiability status of $\mathcal{L}(x)$ is not known, then $\mathcal{L}(x)$ is added to the cache, and its status set to satisfiable if a complete and open completion tree rooted in x can be constructed, and to unsatisfiable otherwise.

Since the satisfiability of a set of formulae L implies the satisfiability of each subset of L, and the unsatisfiability of a set of formulae L implies the unsatisfiability of each superset of L, this basic idea can be extended to check for satisfiable supersets of $\mathcal{L}(x)$ and unsatisfiable subsets of $\mathcal{L}(x)$. However, this requires a considerably more sophisticated data structure if cache operations are to be efficient [100, 86].

Apart from the problem of the storage required for the cache, another more subtle disadvantage of caching is that, in the case where the cache returns "unsatisfiable" for $\mathcal{L}(x)$, there is no information about the cause of the unsatisfiability that can be used to derive the dependency

information required for backjumping. Backjumping can still be performed by combining the dependency sets of all of the formulae in $\mathcal{L}(x)$, but this is likely to overestimate the set of branching points on which the unsatisfiability depends.

Another useful form of caching is a technique known as *model merging* [103, 91]. The idea here is to prove the satisfiability of a node label $\mathcal{L}(x)$ by showing that open and complete completion trees for $L_1, \ldots, L_k$ with $L_1 \cup \ldots \cup L_k = \mathcal{L}(x)$ can be combined into an open and complete completion tree for $\mathcal{L}(x)$ by simply "gluing" their root nodes together. This is possible if there are no "interactions" between the various completion trees, e.g., if there are no j, k such that either $\psi \in L_j$ and $\neg\psi \in L_k$ or $\langle i \rangle \psi \in L_j$ and $[i]\rho \in L_k$ for some i, ψ and ρ. Thus model merging involves (a) cashing satisfiable sets of formulae that occur as root labels of open and complete completion trees, and (b) trying to prove the satisfiability of some $\mathcal{L}(x)$ by finding cached sets L_j that do not interact in the above sense.

4.3 Transitive modalities and $\mathbf{K4}_n$

The main problem one has to overcome when modifying the $\mathbf{K}_n$ tableau algorithm presented in Section 4.2 to $\mathbf{K4}_n$ is *termination*. Please recall that the $\mathbf{K}_n$ tableau algorithm terminates "automatically" since it builds a tree of bounded depth and breadth in a monotonic way. As we will see, this is not the case for $\mathbf{K4}_n$. Consider, e.g., the $\mathbf{K4}_n$ formula $\langle i \rangle \psi \wedge [i]\langle i \rangle \psi$. A $\mathbf{K4}_n$ tableau algorithm would start with a root node x_0 labelled with this formula, then apply the $\wedge$-rule, and then generate an i-successor x_1. Next, the $\Diamond$-rule would be applicable and it would add $\langle i \rangle \psi$ to $\mathcal{L}(x_1)$. Thus the $\Diamond$-rule would generate an i-successor x_2 of x_1. At his point, the difference between $\mathbf{K}_n$ and $\mathbf{K4}_n$ becomes apparent: in $\mathbf{K4}_n$ models, R_i has to be transive, and thus x_2 should be i-accessible from x_0, i.e., $\langle i \rangle \psi$ would also need to be true in (the world represented by) x_2. Hence, we would need a (new) rule that adds $\langle i \rangle \psi$ to $\mathcal{L}(x_2)$. However, this would trigger the applicability of the $\Diamond$-rule, which would generate an i-successor x_3 of x_2. Now we can use R_i's transitivity again to argue that $\langle i \rangle \psi$ needs to be added to $\mathcal{L}(x_3)$, and continue the whole pattern to construct an infinite i-chain. Thus the tableau algorithm would not terminate: in contrast to the $\mathbf{K}_n$ tableau algorithm, the maximal modal depth of formulae in node labels no longer decreases from a node to its successors.

To regain termination, we observe that, creating this infinite path, we keep repeating the same actions. More precisely, the node labels of the nodes $x_1, x_2, \ldots$ are all identical. In the following, we show how we can prevent this "looping" using a cycle detection mechanism called "blocking". Intuitively, after the creation of x_2 and the application of the $\Box$-rule, we could have noticed that $\mathcal{L}(x_2) = \{\psi, \langle i \rangle \psi\} = \mathcal{L}(x_1)$, and decided to *not* apply the $\Diamond$-rule to x_2 because (i) we would continue repeating ourselves and (ii) it is not necessary since $\mathcal{L}(x_1) = \mathcal{L}(x_2)$ implies that we can use (the world represented by) x_1 for the world represented by x_2. The latter means that we can build a model $\mathfrak{M}$ with $(x_1, x_1) \in R_i$ in which $\mathfrak{M}, x_1 \models \psi$ and, from the semantics, $\mathfrak{M}, x_1 \models \langle i \rangle \psi$.

The other problem we have to overcome is how we are going to take care of R_i's transitivity. Consider an i-successor y of a node x. Now if y has in turn an i-successor z, then this situation represents a model in which $(x, z) \in R_i$, i.e., z "should" also be an i-successor of x. That is, if $[i]\psi \in \mathcal{L}(x)$, then ψ should be in $\mathcal{L}(z)$. One possible way to achieve this would be to give up on working on completion *trees*, and instead work on graphs where we would add the additional i-edge between x and z. For implementation purposes, however, trees are clearly advantagous, and thus we choose to employ an alternative technique: the same effect as adding the additional i-edge between x and z can be obtained by adding $[i]\psi$ to $\mathcal{L}(y)$ for each $[i]\psi \in \mathcal{L}(x)$. This will

be realized in a modified $\Box$-rule.

Now we formalise this in our tableau algorithm. First, we define the notion of a *blocked* node. We use ancestors and offsprings in the usual way; a node x is *directly blocked* if it has an ancestor x' with $\mathcal{L}(x) \subseteq \mathcal{L}(x')$; a node is *blocked* if it is directly blocked or if it has an ancestor that is directly blocked. Next, we take this notion into account in the $\mathbf{K4}_n$ expansion rules, which are given in Figure 11. Compared to the $\mathbf{K}_n$ expansion rules, these expansion rules only apply to nodes that are not blocked (however, $\Box$-rule can add formulae to the label of a directly blocked node), and the $\Box-$rule "pushes" box formulae in the way discussed above.

$\wedge$**-rule:**	*If*	there is a node x that is not blocked with $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_1, \psi_2\}$.
$\vee$**-rule:**	*If*	there is a node x that is not blocked with $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \cap \mathcal{L}(x) = \emptyset$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_i\}$ for some $i \in \{1, 2\}$.
$\Diamond$**-rule:**	*If*	there is a node x that is not blocked with $\langle i \rangle \psi \in \mathcal{L}(x)$ and x has no i-successor y with $\psi \in \mathcal{L}(y)$,
	then	create a new i-successor y of x with $\mathcal{L}(y) := \{\psi\}$.
$\Box$**-rule:**	*If*	there is a node x that is not blocked with $[i]\psi \in \mathcal{L}(x)$ and x has an i-successor y with $\psi \notin \mathcal{L}(y)$,
	then	$\mathcal{L}(y) := \mathcal{L}(y) \cup \{\psi, [i]\psi\}$.

Figure 11. The expansion rules for $\mathbf{K4}_n$.

To convince ourselves that this algorithm indeed decides satisfiability of $\mathbf{K4}_n$ formulae, we sketch the same technical lemma as for $\mathbf{K}_n$.

LEMMA 20. *Let ψ be a $\mathbf{K4}_n$ formula and $\mathbf{T}$ a completion tree generated by the tableau algorithm for ψ.*

1. *When applied to ψ, the tableau algorithm terminates.*

2. *If $\mathfrak{M}$ satisfies $\mathbf{T}$ via π and one of the expansion rules is applicable to $\mathbf{T}$, then this rule can be applied in such a way that it yields a $\mathbf{T}'$ satisfied by $\mathfrak{M}$ via (possibly an extension of) π.*

3. *If $\mathbf{T}$ is complete, then there exists a model $\mathfrak{M}$ and a mapping π such that $\mathfrak{M}$ satisfies $\mathbf{T}$ via π iff $\mathbf{T}$ is open.*

Again, we only sketch the proof. Termination is due to the same three observations as in the sketch of Lemma 18, but the reason for the bound of the depth of the tree is more involved (and the bound is now quadratic). Consider three nodes x, y, and z where y is an i-successor of x and z a j-successor of y. If $i \neq j$, then the maximal modal depth of formulae in the label of z is strictly smaller than the one in the label of y. If $i = j$, then either $\mathcal{L}(z) \subseteq \mathcal{L}(y)$ or y was generated for a different different diamond formula in $\mathcal{L}(x)$ than z in $\mathcal{L}(y)$. In the former case, z is blocked. The latter case can only occur linearly often in the length of the input formula. As a consequence, paths in the completion tree are of length at most quadratic in the length of the input formula. Lemma 20 (ii) is similar to the $\mathbf{K}_n$ case, but we have to exploit the transitivity of R_i to explain why pushing $[i]\psi$ from a node to its i-successor preserves $\mathfrak{M}$ being a model via π. Finally, the construction of a model from an open, complete completion tree in Lemma 20 (iii) is slightly modified: firstly, only un-blocked nodes represent worlds in the model. Secondly, we also add (x, y') to R_i if x has an i-successor y which is blocked and y' is an ancestor of y with

$\mathcal{L}(y) \subseteq \mathcal{L}(y')$. Thirdly, we extend R_i so that it is transitively closed, i.e., if $\{(x, y), (y, z)\} \subseteq R_i$, then we also have $(x, z) \in R_i$.

The same reasons as for $\mathbf{K}_n$ then yield the following theorem.

THEOREM 21. *The $\mathbf{K4}_n$ tableau algorithm decides $\mathbf{K4}_n$ satisfiability and can be implemented in polynomial space.*

Implementation Issues

As we have seen, the main difference between the tableau algorithms for $\mathbf{K}_n$ and $\mathbf{K4}_n$ is the introduction of blocking. In fact the blocking condition described above, which specifies a subset relationship between the labels of blocked and blocking nodes, is already optimised w.r.t. the one originally described in [93], which specified label equality. The subset condition means that blocking can occur sooner, thus avoiding possibly costly expansion.

Consider, for example, a node x labelled as follows:

(14) $$\mathcal{L}(x) = \{\rho, \psi, \langle i \rangle \psi, [i]\langle i \rangle \psi\},$$

With subset blocking, an i-successor y of x with $\mathcal{L}(y) = \{\psi, \langle i \rangle \psi, [i]\langle i \rangle \psi\}$ would be blocked by x; with equality blocking, a block would not be established until an i-successor z of y is constructed, with $\mathcal{L}(z) = \mathcal{L}(y)$. This may lead to significant additional work if ψ is itself a large and/or complex formula.

Apart from blocking, the algorithm is very similar to the $\mathbf{K}_n$ case, and most of the optimisation techniques described in Section 4.2 can be applied without modification. Blocking does, however, mean that additional care is required when caching and re-using the satisfiability of a set of formulae, because the satisfiability of the set of formulae in the label of a blocked node is contingent on the satisfiability of the set of formulae in the label of the blocking node [103]. This dependency also extends to the satisfiability of the sets of formulae in the labels of any nodes on the path between the blocking node and the blocked node.

Consider, for example, a node x labelled as in 14 above, where ψ is unsatisfiable. As we have seen, an application of the $\Diamond$-rule to $\langle i \rangle \psi \in \mathcal{L}(x)$, followed by applications of the $\Box$-rule to $[i]\langle i \rangle \psi \in \mathcal{L}(x)$, would lead to the creation of an i-successor y of x with $\mathcal{L}(y) = \{\psi, \langle i \rangle \psi, [i]\langle i \rangle \psi\}$, and no expansion rule would be applicable to y as it would be blocked by x. Updating the cache to indicate that the set of formulae $\mathcal{L}(y)$ is satisfiable would, however, clearly be an error, as ψ is unsatisfiable.

4.4 Non-logical axioms and background theories

Now that we have understood how to handle transitivity in $\mathbf{K4}_n$, understanding how to handle background theories is easy. Consider the satisfiability of a formula ϕ w.r.t. the background theory $\Gamma = \{\gamma_1, \ldots, \gamma_n\}$, and remember that the nodes of our completion tree represent worlds of the model we are trying to build, which has to be a common model of ϕ and Γ. Moreover, $\psi \in \mathcal{L}(x)$ stands for the fact that ψ is true in the world (represented by) x. As before, at least one node (the root node) will carry ϕ in its label. Additionally, we will make sure that all nodes will carry each γ_i in their label. As a consequence, we will have a similar problem with termination as we have seen for $\mathbf{K4}_n$, i.e., the maximal modal depth of formulae in node labels does no longer decrease from a node to its successor. Fortunately, we can use the same blocking technique as for $\mathbf{K4}_n$: a node x is *directly blocked* if it has an ancestor x' with $\mathcal{L}(x) \subseteq \mathcal{L}(x')$, and it is *blocked* if it is directly blocked or if it has an ancestor that is directly blocked. The expansion rules for

$\mathbf{K}_n$ w.r.t. background theories are given in Figure 12: they contain the $\mathbf{K}_n$ $\Box$−rule, an additional Γ-rule that adds Γ to each node label, and the $\mathbf{K4}_n$ restriction to blocked nodes. We call the resulting algorithm the *extended* $\mathbf{K}_n$ tableau algorithm.

$\wedge$**-rule:**	*If*	there is a node x that is not blocked with $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_1, \psi_2\}$.
$\vee$**-rule:**	*If*	there is a node x that is not blocked with $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \cap \mathcal{L}(x) = \emptyset$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_i\}$ for some $i \in \{1, 2\}$.
$\Diamond$**-rule:**	*If*	there is a node x that is not blocked with $\langle i \rangle \psi \in \mathcal{L}(x)$ and x has no i-successor y with $\psi \in \mathcal{L}(y)$,
	then	create a new i-successor y of x with $\mathcal{L}(y) := \{\psi\}$.
$\Box$**-rule:**	*If*	there is a node x that is not blocked with $[i]\psi \in \mathcal{L}(x)$ and x has an i-successor y with $\psi \notin \mathcal{L}(y)$,
	then	$\mathcal{L}(y) := \mathcal{L}(y) \cup \{\psi\}$.
Γ**-rule:**	*If*	there is a node x that is not blocked with $\Gamma \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \Gamma$.

Figure 12. The expansion rules for $\mathbf{K}_n$ with background theories.

We can state and prove an analogous technical lemma as for $\mathbf{K}_n$ and $\mathbf{K4}_n$, and then use the same reasons to conclude the following theorem.

THEOREM 22. *The extended* $\mathbf{K}_n$ *tableau algorithm decides satisfiability w.r.t background theories.*

However, in contrast, we no longer can implement our tableau algorithm in polynomial space: firstly, it is known that satisfiability of $\mathbf{K}_n$ formulae w.r.t. background theories is ExpTime-complete (we can adapt the proofs in [68, 162]). Secondly, we can easily construct a formula and a background theory such that each of their model contains a path of length exponential in the input formulae: we can use propositional variables $p_1, \ldots, p_\ell$ as a "binary counter" for numbers between 0 and $2^\ell - 1$, and non-logical axioms to enforce that, if the p_i at a world w represent a number k, then the p_i at a world w' with $(w, w') \in R_i$ represent the number $k + 1 \mod \ell$. Thirdly, in the worst case, our algorithm indeed constructs completion trees that are of depth exponential in the length of the input formulae: for $\mathbf{K4}_n$, we could argue that the maximal modal depth decreases from a node to a j-successor of its i-successor (if $i \neq j$). For $\mathbf{K}_n$ with background theories, this is no longer true. As a consequence of this exponential length and the non-deterministic $\vee$-rule, our tableau algorithm runs, in the worst case, in non-deterministic double exponential time—which is clearly sub-optimal. In [56], an optimal tableau algorithm for (the description logic) variant of $\mathbf{K}_n$ with background theories was presented; however, to the best of our knowledge, this algorithm has never been implemented, whereas the sub-optimal one described here has proven to work surprisingly well in practice [159, 90].

Implementation Issues

One obvious consequence of the above algorithm is that expansion of the formulae in Γ occurs in every node in the completion tree, and this can easily lead to an explosion in the size of the completion tree or in the number of different possible completion trees that can be (non-deterministically) constructed for a given input formula. For example, if $\Gamma = \{\langle i \rangle \psi_1, \ldots, \langle i \rangle \psi_n\}$, a completion tree containing $nn! + 1$ nodes will be constructed. Similarly, if $\gamma \in \Gamma$, with

$\gamma = ((p_1 \vee q_1) \wedge \ldots \wedge (p_n \vee q_n))$, and the input formula leads to the construction of a completion tree containing k nodes, then there are 2^{kn} different ways to apply the $\wedge$- and $\vee$-rules to the resulting k copies of γ. This explosion in the size of the search space can easily lead to a catastrophic degradation in performance, even when optimisations such as backjumping and caching are employed [102].

Fortunately, optimisations known as *lazy unfolding* and *absorption* have proved to be very effective in reducing the size of the search space, particularly for background theories derived, e.g., from class based knowledge representation formalisms.

Lazy Unfolding In background theories, formulae are often (restricted to be) of the form $p \rightarrow \psi$ or $p \leftrightarrow \psi$ for some propositional variable p. A theory

$$\Gamma = \{p_1 \leftrightarrow \psi_1, \ldots, p_\ell \leftrightarrow \psi_\ell, p_{\ell+1} \rightarrow \psi_{\ell+1}, \ldots, p_{\ell+m} \rightarrow \psi_{\ell+m}\}$$

is said to be *unfoldable*, if it satisfies the following conditions.

- Formulae in Γ are *unique*. I.e., for each propositional variable p, Γ contains at most one formula of the form $p \leftrightarrow \psi$ (i.e., $p_i \neq p_j$ for $1 \leqslant i < j \leqslant \ell$), and if it contains a formula of the form $p \leftrightarrow \psi$, then it does not contain any formulae of the form $p \rightarrow \psi$. (Note that an arbitrary set of formulae $\{p \rightarrow \psi_1, \ldots, p \rightarrow \psi_n\}$ can be combined into a single formula $p \rightarrow (\psi_1 \wedge \ldots \wedge \psi_n)$.)

- Γ is *acyclic*. I.e., there is no formula $p_i \leftrightarrow \psi_i \in \Gamma$ such that p_i occurs either directly or indirectly in ψ_i.[3] A propositional variable p occurs indirectly in a formula ψ if there is a propositional variable formula p' such that p' occurs directly in ψ, and there is a formula $p' \leftrightarrow \psi' \in \Gamma$ such that p occurs either directly or indirectly in ψ'.

Instead of being dealt with using the Γ-rule, such a set of formulae can be lazily *unfolded* during the tableau expansion. I.e., for a formula $p_1 \rightarrow \psi_1 \in \Gamma$, if p_i is added to $\mathcal{L}(x)$ for some node x, then ψ_i is also added to $\mathcal{L}(x)$, and for a formula $p_j \leftrightarrow \psi_j \in \Gamma$, if p_j ($\neg p_j$) is added to $\mathcal{L}(x)$ for some node x, then ψ_j (resp. $\neg\psi_j$) is also added to $\mathcal{L}(x)$.

It is obvious that an arbitrary background theory Γ can be divided into an unfoldable part Γ_u and a general part Γ_g such that $\Gamma_u \cup \Gamma_g = \Gamma$ and $\Gamma_u \cap \Gamma_g = \emptyset$. The unfoldable part Γ_u can then be dealt with using lazy unfolding while the general part Γ_g is dealt with using the Γ-rule.

In fact it has been shown that the definition of an unfoldable theory can be extended somewhat while still allowing the use of the above lazy unfolding technique. In particular, the formulae occurring on the left hand side of (bi-) implications can also be negated propositional variables, and the acyclicity condition can be relaxed by distinguishing positive and negative occurrences of propositional variables in a stratified theory [109, 132].

Absorption Given the effectiveness of lazy unfolding in dealing with the unfoldable part of a background theory Γ, it makes sense to try to rewrite the formulae in Γ so that the size of Γ_g can be reduced. Absorption is just such a rewriting optimisation.

The idea behind absorption derives from the observation that (apparently non-unfoldable) formulae in Γ_g are often of the form $p \wedge \rho \rightarrow \psi$. This formula can be rewritten as $p \rightarrow (\psi \vee \neg\rho)$, which allows it to be moved from Γ_g to Γ_u, provided that Γ_u does not already contain a formula of the form $p \leftrightarrow \psi'$. In case Γ_u does contain such a formula, then the technique can be extended by using the formulae in Γ_u to perform further rewriting. E.g., if $p \leftrightarrow \psi_i \in \Gamma_u$ and $p \rightarrow \psi_j \in \Gamma_g$, then the second formula can be rewritten as $\psi_i \rightarrow \psi_j$ and, if ψ_i is of the form $q \wedge \psi_i'$, the formula

[3] For the purposes of lazy unfolding, only cycles consisting entirely of $\leftrightarrow$ axioms are problematical.

can be further rewritten as $q \to \psi_j \vee \neg\psi_i'$. A more detailed description of the various re-writings used in absorption can be found in [109].

4.5 Converse modalities

So far, our tableau algorithms only use expansions rules that are either local to a single node, create new successors, or push formulae from a node label into the label of a *successor*. The objective of this section is to discuss a tableau algorithm for $\mathbf{K}_n^{\smile}$, i.e., $\mathbf{K}_n$ with converse modalities. It is well-known that satisfiability in $\mathbf{K}_n^{\smile}$ can be polynomially reduced to the satisfiability of $\mathbf{K}_n$ w.r.t. background theories [43]. However, from an implementation perspective, this approach is not feasible since it leads to a dramatic performance degradation, and we thus present a direct algorithm.

As mentioned in Section 2, $\mathbf{K}_n^{\smile}$ requires reasoning in both ways over relations R_i. For our tableau algorithm, this will simply mean that we push formulae up and down in a completion tree. To realize this, we define the notion of an i-neighbour, which requires a few other concepts: firstly, to avoid numerous case distinction, we introduce a function $\mathsf{Cv}(\cdot)$ on modal parameters as follows:[4] $\mathsf{Cv}(i) = i^{\smile}$ and $\mathsf{Cv}(i^{\smile}) = i$. Next, we consider completion trees where each edge is labelled with a possibly converse modal parameter i or $i^{\smile}$. Finally, for α a (possibly converse) modal parameter, we call a node y an *α-neighbour* of a node x if y is an α-successor of x or if x is a $\mathsf{Cv}(\alpha)$-successor of y. The expansion rules for $\mathbf{K}_n^{\smile}$ are identical to those for $\mathbf{K}_n$, with the only difference being that the $\Box$- and the $\Diamond$-rules now consider α-neighbours instead of α-successors (but the $\Diamond$-rule still generates an α-successor if no appropriate α-neighbour is available); they can be found in Figure 13.

$\wedge$-rule:	*If*	there is a node x with $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_1, \psi_2\}$.
$\vee$-rule:	*If*	there is a node x with $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \cap \mathcal{L}(x) = \emptyset$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_i\}$ for some $i \in \{1, 2\}$.
$\Diamond$-rule:	*If*	there is a node x with $\langle\alpha\rangle\psi \in \mathcal{L}(x)$ and x has no α-neighbour y with $\psi \in \mathcal{L}(y)$,
	then	create a new α-successor y of x with $\mathcal{L}(y) := \{\psi\}$.
$\Box$-rule:	*If*	there is a node x with $[\alpha]\psi \in \mathcal{L}(x)$ and x has an α-neighbour y with $\psi \notin \mathcal{L}(y)$,
	then	$\mathcal{L}(y) := \mathcal{L}(y) \cup \{\psi\}$.

Figure 13. The expansion rules for $\mathbf{K}_n^{\smile}$.

We can state and prove an analogous technical lemma as for $\mathbf{K}_n$, and then use similar reasons to conclude the first part of following theorem.

THEOREM 23. *The $\mathbf{K}_n^{\smile}$ tableau algorithm decides $\mathbf{K}_n$ satisfiability and can be implemented in polynomial space.*

To implement the $\mathbf{K}_n^{\smile}$ tableau algorithm in polynomial space, we can use the following "restart" technique: for each node x, we first apply the $\wedge$- and the $\vee$-rule exhaustively.[5] Next, if a formula is added to $\mathcal{L}(x)$ by the $\Box$-rule for some $[\alpha]\psi$ in a $\mathsf{Cv}(\alpha)$-successor of x, then we disregard the whole sub-tree below x and re-start its construction from scratch. As a consequence of this "strategy", all branches of a completion tree are independent, and we can still construct a completion tree depth first.

[4] Remember that $\mathbf{K}_n$ with converse modalities provides modal parameters i and $i^{\smile}$ for $1 \leq i \leq m$.

[5] Please note that we never made any assumptions or restrictions on the order in which the rules are to be applied.

Implementation Issues

Although the restart technique can be used to enable $\mathbf{K}_n^{\smile}$ completion trees to be constructed using a depth first strategy, the technique is not used in practice as rebuilding discarded parts of the completion tree can be very costly (and space usage is rarely a problem in practice). Without this technique, however, extra care is required when using some of the optimisation techniques described above.

Without the depth first strategy, the satisfiability of (the formula represented by) the label of a node x can no longer be treated as an independent problem, because the results of expanding x might affect its predecessor (unless x is the root node). This means that, although we can re-use cached unsatisfiability results from the cache as before, we must either disregard satisfiable results, or use more sophisticated caching techniques (e.g., storing additional information that would allow us to check for possible interactions with the predecessor node) [103].

Computation of the dependencies used in backjumping is also made more difficult by the loss of the depth first strategy. In particular we need to consider the dependency set of the $\langle i \rangle$ formula in x that led to the generation of an i-successor y in order to compute $\mathsf{dep}(\psi, y)$ when ψ is added to $\mathcal{L}(y)$ as a result of a $\Box$-rule application to a formula $[i]\psi \in \mathcal{L}(x)$. With depth first expansion, this is usually accomplished by combining $\Diamond$-rule applications with all relevant $\Box$-rule applications. Without depth first expansion, this is usually achieved by extending the labelling of either nodes or edges with the dependency set of the $\Diamond$-formula that caused them to be added to the completion tree.

Finally, without the depth first strategy it is necessary, in general, to save the state of the whole completion tree at each $\vee$-rule application (as mentioned above, the depth first strategy allows state saving and restoring to be restricted to a single node label). This problem can be ameliorated by using a lazy state saving strategy, where node labels are only saved when they are about to be extended by some rule application.

4.6 Converse modalities and background theories

In the last sections, we have seen how to extend the basic $\mathbf{K}_n$ tableau algorithm to a decision procedure for $\mathbf{K4}_n$, for $\mathbf{K}_n$ with background theories, and for $\mathbf{K}_n^{\smile}$. For the first two extensions, we discussed a technique to "artificially" ensure termination while preserving soundness and completeness. For the third extension, we introduced the concept of *neighbours* and modified the expansion rules as to work up and down the completion tree. In this section, we will put these techniques and concepts together—and show that their combination requires a further adjustment.

To be more precise, in this section, we discuss a tableau algorithm for $\mathbf{K}_n^{\smile}$ with background theories, i.e., converse modal parameters can occur both in the input formula and in the formulae of the background theory. Next, we discuss the expansion rules, which are given in Figure 14. Clearly, in the presence of converse modal parameters, we use the notion of α-neighbours. Similarly, in the presence of background theories, we use the Γ-rule, and we use blocking to ensure termination. However, the combination of background theories with converse modal parameters requires two modifications. Consider an i-successor y of x with $[i^{\smile}]\psi \in \mathcal{L}(y)$, and assume that y is blocked and x is not blocked. Hence there is some node y' with $\mathcal{L}(y) \subseteq \mathcal{L}(y')$. In case the tableau algorithm stops with an open, complete completion tree, we will try to construct a model $\mathfrak{M}$ from this tree, and we will have $(x, y') \in R_i$. Now $\mathcal{L}(y) \subseteq \mathcal{L}(y')$ implies that $[i^{\smile}]\psi \in \mathcal{L}(y')$, and we thus have to show that $\mathfrak{M}, x \models \psi$. However, if we would not apply the $\Box$-rule to y

because y is blocked, we might not find $\psi \in \mathcal{L}(x)$, and thus our construction might fail. This observations leads to the first modification:

1. we call a node *indirectly blocked* if it is blocked, and if its predecessor is blocked as well. Then we apply all but the $\Diamond$-rule to nodes that are not indirectly blocked.

In our example case, y was indirectly blocked, and thus the $\Box$-rule would add ψ into $\mathcal{L}(x)$. Next, consider some $[i^{\smile}]\psi' \in \mathcal{L}(y') \setminus \mathcal{L}(y)$. The same reasons as for $[i^{\smile}]\psi$ imply that we should find $\psi' \in \mathcal{L}(x)$—which we would not since our blocking condition only requires $\mathcal{L}(y) \subseteq \mathcal{L}(y')$. This observation leads to the second modification:

2. a node x is *directly blocked* if it has an ancestor x' with $\mathcal{L}(x') = \mathcal{L}(x)$.

For obvious reasons, we refer to the former blocking condition as *subset blocking*, and to this new condition as *equality blocking*. Please note that, in this setting, it is unavoidable that blocking is "dynamic", that is, a blocked node can later become not blocked. In contrast, with a certain strategy for the order of rule applications, this can be avoided in the $\mathbf{K}_n$ case.

$\wedge$**-rule:**	*If*	there is a node x that is not indirectly blocked with $\psi_1 \wedge \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_1, \psi_2\}$.
$\vee$**-rule:**	*If*	there is a node x that is not indirectly blocked with $\psi_1 \vee \psi_2 \in \mathcal{L}(x)$ and $\{\psi_1, \psi_2\} \cap \mathcal{L}(x) = \emptyset$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \{\psi_i\}$ for some $i \in \{1, 2\}$.
$\Diamond$**-rule:**	*If*	there is a node x that is not blocked with $\langle\alpha\rangle\psi \in \mathcal{L}(x)$ and x has no α-neighbour y with $\psi \in \mathcal{L}(y)$,
	then	create a new α-successor y of x with $\mathcal{L}(y) := \{\psi\}$.
$\Box$**-rule:**	*If*	there is a node x that is not indirectly blocked with $[\alpha]\psi \in \mathcal{L}(x)$ and x has an α-neighbour y with $\psi \notin \mathcal{L}(y)$,
	then	$\mathcal{L}(y) := \mathcal{L}(y) \cup \{\psi\}$.
Γ**-rule:**	*If*	there is a node x that is not indirectly blocked with $\Gamma \not\subseteq \mathcal{L}(x)$,
	then	$\mathcal{L}(x) := \mathcal{L}(x) \cup \Gamma$.

Figure 14. The expansion rules for $\mathbf{K}_n^{\smile}$ with background theories.

4.7 *Other extensions (counting, nominals, transitive closure, and fixpoints)*

In this section, we discuss two other extensions of our tableau algorithms. Firstly, we discuss $\mathbf{K}_n^{\smile,o}$, the extension of $\mathbf{K}_n^{\smile}$ with background theories and *nominals*. Secondly, we discuss $\mathbf{K}_n^c$, the extension of $\mathbf{K}_n$ with graded modalities, and also how to ensure termination in the additional presence of background theories. Finally, we discuss modal logics with a transitive closure operator and fixpoints.

Further add nominals to $\mathbf{K}_n^{\smile}$ with background theories

$\mathbf{K}_n^{\smile,o}$ with background theories is of interest because it lacks the tree models property and because it requires another form of non-local reasoning. The former point was already discussed in Section 2. To see the latter point, consider the formula $\langle i\rangle(p \wedge \langle\ell\rangle o) \;\wedge\; \langle j\rangle o \;\wedge\; [j][\ell^{\smile}]\langle i\rangle(p \wedge \langle\ell\rangle o) \wedge \langle j\rangle(o \wedge [\ell^{\smile}]q)$. The first three conjuncts imply the existence of an infinite

(possibly cyclic) R_i-path $w_1, w_2, \ldots$ such that *the* world in which o is true is ℓ-accessible from each w_k. The fourth conjunct implies that, in all w_k, q is true—however, this is only "detected" when the $\Diamond$-rule is applied to the fourth conjunct.

To handle, additionally, nominals, we can further modify our extended $\mathbf{K}_n^{\smile}$ tableau algorithm as follows. Firstly, we give up completion trees. More precisely, if $o_1, \ldots, o_\ell$ are all nominals occurring in ϕ and Γ, we start our tableau with $\ell + 1$ root nodes x_i, where $\mathcal{L}(x_0) = \{\phi\}$ and $\mathcal{L}(x_i) = \{o_i\}$, for each $1 \leq i \leq \ell$. Then, whenever we find a nominal o_i in a node $x \neq x_i$, we *merge* x into x_i; that is, we merge x and x_i's labels and incoming and outgoing edges. As a consequence of this merging, we will possibly find several edges going into a nominal node x_i; however, removing these edges clearly yields a forest structure. Correctness is then straightforward, and termination is due to the fact that (a) each path starting at some x_j is of bounded length because of blocking, and (b) if a successor node was created for some $\Diamond i \psi \in \mathcal{L}(x)$, then we will not create it "again", even if x was merged into another node. For details, see [5, 106].

Further add graded modalities to $\mathbf{K}_n$

In this section, we will discuss, on a rather abstract level, what modifications are necessary to handle graded modalities $\langle i \rangle_n \phi$ and $[i]_n \phi$; for a more detailed description, see [108, 101].

Firstly, following our previous approach, it is quite obvious that, when we find $\langle i \rangle_n \psi \in \mathcal{L}(x)$, we should make sure that we find $n + 1$ i-successors y_j of x with $\psi \in \mathcal{L}(y_j)$. Usually, when we do not find them, we create them all in a single step. Similarly, if we find $[i]_n \psi \in \mathcal{L}(x)$, we must make sure that we do not find more than n i-successors y_j of x with $\psi \in \mathcal{L}(y_j)$. Thus, if there are more such i-successors, we *merge* two of them, say y_j and y_k, i.e., we merge y_k's node label and outgoing edges into y_j's and remove y_k, thus reducing the number of such i-successors by one.

Secondly, in the presence of contradicting graded modalities $\langle i \rangle_n \psi$ and $[i]_{n'} \psi'$ with $\psi \rightarrow \psi'$ and $n' \leq n$ in the label of a node x, the above naive approach would lead to the repeated generation and merging of i-successors of x, and thus to non-termination. To prevent this "yoyo"-effect, when introducing $n+1$ i-successors for some $\langle i \rangle_n \psi \in \mathcal{L}(x)$, we use an explicit inequality relation between these i-successors, do not merge "explicitly unequal" nodes, and extend the notion of a clash to also cover the case where $[i]_n \psi \in \mathcal{L}(x)$ but x has more than n "explicitly unequal" i-successors with ψ in their label.

Thirdly, these modification yield a terminating yet unsound decision procedure: consider, for example, the formula $[i]_1 p \wedge [i]_1 \neg p \wedge \langle i \rangle_2 q$. With the modifications made so far, our tableau algorithm would generate three (explicitly unequal) i-successors y_j of a root node x_0 with $q \in \mathcal{L}(y_j)$, stop, and return "satisfiable", which is clearly the wrong answer. The reason for this incorrect answer is that we only merge surplus i-successors for some $[i]_n \psi$ if we already know that they must satisfy ψ, i.e., if ψ is found in their label. However, as the previous example shows, this is not enough: if $[i]_n \psi \in \mathcal{L}(x)$, we must determine, for each i-successor y_j, whether it does or does not satisfy ψ. We can do this using an additional, non-deterministic *choose*-rule that adds, to each such i-successor, either ψ or the negation normal form of $\neg \psi$.

For $\mathbf{K}_n$, these modifications lead to a decision procedure for satisfiability, even in the presence of either background theories or converse modalities (where we only have to take care to count and merge *i-neighbours* correctly). However, for $\mathbf{K}_n^{\smile}$ with background theories, we need a further modification, namely one to the blocking condition: otherwise, the algorithm is not correct (see, e.g., the example in [105]). Since this logic lacks the finite model property, a construction

of a model from a completion tree uses standard unravelling where, instead of a path going to a blocked node, it goes to the node blocking it. Now, in the presence of graded modalities, we must make sure that this does not lead to additional i-accessible worlds which thus would violate some graded modal formulae. Roughly speaking, we ensure this using *double blocking*, i.e., instead of a node being blocked by an ancestor, a node and its predecessor is blocked by an ancestor and its respective predecessor. For details, see [105, 108].

Implementation Issues

As we have seen, the tableau algorithm $\mathbf{K}_n^{\smile}$ requires a more complex blocking condition in order to ensure that a completion tree can be unravelled into an infinite tableau. This can adversely affect performance, because blocks can take (much) longer to establish, and the completion tree can thus grow (much) larger. The problem can be ameliorated by using a more precise (weaker) blocking condition that identifies the cases where double blocking is really needed (i.e., where a cyclical model cannot be built from a branch of the completion tree blocked using the original single blocking condition), and compares only those parts of the node label pairs that are relevant to determining if the completion tree could be unravelled to give an infinite tableau [107].

Transitive Closure and Fixpoints

There are various extension of modal logics with transitive closure operators and general fixpoints, see Chapter 12 of this handbook. However, there are only few “practicable” satisfiability algorithms in the sense that one could dare to implement them and expect a reasonable behaviour in any non-trivial case.[6] To the best of our knowledge, there are only two such algorithms based on tableau, namely the ones described in [11, 45] for extensions of $\mathbf{K}_n$ with transitive closure, and there has only been a single attempt at an implementation, namely in the system DLP [159]. For this kind of extensions, automata-based techniques (see 5.1) seem to be suited best: for example, the only known decision procedure for the μ-calculus is based on automata, see Chapter 12 of this handbook.

5 OTHER COMPUTATIONAL APPROACHES

5.1 Automata-based algorithms

Roughly speaking, automata-based algorithms work as follows. To decide the satisfiability of a logic $\mathcal{L}$, we first show an appropriate tree-model property for $\mathcal{L}$, i.e., prove that each satisfiable $\mathcal{L}$ formula is satisfiable in a model (or an abstraction of a model) whose relational structure forms a tree. For example, it is well-known that each satisfiable $\mathbf{K}_n$ formula is satisfiable in a tree model which is, additionally, finite [93]. For other logics, e.g., $\mathbf{K4}_n$, we can easily show that each satisfiable formula has a model with an infinite tree *abstraction*, where we can obtain a model from such an abstraction by transitively closing the accessibility relations [93]. Secondly, for an $\mathcal{L}$ formula ϕ, we define an automaton $\mathcal{A}_\phi$ such that $\mathcal{A}_\phi$ accepts all tree models of ϕ (or abstractions thereof). Depending on the logic and its model properties, we use automata on finite or on infinite trees. Thus we have reduced the satisfiability of formulae in $\mathcal{L}$ to the emptiness

[6] For other reasoning problems such as model checking, these algorithms exist and have been implemented successfully, see Chapter 17 of this handbook.

problem of a certain class of automata, and we can use well-known algorithms to decide these emptiness problems.

For a variety of logics, this approach has several of advantages. Consider, for example, $\mathbf{K}_n$ with background theories. It can easily be seen that this logic enjoys the tree model property, and thus we only need to devise the construction of an automaton $\mathcal{A}_\phi$. Using *alternating automata*, this construction is quite straightforward and yields, surprisingly, a (worst-case) optimal decision procedure (for a similar construction for a more powerful logic see, e.g., [188]): the automaton $\mathcal{A}_\phi$ is of size polynomial in the input tree, and testing its emptiness can be done in deterministic exponential time [128]. Thus, in contrast to the tableau algorithm described in Section 4.4, we effortlessly obtain a *deterministic* algorithm, and do not even need to take care of termination or finite models: using automata on infinite trees makes this unnecessary.

Concerning the implementability of automata-based approaches, we observe that their worst-case complexity often coincides with their best-case complexity: to decide the emptiness of alternating automata, we first translate them into non-deterministic ones that are then tested for emptiness, i.e., we first build a structure of exponential size, for which we then decide emptiness in polynomial time [128]. In case we directly use non-deterministic automata, they tend to be of size exponential in the size of the input formula, and we are thus confronted with the same problem. Thus, any naive implementation is doomed to failure. However, there are at least two ways out: in [158], it was shown how BDDs can be used to efficiently represent and handle large automata, thus proving that (variations of) automata-based algorithms can be implemented efficiently using appropriate data structures. In [12], it was shown how an automata-based approach can be transformed mechanically into a tableau-based decision procedure: as a consequence, we only need to "hand-craft" the automata-based algorithm, and then get both a (possibly optimal) worst-case upper bound and a (possibly practicable) tableau-based algorithm for free.

5.2 Modal resolution

In the late 1980s and early 1990s various direct resolution methods for modal logics have been investigated [1, 10, 33, 46, 59, 61, 72, 79, 126, 139, 140]. According to [139] a *resolution method* for a logic L is determined by specifying (i) a class of formulae called clauses, (ii) a reduction method which allows us to transform any formula of L into a finite set of clauses, (iii) a calculus consisting of a set of resolution rules for deriving clauses (and possibly redundancy elimination and simplification rules), and (iv) a derivation process which starts from an initial set of clauses and constructs a sequence of derivable clauses. One can then define a *modal resolution method* to be a resolution method in which clauses are formulae of the modal logic L under consideration. This definition excludes methods which do not use a clausal form from the outset, e.g. destructive modal resolution [72], or methods which use auxiliary labels, e.g. prefixed resolution [6] and labelled modal resolution [7]. Methods which use additional modal operators like the resolution calculus for temporal logics of knowledge presented in [54] can be considered to be borderline cases.

In the following we focus on the modal resolution method of [59] but follow the presentation in the survey paper [64], where a more complete overview of various direct resolution methods and other methods can be found.

A modal formula of $\mathbf{K}$ is in *disjunctive normal form* iff it is a (possibly empty) disjunction of the form $\bigvee L_i \vee \bigvee \Box D_j \vee \bigvee \Diamond A_k$ where each L_i is a propositional literal, each D_j is a modal formula in disjunctive normal form, and each A_k is a modal formula in conjunctive normal form. A modal formula is in *conjunctive normal form* iff it is a conjunction $\bigwedge D_l$ where each

Axioms			
axiom1:	$p, \neg p \Rightarrow \bot$	axiom2:	$\bot, A \Rightarrow \bot$

Resolution rules

$\vee$-simp2:	$A \vee A \vee D \rightarrow A \vee D$	$\wedge$-simp:	$\bot, N \rightarrow \bot$

Figure 15. Modal resolution rules of [59] for $\mathbf{K}$. (The symbols A, B, C, D, D' denote clauses, N denotes a set of clauses, and (A, N) denotes the union of $\{A\}$ and N. No distinction is made between a set N of clauses and the conjunction of its elements.)

D_l is a modal formula in disjunctive normal form. A formula in disjunctive normal form is also called a *(modal) clause*. Any modal formula φ can be transformed into an equivalent formula in conjunctive normal form $\mathrm{cnf}(\varphi)$. In the following, we do not distinguish between a conjunction of clauses and a set of clauses.

The calculus $C_{\mathbf{K}}$ of [59] is given by the set of axioms, resolution rules, and simplification rules shown in Figure 15. The intended meaning of $A, B \Rightarrow C$ and $A \Rightarrow C$ is that the conjunction of the formulae on the left-hand side of $\Rightarrow$ implies the formula on its right-hand side. In contrast, the meaning of $A, B \rightarrow C$ is that occurrences of A and B in a conjunction can be simplified to, that is, replaced by, C. Analogously, $A \rightarrow C$, means that occurrences of A can be replaced by C. Every formula A has a unique normal form $\mathrm{nf}(A)$ under the simplification rules of Figure 15 (modulo commutativity and associativity of $\vee$ and $\wedge$).

Various extensions of $\mathbf{K}$ have been considered, including extensions by the axiom schemas $\mathbf{D}$, $\mathbf{T}$, and $\mathbf{4}$. For each of these axiom schemas the calculus $C_{\mathbf{K}}$ needs to be extended with additional rules: for $\mathbf{D}$ with $\Box\bot \Rightarrow \bot$, for $\mathbf{T}$ with $\Box A, B \Rightarrow C$ if $A, B \Rightarrow C$, while for $\mathbf{4}$ with the two rules $\Box A, \Box B \Rightarrow \Box C$ if $\Box A, B \Rightarrow C$ and $\Box A, \Diamond(B, N) \Rightarrow \Diamond(B, C, N)$ if $\Box A, B \Rightarrow C$. We denote the calculi obtained by adding these rules to $C_{\mathbf{K}}$ by $C_{\mathbf{KD}}$, $C_{\mathbf{KT}}$, and $C_{\mathbf{K4}}$, respectively.

Let L be one of $\mathbf{K}$, $\mathbf{KD}$, $\mathbf{KT}$, $\mathbf{K4}$. Given sets of clauses N and (C, N) we say (C, N) can be *derived in one step* from N in C_L iff either there are clauses A and B in N such that $A, B \Rightarrow C'$ in C_L or there is a clause A in N such that $A \Rightarrow C'$ in C_L, and $C = \mathrm{nf}(C')$ in C_L. A *derivation* of N' from N in C_L is a sequence $N = N_0, N_1, \ldots, N_n = N'$ such that for every i, $0 \leq i < n$, N_{i+1} can be derived from N_i in one step. A *refutation* of N in C_L is a derivation of $\bot$ from N in C_L. If a refutation of N exists, then N is C_L*-refutable*.

In [59] it is shown that a modal formula φ is valid in L iff $\mathrm{cnf}(\neg\varphi)$ is C_L-refutable. This soundness and completeness result is shown in [10] to also hold for a number of refinements of this modal resolution method and the extension by subsumption deletion.

So far, little work seems to have been conducted on devising specialised and efficient data structures and algorithms for modal resolution methods. Due to the extra structural information

that modal formulae carry, which is reflected in the more complicated clausal form, the data structures and algorithms developed for efficient propositional and first-order resolution provers cannot be utilised easily to implement modal resolution methods.

5.3 Sequent-based approaches

Sequent calculi were introduced by Gentzen [80] as a tool for studying natural deduction. The central property of sequent calculi is cut elimination which usually yields consistency as an easy corollary. The first sequent calculi and cut elimination results for modal logics have been established in the early fifties [39], see [89] for further historic references.

A *sequent* is a structure of the form $\Gamma \vdash \Delta$, where Γ and Δ are (finite) lists, multisets, or sets of formulae; Δ is also quite often restricted to be a singleton set or the empty set. A *sequent calculus* for a logic L consists of two parts: (i) a finite set of axioms, (ii) a finite set of rules of the form $\frac{S_1}{S}$ or $\frac{S_1\ S_2}{S}$ with conclusion S and premises S_1 and S_2, where S, S_1, and S_2 denote sequents. The rules can usually be divided into two major groups: *logical rules*, which introduce a new logical formula either on the left or on the right of the turnstile $\vdash$, and *structural rules*, which operate on the structure of the sequents. Of particular interest, both from a proof-theoretical and a computational point of view is the *cut rule*, a rule of the form

$$\frac{\Gamma_1 \vdash \Delta_1, A \qquad A, \Gamma_2 \vdash \Delta_2}{\Gamma_1, \Gamma_2 \vdash \Delta_1, \Delta_2}$$

where, in general, A is an arbitrary formula, called the *cut formula*. A *sequent calculus proof* of a *goal sequent* S is a tree whose nodes are labelled with sequents, such that (i) the root of the tree is labelled with S, (ii) each leaf node is an instance of an axiom of the calculus, and (iii) each sequent labelling a non-leaf node n follows by one of the rules of the calculus from the sequents labelling the children of n. This notion of a proof does not prescribe a particular approach to the construction of the proof of a sequent S. However, it is quite natural to proceed by *backward reasoning*, that is, to start with a tree consisting only of the root node labelled with S and to apply rules from bottom to top, taking the sequent labelling a node of the tree to be the conclusion of a rule and adding children to the tree labelled with the premises of the rule. The construction is complete if all the current leaf nodes are labelled with instances of axioms. In contrast, in *forward reasoning* one would start with one or more leaf nodes labelled with instances of axioms and build the tree toward its root node labelled with S. This approach is basically taken in the *inverse method*, see Section 5.4. For further details on sequent calculi see Sections 7 and 8 of Chapter 2 of this handbook.

From a computational point of view, sequent calculi pose several challenges and also provide insights that can help to improve systems based on tableau calculi or the inverse method.

First, the cut rule is problematic for backward reasoning, since we can choose an arbitrary formula to be the cut formula. We can try to show that we can restrict ourselves to cut formulae which are subformulae of formulae in the goal sequent S while retaining completeness of the calculus. The result would be a calculus with *analytic cut*. However, from a practical point of view, while for analytic cuts we can only choose finitely many different cut formulae, the search space may still be too large. Alternatively, one can try to show that for any sequent S there exists a proof without any application of the cut rule. In such a case, we can omit the cut rule from the calculus and obtain a *cut-free sequent calculus*. While for some modal logics it is rather straightforward to devise cut-free sequent calculi, for others it is much more challenging, for example, for **S5** [30, 151, 152], and for some it is an open problem, for example, for **PDL**

and converse **PDL** [127]. We are also not aware of cut-free systems for modal logics with the common knowledge operator.

Second, in the presence of the axiom schema **4**, systems based on sequent calculi face the same non-termination problems as systems based on tableau calculi. Recall from Section 7 of Chapter 2 one of the additional rules required for **K4**,

$$\frac{\Box Y_1, \ldots, \Box Y_m, Y_1, \ldots, Y_m, A \vdash \Diamond Z_1, \ldots, \Diamond Z_n, Z_1, \ldots, Z_n}{\Gamma, \Box Y_1, \ldots, \Box Y_m, \Diamond A \vdash \Diamond Z_1, \ldots, \Diamond Z_n, \Delta}$$

where Γ and Δ are sequences of formulae not containing a $\Box$-formula and $\Diamond$-formula, respectively. Here, the premise is not necessarily 'simpler' than the conclusion which can lead to situations in which this rule can be applied infinitely many times when using backward reasoning. To ensure termination a form of *loop-check* has to be used, that is, a check which detects whenever the 'same' sequent occurs twice on a branch of a proof. If in turn we would like to formulate the rules of our calculus in such a way that the applicability of rules does not depend on information about the whole branch of a proof or even the whole proof, additional *history information* has to accompany each sequent in a proof. What minimal history information for loop-checks is necessary to ensure termination on a variety of modal logics, including **KT** and **S4**, is investigated in [96, 98]. These results transfer directly to tableau calculi.

Finally, sequent-based systems face the same problems as tableau-based systems when trying to prove formulae involving disjunctions on the left or conjunctions on the right of the turnstile. Naturally, similar solutions as presented in Section 4, in particular, simplification and forms of intelligent backtracking, have also been considered in the context of sequent-based systems, most notably in the work of [25, 96, 97].

5.4 *Inverse method*

The inverse method is a variant of the sequent calculus [51, 135] which carries its name because it works from sub-goals to goals, whereas standard sequent-based approaches work in the other direction. For example, if it has already been proven that ϕ is false and ψ is true, then the inverse method will deduce from this that $\phi \to \psi$ is true. For this kind of forward reasoning to work, we need to be able to focus on an acceptably small set of axioms, and an acceptably small set of goals and sub-goals. For many modal logics, we can restrict our attention to such 'acceptably small' sets of formulae since they enjoy the sub-formula property, i.e. every valid formula ϕ has a derivation in which only (negated or unnegated) sub-formulae of ϕ occur [51]. Calculi for modal logics using the inverse method have been developed in [139, 140, 190]. The inverse method has been shown to be suitable for efficient modal logic theorem proving and is amenable to optimisations [190].

Interestingly, the inverse method is closely related to automata-based approaches [13]. More precisely, the algorithm that decides emptiness of automata (the problem to which satisfiability of a variety of modal logics can be reduced, see Section 5.1) can be viewed as being a notational variant of the inverse method. Both start with propositional axioms (in the automata emptiness test, these correspond to unreachable states), and saturate these axioms using basically the same deduction rules. As a consequence, it should be possible to translate a variety of automata-based decision procedures into the inverse method, thus obtaining an efficient implementation (or a good starting point for its implementation) basically for free.

6 OTHER REASONING PROBLEMS

In this chapter, we have focused on one specific reasoning problem, satisfiability or, dually, validity. There are, however, other interesting reasoning problems for modal logics that are useful for certain applications. We will discuss some of them in this section and we refer the reader to Section 5 of Chapter 13 of this handbook for reasoning problems that are motivated by applications of description logics.

6.1 Model checking

Model checking is the problem of deciding whether $\mathfrak{M}, w \models \varphi$ for a given Kripke structure $\mathfrak{M}$, a world w, and a modal formula φ. It is used for system verification, e.g. to verify a piece of soft- or hardware, as follows:

- $\mathfrak{M}$ represents the system: worlds are viewed as *states* the systems can be in,
- modal parameters represent actions which take the system from one state into another (or several others),
- w is some initial state, and
- φ is a temporal logic formula describing a desired behaviour of the system.

Whereas satisfiability algorithms have to reason w.r.t. *all* structures (possibly from a given class), model checking is concerned with a single structure, and thus quite different: model checking is often less complex than satisfiability, and there are industrial strength implementations of model checking algorithms capable of handling large systems and formulae from rather expressive logics. We refer the interested reader to Chapter 17 of this handbook and [34, 35].

6.2 Proof checking

Proof checking is the problem of deciding whether a given derivation P is a proof of a given formula φ, commonly with respect to a fixed calculus C for a logic L. It requires a language in which we are able to formalise derivations. The formalisation of a derivation may simply be a sequence or a tree-structure of formulae, but may also contain additional information about which and how inference rules of the calculus C have been used in each step of the derivation.

The motivation for proof checking is the fact that advanced theorem proving systems are rarely verified. Thus, like any other piece of software they invariably include errors which can lead the system to provide incorrect answers, including, providing an incorrect proof P for a given formula φ. Simplifying theorem proving systems to an extend that would allow their verification in all likelihood results in systems which are too slow to be useful. However, such system may still be sufficiently powerful to check the correctness of a given derivation P. Thus, a natural approach is to use a highly optimised but unverified system to find a proof P for a given formula φ which is then independently checked for correctness by a slower, verified system.

Proof checking has received considerable attention in the context of higher-order logic [155, 195] and is taken seriously in the context of first-order logic [136]. However, we are not aware of any work in this direction in the context of modal logics, although the problem of incorrect theorem provers also exists in this field. Note that in the context of the translation approach we can rely on first-order proof checkers augmented with a verified program for translating modal formulae into first-order clause sets.

Even more complex is the problem of verifying the non-existence of a proof. For the modal logics we have considered in this chapter we would also expect decision procedures to correctly determine in finite time that a given formula φ has no proof. A justification for this can be given by a model or representation of a model $\mathfrak{M}$ for $\neg\varphi$, produced by the decision procedure. A verified model checker could then be used to independently verify that $\mathfrak{M}$ is indeed a model of $\neg\varphi$.

6.3 Computing correspondences

Recall from Chapter 1 of this handbook the notion of a modal formula $\varphi(p_1, \ldots, p_n)$ over propositional variables $p_1, \ldots, p_n$ being *true in frame* $\mathfrak{F}$ iff for every world w and every valuation mapping V for its propositional variables we have $(\mathfrak{F}, V), w \models \varphi$, and the notion of a modal formula φ defining a class of frames iff φ is true in precisely the frames in the class. It straightforward to see that a modal formula φ over $p_1, \ldots, p_n$ is true in a frame $\mathfrak{F}$ iff the monadic second-order formula $\forall P_{p_1} \ldots P_{p_n} \forall x\, \pi_r(\varphi, x)$ is true in the class of all models over the frame $\mathfrak{F}$. There are methods for reducing such second-order formulae to equivalent first-order formulae and there are methods for reducing the second-order logic formulation of modal axioms to the corresponding frame properties. Computing the first-order equivalents of modal formulae (if they exists) amounts to the elimination of the universal or existential monadic second-order quantifiers. For example, if we are interested in establishing the *relational frame properties* corresponding to a modal formula φ, then we either have to eliminate the universal monadic second-order quantifiers from $\forall P_{p_1} \ldots P_{p_n} \forall x\, \pi_r(\varphi, x)$, or, equivalently, the existential monadic second-order quantifiers from $\exists P_{p_1} \ldots P_{p_n} \exists x\, \pi_r(\neg\varphi, x)$. There can be no algorithm which is guaranteed to find a first-order equivalent formula if there exists one. Still, a number of automated algorithms are known which provide a partial solution to the quantifier elimination problem, namely SCAN [75, 58], DLS [55, 185] and SQEMA [37]. SCAN and DLS are based on a form of resolution while SQEMA can be viewed as a modalized DLS algorithm. Here we briefly review the SCAN algorithm, but more details of DLS and other quantifier elimination algorithms can be found in [36, 147].

The SCAN algorithm involves three stages:

(i) transformation to clausal form and (inner) Skolemisation;

(ii) C-resolution;

(iii) reverse Skolemisation (unskolemisation).

The input of SCAN is a second-order formula of the form $\exists Q_1 \ldots \exists Q_k\, \psi$, where the Q_i are unary predicate variables and ψ is a first-order formula. In the first stage SCAN converts ψ into clausal normal form by transformation into conjunctive normal form, Skolemisation, and clausifying the Skolemised formula. In the second stage SCAN performs a special kind of constraint resolution, called *C-resolution*, the two main inference rules are given in Figure 16. It generates all and only resolvents and factors with the second-order variables that are to be eliminated, which in the case of computing frame correspondence properties includes all existentially quantified second-order variables. When all C-resolvents and C-factors with respect to a particular Q_i-literal and the rest of the clause set have been generated, purity deletion removes all clauses in which this literal occurs. The subsumption deletion rule is optional for the sake of soundness, but helps simplify clause sets in the derivation.

If the C-resolution stage terminates, it yields a set N of clauses in which the specified second-order variables are eliminated. This set is satisfiability equivalent to the original second-order

formula. If no clauses remain after purity deletion, then the original formula is a tautology; if C-resolution produces the empty clause, then it is unsatisfiable. If N is non-empty, finite and does not contain the empty clause, then in the third stage, SCAN attempts to restore the quantifiers from the Skolem functions by reversing Skolemisation. This is not always possible, for instance if the input formula is not first-order definable.

If the input formula is not first-order definable and stage two terminates successfully yielding a non-empty set not containing the empty clause then SCAN produces equivalent second-order formulae in which the specified second-order variables are eliminated but quantifiers involving Skolem functions occur and the reverse Skolemisation typically produces Henkin quantifiers. If SCAN terminates and reverse Skolemisation is successful, then the result is a first-order formula logically equivalent to the second-order input formula.

SCAN can compute the frame correspondence properties for very many well-known axioms including $\mathbf{T}$, $\mathbf{4}$, and $\mathbf{5}$. Recent work has in fact shown that the SCAN algorithm is complete for the class of all Sahlqvist formulae, in the sense that, when given a Sahlqvist formula it will successfully compute an equivalent first-order formula for it [88].

6.4 Model generation

A problem closely related to the satisfiability problem is the problem of generating (counter-) models. Ideally we want to construct finite models if they exist. It is possible to use both tableau and resolution methods to prove that logics have the finite model property and also to give procedures for constructing standard Kripke models.

Although tableau provers do not always output models, it is well-known that tableau procedures implicitly generate models (of some kind) for satisfiable input problems. This is especially true for semantic tableau procedures which are defined by structural rules and use explicit accessibility relations. Modal tableau procedures of the kind described in Section 4 which use propagation rules for handling the additional axioms do construct models but often they are just skeleton models which need to be completed with respect to the relational correspondence properties and then give standard Kripke models.

In first-order logic it is well-known that hyperresolution like tableau methods can be employed both as a reasoning method and a Herbrand model builder [31, 65]. It has been shown that the methods using $\mathsf{R}^{\mathsf{hyp}}$ and the relational translation described in Section 3 require hardly any extra effort to construct a modal model [49, 121, 180]. It is usually a simple matter to read off a Kripke model from the saturated set of ground unit clauses which represents a Herbrand model. In general this set will be infinite in the limit, but when $\mathsf{R}^{\mathsf{hyp}}$ is a decision procedure then the set is finitely bounded and consequently a finite Kripke model can be defined.

In more detail, a *Herbrand interpretation* is a set of ground atoms. By definition a ground atom A is *true* in an interpretation H iff $A \in H$ and it is *false* in H iff $A \notin H$. Now, extend the

C-Resolution: $$\frac{C \vee Q(s_1, \ldots, s_n) \quad \neg Q(t_1, \ldots, t_n) \vee D}{C \vee D \vee s_1 \not\approx t_1 \vee \ldots \vee s_n \not\approx t_n}$$
provided the two premises have no variables in common and are distinct clauses

C-Factoring: $$\frac{C \vee Q(s_1, \ldots, s_n) \vee Q(t_1, \ldots, t_n)}{C \vee Q(s_1, \ldots, s_n) \vee s_1 \not\approx t_1 \vee \ldots \vee s_n \not\approx t_n}$$

Figure 16. The calculus of SCAN

definition as expected to the Boolean combination of ground atoms. A clause C is true in H iff for all ground substitutions σ there is a literal L in $C\sigma$ which is true in H. A set N of clauses is true in H iff all clauses in N are true in H. If a set N of clauses is true in an interpretation H then H is referred to as a *Herbrand model* of N. It is proved in [49, 121] that the combination of the relational translation and R^{hyp} can be used as a finite Herbrand model generator for the modal logics $\mathbf{K}_n$, $\mathbf{K}_n^{\smile}$ and the extensions with $\mathbf{T}$, $\mathbf{D}$, $\mathbf{B}$ (actually more general results are proved).

In general Herbrand models are not unique and can be large. Therefore it is useful to have a method for generating minimal Herbrand models. An interpretation H is a *minimal Herbrand model* for a set N of clauses iff H is a Herbrand model of N and for no Herbrand model H' of N, $H' \subset H$ holds. Various approaches to generating minimal Herbrand models with hyperresolution are known [26, 31, 94, 144]. It follows from [31] and investigations of $\mathbf{GF}^-$ and the class $\mathcal{BU}$ in [81, 82] that with a moderate extension of R^{hyp}, denoted here by $R^{\mathsf{hyp}}_{\mathsf{min}}$, it is possible to guarantee the generation of all and only minimal Herbrand models for any modal and description logic reducible to a decidable class of range restricted clauses. It is necessary to use a depth-first strategy, a complement splitting rule should be used so that the first model generated is a minimal Herbrand model, and a model constraint propagation rule is necessary to prevent the generation of non-minimal Herbrand models (see Figure 17). The procedure $R^{\mathsf{hyp}}_{\mathsf{min}}$ is generally sound and complete and is a minimal Herbrand model building procedure for range-restricted clauses [31]. An alternative is to use the generalisation [81, 82] of an approach of [144].

It is not difficult to see that model generation procedures and the mentioned minimal Herbrand model generation procedures can be developed by using hyperresolution and the other translation methods. Because of the close connection to tableau, corresponding tableau procedures can be defined and all results carry over to the tableau setting (see [49, 121]).

6.5 Bisimulation

Chapter 1 of this handbook has introduced the notion of a bisimulation between two Kripke models. A *bisimulation* between models $\mathfrak{M} = \langle W, R, V\rangle$ and $\mathfrak{M}' = \langle W', R', V'\rangle$ is a binary relation $E \subseteq W \times W'$ such that whenever $E(w, w')$ the following three properties hold:

Atomic: for all propositional variables p, $w \in V(p)$ iff $w \in V'(p)$;

Zig: if $R_i(w, v)$ for some i, then there exists v' in $\mathfrak{M}'$ such that $E(v, v')$ and $R'_i(w', v')$; and

Zag: if $R'_i(w', v')$ for some i, then there exists v in $\mathfrak{M}$ such that $E(v, v')$ and $R_i(w, v)$.

Complement splitting: $$\frac{N \cup \{C \vee D\}}{N \cup \{C, \neg D\} \quad | \quad N \cup \{D\}}$$

where D is a ground clause.

Model constraint propagation: $$\frac{N}{N \cup \{\neg A_1 \vee \ldots \vee \neg A_n\}}$$

where $\{A_1, \ldots, A_n\}$ is the finite Herbrand model of an open branch which is complete with respect to R^{hyp}. The model constraint propagation rule extends all branches in the derivation tree (to the right) which are not complete with respect to $R^{\mathsf{hyp}}_{\mathsf{min}}$.

Figure 17. Additional rules for minimal Herbrand model generation

One important property of bisimilar models is that they satisfy the same μ-calculus formulae, that is, let $E(w, w')$ hold then a μ-calculus formula φ is true at w in $\mathfrak{M}$ iff φ is true at w' in $\mathfrak{M}'$. The notion of bisimulation not only plays an important rôle in modal logic, as an equivalence principle between Kripke models, but also in other fields, for example, concurrency theory, set theory, and formal verification. An algorithm for 'on the fly' verification of bisimulations is presented in [66].

A related problem is that of *bisimulation minimisation*, that is, the problem of finding the minimal Kripke model bisimilar to a given Kripke model. In particular, in the context of formal verification by model checking (see Section 6.1 and Chapter 17 of this handbook for further details), bisimulation minimisation provides an easily and automatically computable way to reduce the number of states of a model while preserving the truth and falsehood of the formulae that hold in it.

Let $\mathfrak{M} = \langle W, R, V\rangle$ be a Kripke model and E be an equivalence relation on W. Let $[w]_E$ denote the equivalence class of a world $w \in W$ with respect to E. The set of all equivalence classes is a *partition* of W and $\mathfrak{M}$. The bisimulation minimisation of a Kripke model $\mathfrak{M}$ is the quotient $\mathfrak{M}/E = \langle W', R', V'\rangle$ where

$$\begin{aligned} W' &= \{[w]_E \mid w \in W\}, \\ R' &= \{([w]_E, [w']_E) \mid w, w' \in W \wedge R'(w, w')\}, \text{ and} \\ V'(p) &= \{[w]_E \mid w \in V(p)\} \end{aligned}$$

for every propositional variable p such that E is the maximal equivalence relation on W which is also a bisimulation between $\mathfrak{M}$ and itself. A partition P is *stable* with respect to E iff for each pair $[w]_E$, $[w']_E$ of equivalence classes with respect to E either $[w]_E \subseteq E^{-1}([w']_E)$ or $[w]_E \cap E^{-1}([w']_E) = \emptyset$.

In the computation of the bisimulation minimisation of a Kripke model we can basically follow two strategies. One is a negative strategy in which we start with the coarsest partition P such that $E(w, w')$ iff $w \in V(p)$ iff $w' \in V(p)$ for every positional variable p and split classes whenever P is not stable. Another is a positive strategy in which we start with the finest partition P in which each equivalence class consists of a single world and the bisimulation minimisation is constructed via a sequence of steps in which we merge two or more classes. An algorithm following the negative strategy is presented in [156] which has the optimal worst-case running time, namely $O(|R| log |W|)$. An implementation of this algorithm is presented in [67]. Other algorithms following a negative strategy are presented in [28, 130]. They take advantage of the fact that in a number of applications we are only interested in the part of a Kripke model reachable from a designated start world. In this case, equivalence classes associated with unreachable worlds need not be taken into account when considering the stability of an equivalence class associated with a reachable world. An algorithm following the positive strategy is presented in [157]. Recently, [57] has introduced an algorithm combines both the positive and negative strategy by using the algorithms of [156] and [157] as subroutines. For a range of special cases this algorithm terminates in time $O(|R| + |W|)$.

Finally, [71] presents on-the-fly model checkers for invariant properties incorporating the bisimulation minimisation algorithms of [28, 130, 156]. From an empirical comparison they draw the conclusion that in this context an optimised version of the algorithm of [156] performs better than the other two.

6.6 Modal logic programming

The problem of extending logic programming languages with modal operators has received a lot of attention in the late 1980s and early 1990s, at about the same time most of the direct resolution methods mentioned in Section 5.2 were developed and also work on the translation methods described in Section 3 intensified. Consequently, work in this area can again be divided between direct approaches and translation approaches.

Following the direct approach, [21, 20] presents a declarative semantics and an SLD resolution calculus for a class of modal logic programs in modal logics $\mathbf{KD}$, $\mathbf{KT}$, and $\mathbf{S4}$, while [22, 23] present a framework for developing the fixpoint and operational semantics of a class of multi-modal logic programs where additional properties of modal operators can be described by axiom schemas of the form $[i_1][i_2]\cdots[i_m]p \rightarrow [j_1][j_2]\cdots[j_n]p$, so-called inclusion axioms. More recent work includes [142] presenting a fixpoint semantics, least model semantics, and an SLD resolution calculus for modal logic programs in modal logics extending $\mathbf{K}$ with a non-empty selection of the axiom schemas $\mathbf{B}$, $\mathbf{D}$, $\mathbf{T}$, $\mathbf{4}$ and $\mathbf{5}$. Also, modal logic programs in [142] are as expressive as the general modal Horn fragment which allows arbitrary occurrences of the modal operators $\Box$ and $\Diamond$ in programs clauses and goals.

Following the translation approach, [50] applies the functional translation to multi-modal logic programs in the modal logics $\mathbf{KD}$, $\mathbf{KT}$, $\mathbf{KD4}$, $\mathbf{KT4}$, $\mathbf{KF}$ ($\mathbf{F}$ is the functionality axiom), and simple inclusion axioms of the form $[i]p \rightarrow [j]p$. In these logics, the functional translation of goals and program clauses in the general modal Horn fragment are in the first-order Horn fragment. For computations SLD resolution extended by theory unification is used. In [146] presents an application of the *semi-functional translation* [145, 148] to modal logic programs in modal logics $\mathbf{KB}$ and $\mathbf{KDB}$, as well as $\mathbf{KD}$, $\mathbf{KT}$, and their extension by one or both of the axiom schemas $\mathbf{4}$ and $\mathbf{5}$. The semi-functional translation combines features of the relational and functional translation. For modal formulae in negation normal form, subformulae of the form $\Box\varphi$ are translated using the relational translation, while subformulae of the form $\Diamond\varphi$ are translated using the functional translation. A *functional simulator axiom* needs to be added to the translation to link the relational and functional aspects of the translation. The semi-functional translation has the advantage over the functional translation that the frame properties of many modal logics, including the ones listed above, can be specified by simple first-order Horn theories without equality. Consequently, the use of theory unification and theory resolution can be avoided. Furthermore, if the semi-functional translation is applied to goals and program clauses in the general modal Horn fragment, then the resulting first-order clauses are themselves Horn. Together with the fact that the frame properties are expressed by Horn clauses, this implies that unmodified SLD resolution can be used to execute the translated modal logic programs.

The functional and semi-functional translation have been incorporated into MSPASS [120, 174]. Implementations of systems based on the direct approach include MOLOG [62, 63], MProlog [141, 143], and TIM [21]. However, just as for the direct resolution approaches described in Section 5.2, little work seems to have been conducted on developing specialised and efficient data structures and algorithms for such systems, with the exception of [2] which describes an abstract machine model for MOLOG, in analogue to the Warren Abstract Machine model for Prolog [191].

There has also been considerable work on temporal logic programming. For surveys on this work which also cover some of the approaches to modal logic programming mentioned above see [154, 70, 84].

There is currently renewed interest in modal and temporal logic programming in the context of multi-agent system development [24, 53, 69] and related areas.

7 REVIEW AND DISCUSSION

In this chapter we have examined computational approaches to modal logics. Although we have considered a variety of computational approaches and reasoning problems, we have focused on the use of translation-based and tableau-based algorithms for deciding the satisfiability of a formula, both with and without reference to a background theory. This focus was motivated by the dominance of translation-based and tableau-based approaches in implemented systems, and by the importance of satisfiability testing in applications such as the verification of multi-agent systems and ontology engineering.

The reason for the dominance of these two approaches is that they have proved amenable to implementation and optimisation techniques that dramatically improve typical case performance; the use of such techniques is crucial if reasoning systems are to be effective in applications. The applicability and effectiveness of optimisation techniques and refinements is, however, highly dependent on the logic under consideration and on the class of problem being solved. For example, in the context of tableau-based algorithms, caching must be used with care in the presence of converse modalities, and semantic branching search, while highly effective for randomly generated problems, may be ineffective (and perhaps even counter productive) for problems derived from ontology engineering applications. Similarly, in the context of translation-based algorithms, hyperresolution may be the most suitable approach for randomly generated problems in the modal logic $\mathbf{K}_n$, while ordered resolution is more effective for problems derived from ontology engineering applications.

Regarding the two approaches, both have advantages and disadvantages. Tableau-based methods generally require full implementation, but this allows the implementor to choose and fine-tune the optimisations, data structures, and algorithms for effective operation in the intended application. In contrast, no major implementation effort is needed for translation-based methods, but a careful choice of translation, refinement of resolution, and operational parameters is required to guarantee termination and effectiveness of the first-order logic prover on the class of problems being solved. The choice of approach may ultimately depend on the logic in question: tableau-based methods seem to have some advantages in the presence of graded modalities (counting), for example, whereas translation-based methods can handle and may be better for boolean modal logics (role negation). Currently, tableau-based approaches are the most widely used in ontology applications, with description logic systems such as FaCT++, Racer and Pellet [159, 90, 160]. In contrast, translation-based methods have a number of other uses, for example, computing correspondence properties and modal logic programming.

The use of implemented systems in realistic applications brings with it new challenges, both with respect to the expressive power of the logics being used, and the size and complexity of the problems to be solved. The W3C standard ontology language OWL, for example, corresponds to a logic with transitive, converse and graded modalities, as well as nominals, and ontology applications may call for reasoning with respect to very large background theories. For the logic corresponding to OWL, a tableau-based algorithm has only recently been introduced [110], a translation-based algorithm using the basic superposition calculus is still under development [112], and the development of computational and optimisation techniques is the subject of considerable ongoing research. Similarly, as mentioned in the introduction, agent frameworks consist of complex multi-modal logics, typically including a dynamic component, allowing the representation of dynamic activity via a temporal or a dynamic logic. Ongoing research is focusing on developing advanced computational methods and optimisation techniques for such frameworks.

INTRODUCTION

Model theory is about semantics; it studies the interplay between a logical language (logic) and the models (structures) for that language. Key issues therefore are *expressiveness* and *definability.* At the basic level these concern the questions which structural properties are expressible and which classes of structures are definable in the logic. These basic questions immediately lead to the study of *model constructions*; to the *analysis of models and of model classes* for given formulae or theories; to notions of *equivalence between structures* with respect to the truth of formulae; and to the study of preservation phenomena.

Modal logics[1] come as members of a loosely knit family and have various links to other logics – classical first- and second-order logic as well as, for instance, temporal and process logics stemming from particular applications. Correspondingly, the key issues mentioned above may also be studied comparatively, both within the family and in relation to other relevant logics. Such a comparative view can support an understanding of the internal coherence of the rich family of modal logics. It also offers a perspective to place modal logics in the wider logical and model theoretic context.

In regard to the coherence of the family of modal logics, it is important to understand in model theoretic terms what it is that makes a logic 'modal'. For that aim we devote a major part of this chapter to the discussion of *bisimulation.* Many other features of the 'modal character' can be understood in terms of bisimulation invariance; this is true most notably of the *local* and *restricted nature of quantification.* Due to these features modal logic enjoys very specific features, and in many respects its model theory can be developed along lines that have no direct counterparts in classical model theory.

In regard to the wider logical context, there is a rich body of classical work in modal model theory that measures modal logic against the backdrop of classical first- and second-order logic into which it can be naturally embedded. But, beside this 'classical picture', there are also many links with other logics, partly designed for other purposes or studied with a different perspective from that of classical model theory.

In the classical picture, both first- and second-order logic have their role to play. This is because modal logic actually offers several distinct semantic levels, as will be reviewed in the following section which provides an introduction to the model theoretic semantics of modal logic. So, a modal formula is traditionally viewed in four different ways, subject to two orthogonal dichotomies – *Kripke structures* (also called *Kripke models*) versus *Kripke frames* and *local* versus *global.*

The fundamental semantic notion in basic modal logic is *truth of a formula at a state in a Kripke structure*; this notion is *local* and of a *first-order* nature. Semantics in Kripke frames is obtained, if instead one looks at all possible propositional valuations

[1]In this chapter we use the term *modal logic* (despite the established tradition in the literature on modal logic) in a typical model-theoretic sense, as a (propositional) modal language equipped with suitable relational (Kripke) semantics, rather than proof systems over such languages, determined by a set of axioms and inference rules, such as K, S4, etc. We refer to the latter as 'axiomatic extensions'.

over the given frame (in effect an abstraction through implicit universal second-order quantification over all valuations); this semantics, accordingly, is of essentially *second-order* nature. On the other hand, the passage from local to *global* semantics is achieved if one looks at truth in all states (an abstraction through implicit universal first-order quantification over all states).

While all these semantic levels are ultimately based on the local semantics in Kripke structures, the two independent directions of generalisation, and in particular the divide between the (first-order) Kripke structure semantics and the (second-order) frame semantics, give rise to very distinct model theoretic flavours, each with their own tradition in the model theory of modal logic. Still, these two semantics meet through the notion of a *general frame* (closely related to a *modal algebra*).

History. The origins of model theory of modal logic go back to the fundamental papers of Jónsson and Tarski [78, 79], and Kripke [86, 87] laying the foundations of the *relational (Kripke) semantics*, followed by the classical work of Lemmon and Scott [91].

Some of the most influential themes and directions of the classical development of the model theory of modal logic in the 1970/80s have been: the *completeness theory* of modal axiomatic systems with respect to the frame-based semantics of modal logic, and the closely related *correspondence theory* between that semantics and first-order logic [117, 28, 123, 124, 113, 42, 51, 125, 127, 128]; and the *duality theory* between Kripke frames and modal algebras, via general frames [42, 43, 44, 45, 114]. Also at that time, the *theory of bisimulations and bisimulation invariance* emerged in the semantic analysis of modal languages in [125, 128]. For detailed historical and bibliographical notes see [5], and the survey [49] for a recent and comprehensive historical account of the development of modal logic, and in particular its model theory.

Overview. The sections of this chapter are roughly arranged in three parts or main tracks, reflecting the semantic distinctions outlined above.

The first part provides a common basic introduction to some of the key notions, in particular the different levels of semantics in section 1, followed by the concept of bisimulation and bisimulation respecting model constructions in section 2. This more general thread is taken up again in section 6 with some more advanced model constructions, and also in the final section 9 devoted to some ideas in the finite model theory of modal logic.

A second track, comprising sections 3 to 5, is primarily devoted to modal logic as a logic of Kripke structures (first-order semantics): section 3 continues the bisimulation theme; section 4 is specifically devoted to the role of modal logic as a fragment of first-order logic; section 5 illustrates some of the richness of modal logics over Kripke structures in terms of variations and extensions.

The third track is devoted to a study of modal logic as a logic of frames (the second-order semantics). This comprises more advanced constructions such as ultrafilter extensions and ultraproducts in section 6, basic model theory of general frames in section 7, and a survey of classical results on frame definability and relations with second-order logic in section 8.

Most of the other chapters in this handbook supplement this chapter with important model-theoretic topics and results. In particular, we refer the reader to Chapters 1, 3, 6, 7 and 8.

1 SEMANTICS OF MODAL LOGIC

1.1 Modal languages

A (unary, poly-)*modal similarity type* is a set τ of *modalities* $\alpha \in \tau$. Beside τ, we fix a (countable) set Φ of *propositional variables* or *atomic propositions.* With τ and Φ we associate the *modal language* $\mathrm{ML}(\tau, \Phi)$, in which every $\alpha \in \tau$ labels a modal *diamond operator* $\langle\alpha\rangle$. The formulae of $\mathrm{ML}(\tau, \Phi)$ are recursively defined as follows:

$$\varphi := \bot \mid p \mid (\varphi_1 \to \varphi_2) \mid \langle\alpha\rangle\varphi,$$

where $p \in \Phi$ and $\alpha \in \tau$, and unnecessary outer parentheses are dropped. The logical constant $\top$ and connectives $\neg, \wedge, \vee, \leftrightarrow$ may be introduced on an equal footing or are regarded as standard abbreviations. The operator $[\alpha]$, defined by $[\alpha]\,\varphi := \neg\langle\alpha\rangle\neg\varphi$, is the *box operator dual to* $\langle\alpha\rangle$. A formula not containing atomic propositions is called a *constant formula*.

To keep the notation simple, we regard the set Φ as fixed, and will usually not mention it explicitly. So we write $\mathrm{ML}(\tau)$, or also just ML when τ is clear from the context or irrelevant. We use the same notation for the set of all formulae of $\mathrm{ML}(\tau, \Phi)$, and in general identify notationally logical languages with their sets of formulae. In the *mono-modal* case of a modal similarity type consisting of a single unary modality, the only diamond and box are denoted by just $\Diamond$ and $\Box$, respectively.

DEFINITION 1. The *nesting depth* δ of a formula is defined recursively as follows:
$\delta(\bot) = \delta(p) = 0$;
$\delta(\varphi_1 \to \varphi_2) = \max(\delta(\varphi_1), \delta(\varphi_2))$;
$\delta(\langle\alpha\rangle\,\varphi) = \delta(\varphi) + 1$.
The fragment $\mathrm{ML}_n(\tau)$ comprises all formulae of $\mathrm{ML}(\tau)$ with nesting depth $\leq n$.

1.2 Kripke frames and structures

With the modal similarity type τ we associate a *relational similarity type* consisting of binary relations R_α for $\alpha \in \tau$. For simplicity we also denote this derived relational type by τ.

DEFINITION 2. A (*Kripke*) τ*-frame* is a relational τ-structure $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ where $W \neq \emptyset$ and $R_\alpha \subseteq W \times W$ for each $\alpha \in \tau$. The domain W of $\mathfrak{F}$ is denoted by $\mathrm{dom}(\mathfrak{F})$. The relations $(R_\alpha)_{\alpha\in\tau}$ are the *accessibility* or *transition relations* in $\mathfrak{F}$. The elements of W, traditionally called *possible worlds*, will also be referred to, depending on the context, as *states, points, or nodes.* A *pointed* τ*-frame* is a pair $(\mathfrak{F}, w)$ where $w \in \mathrm{dom}(\mathfrak{F})$.

We also write $wR_\alpha u$ rather than $R_\alpha wu$ or $(w, u) \in R_\alpha$. Given a τ-frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$, every R_α defines two unary operators, $\langle R_\alpha\rangle$ and its dual $[R_\alpha]$, on $\mathcal{P}(W)$ as follows:

$$\langle R_\alpha\rangle\,(X) := \{w \in W \mid wR_\alpha u \text{ for some } u \in X\} \qquad \text{and} \qquad [R_\alpha](X) := \overline{\langle R_\alpha\rangle(\overline{X})}$$

where $\overline{X} := W \setminus X$ denotes the complement of X in W.

DEFINITION 3. A *Kripke structure* (*Kripke model*) over a τ-frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ is a pair $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$ where $V : \Phi \to \mathcal{P}(W)$ is a *valuation*, assigning to every atomic proposition p the set of states in W where p is declared true. The set W is the *domain of* $\mathfrak{M}$, denoted $\mathrm{dom}(\mathfrak{M})$. We often specify Kripke structures directly: $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$. A *pointed Kripke structure* is a pair $(\mathfrak{M}, w)$ where $w \in \mathrm{dom}(\mathfrak{M})$.

In any Kripke structure $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$ the valuation V can be extended to a valuation of all formulae, which is again denoted by V. That extension is defined recursively as follows:[2]

$V(\bot) := \emptyset$;
$V(\varphi_1 \to \varphi_2) := \overline{V(\varphi_1)} \cup V(\varphi_2)$;
$V(\langle\alpha\rangle\,\varphi) := \langle R_\alpha\rangle\,(V(\varphi))$ (and $V([\alpha]\,\varphi) = [R_\alpha]\,(V(\varphi))$.

While first-order sentences express properties of a structure as a whole, modal formulae always make implicit reference to a distinguished (current) state in a Kripke structure. So the basic semantic notion in modal logic is *truth of a formula at a state of a Kripke structure*, with derived notions of validity also in Kripke structures and frames.

DEFINITION 4. A τ-formula φ is:

(i) *true at the state w of the τ-structure* $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$, denoted $\mathfrak{M}, w \models \varphi$, if $w \in V(\varphi)$. This is the same as saying that φ is *true in the pointed structure* $(\mathfrak{M}, w)$. A formula that is true at a state of some τ-structure is *satisfiable.*

(ii) *valid in* $\mathfrak{M}$, denoted $\mathfrak{M} \models \varphi$, if $\mathfrak{M}, w \models \varphi$ for every $w \in \mathrm{dom}(\mathfrak{F})$, i.e., if $V(\varphi) = \mathrm{dom}(\mathfrak{F})$.

(iii) *(locally) valid at the state w of* $\mathfrak{F}$, denoted $\mathfrak{F}, w \models \varphi$, if $\mathfrak{M}, w \models \varphi$ for every τ-structure $\mathfrak{M}$ over $\mathfrak{F}$.
This is the same as saying that φ is *valid in the pointed frame* $(\mathfrak{F}, w)$.

(iv) *valid in* $\mathfrak{F}$, denoted $\mathfrak{F} \models \varphi$, if $\mathfrak{F}, w \models \varphi$ for every $w \in \mathrm{dom}(\mathfrak{F})$.
Equivalently: $\mathfrak{M} \models \varphi$ for every τ-structure $\mathfrak{M}$ over $\mathfrak{F}$.

(v) *valid*, denoted $\models \varphi$, if $\mathfrak{F} \models \varphi$ for every τ-frame $\mathfrak{F}$.

1.3 The standard translations into first- and second-order logic

With the modal language $\mathrm{ML}(\tau, \Phi)$, we associate the following purely relational vocabularies:

- the relational version of τ itself, consisting of R_α for $\alpha \in \tau$, and again denoted by just τ.
- the expansion τ_Φ of the relational vocabulary τ by unary predicates $\{P_0, P_1, \ldots\}$ associated with the atomic propositions $p_0, p_1, \ldots \in \Phi$.

Correspondingly, $\mathrm{FO}(\tau)$ and $\mathrm{FO}(\tau_\Phi)$ are the first-order languages with vocabularies τ and τ_Φ, respectively. We regard a τ-frame as a τ-structure in the usual sense, and a Kripke structure over a τ-frame as a τ_Φ-structure, with P_i interpreted as $V(p_i)$. We use the same notation for Kripke structures and for the associated first-order structures, as this causes no confusion. Wherever necessary, we will highlight the distinction by writing $\models_{\mathrm{FO}}$ to explicitly appeal to first-order semantics.

[2] In algebraic terms (see Chapter 6), the extended valuation is the unique homomorphism from the free τ-algebra of formulae to the modal algebra associated with the model $\mathfrak{M}$, extending V.

Truth and validity of a modal formula in a Kripke structure are *first-order notions* in the following sense. Let $\mathrm{VAR} = \{x_0, x_1, \ldots\}$ be the set of first-order variables of $\mathrm{FO}(\tau_\Phi)$. The formulae of $\mathrm{ML}(\tau)$ are translated into $\mathrm{FO}(\tau_\Phi)$ by means of the following *standard translation* [124, 127], parameterised with the variables from VAR:

- $\mathrm{ST}(p_i; x_j) := P_i x_j$ for every $p_i \in \Phi$;
- $\mathrm{ST}(\bot; x_j) := \bot$;
- $\mathrm{ST}(\varphi_1 \to \varphi_2; x_j) := \mathrm{ST}(\varphi_1; x_j) \to \mathrm{ST}(\varphi_2; x_j)$;
- $\mathrm{ST}(\langle\alpha\rangle\, \varphi; x_j) := \exists y(x_j R_\alpha y \wedge \mathrm{ST}(\varphi; y))$, where y is the first variable in $\mathrm{VAR} \setminus \{x_j\}$.

Note that only x_j is free in $\mathrm{ST}(\varphi; x_j)$. Furthermore, for the standard translation it suffices to use only the variables x_0 and x_1 (free or bound) in an alternating fashion. This yields a translation into the *two-variable fragment* FO^2 of first-order logic. Also, the standard translation of any modal formula falls into the *guarded fragment* of first-order logic. These observations are taken up in section 4.

The standard translation is semantically faithful in the following sense.

PROPOSITION 5. *For every pointed Kripke structure* $(\mathfrak{M}, w)$ *and* $\varphi \in \mathrm{ML}(\tau)$,

$$\mathfrak{M}, w \models \varphi \;\; \textit{iff} \;\; \mathfrak{M}, w \models_{\mathrm{FO}} \mathrm{ST}(\varphi; x_0).$$

While the semantics and validity for modal formulae over Kripke structures is thus essentially first-order, validity of a modal formula in a frame goes beyond first-order logic. Indeed, paraphrasing the definition in terms of the standard translation, a modal formula φ is valid in a frame iff its standard translation is true in that frame under *every* interpretation of the unary predicates occurring in it.

PROPOSITION 6. *For every pointed Kripke frame* $(\mathfrak{F}, w)$ *and* $\varphi \in \mathrm{ML}(\tau)$ *with atomic propositions among* $p_0, \ldots, p_n$*:*

$$\mathfrak{F}, w \models \varphi \;\; \textit{iff} \;\; \mathfrak{F}, w \models \forall P_0 \ldots \forall P_n \mathrm{ST}(\varphi; x_0).$$

Consequently, $\mathfrak{F} \models \varphi$ *iff* $\mathfrak{F} \models \forall P_0 \ldots \forall P_n \forall x_0 \mathrm{ST}(\varphi; x_0)$.

1.4 Theories, equivalence and definability

With every logic $\mathcal{L}$ comes an associated notion of logical equivalence between structures. Two structures of the appropriate type are equivalent with respect to $\mathcal{L}$ if no property expressible in $\mathcal{L}$ distinguishes between them, i.e., if their $\mathcal{L}$-theories are the same. In this sense, first-order logic gives rise to the notion of elementary equivalence. Correspondingly, *modal equivalence* is indistinguishability in modal logic. Each view of the semantics of modal logic – in terms of (pointed or plain) structures or frames – corresponds to a notion of modal theories and modal equivalence.

DEFINITION 7. The *modal theory* of a pointed Kripke τ-structure $(\mathfrak{M}, w)$ is the set of all formulae of $\mathrm{ML}(\tau)$ satisfied in $(\mathfrak{M}, w)$: $\mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}, w) := \{\varphi \in \mathrm{ML}(\tau) \mid \mathfrak{M}, w \models \varphi\}$.

Correspondingly, the modal theory of $\mathfrak{M}$ is $\mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}) := \{\varphi \in \mathrm{ML}(\tau) \mid \mathfrak{M} \models \varphi\}$. The modal theories of a frame and pointed frame, as well as of classes of (pointed) Kripke structures or frames, are defined likewise.

The basic notion of modal equivalence, corresponding to the notion of truth at a state of a Kripke structure, is an equivalence relation on the class of *pointed Kripke structures* $(\mathfrak{M}, w)$. Natural variants cover the derived notions for plain Kripke structures, and for pointed or plain frames.

DEFINITION 8. For two pointed Kripke τ-structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$: $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ are ML-*equivalent*, denoted $(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')$, iff they satisfy exactly the same formulae of ML, i.e., iff $\mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}, w) = \mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}', w')$. Modal equivalence between Kripke structures, frames, and pointed frames are defined likewise.

Definability in modal logic means different things corresponding to the different levels of the semantics. We distinguish local versus global definability (truth at a state versus validity throughout a frame/structure), and definability at the level of structures versus frames (truth/validity for a given valuation versus for all valuations).

Given a formula $\varphi \in \mathrm{ML}(\tau)$, the classes of pointed Kripke structures, Kripke structures, pointed frames and frames defined by φ are denoted as $\mathrm{KS}(\varphi)$, $\mathrm{PKS}(\varphi)$, $\mathrm{FR}(\varphi)$, and $\mathrm{PFR}(\varphi)$, respectively:

$$\mathrm{PKS}(\varphi)=\{(\mathfrak{M}, w) \mid \mathfrak{M}, w \models \varphi\} \qquad \mathrm{PFR}(\varphi)=\left\{(\mathfrak{F}, w) \;\middle|\; \begin{array}{l}(\mathfrak{F}, V), w \models \varphi \\ \text{for all valuations } V\end{array}\right\}$$

$$\mathrm{KS}(\varphi)=\{\mathfrak{M} \mid \mathfrak{M} \models \varphi \text{ for all } w \in \mathrm{dom}(\mathfrak{M})\} \qquad \mathrm{FR}(\varphi)=\left\{\mathfrak{F} \;\middle|\; \begin{array}{l}(\mathfrak{F}, V), w \models \varphi \text{ for all } w \\ \text{and for all valuations } V\end{array}\right\}$$

DEFINITION 9. A class $\mathcal{P}$ of pointed Kripke τ-structures is *(modally) definable* in the language $\mathrm{ML}(\tau)$ if $\mathcal{P} = \mathrm{PKS}(\varphi)$ for some formula $\varphi \in \mathrm{ML}(\tau)$. Definable classes of Kripke structures, frames, and pointed frames are defined likewise.

EXAMPLE 10. Here are some examples of modally definable classes of Kripke frames and structures.

The class of pointed Kripke structures $(\mathfrak{M}, w)$, where $\mathfrak{M} = \langle W, R, V\rangle$, such that w has at least one successor not satisfying p for which every successor satisfies q, is defined by the formula $\Diamond(\neg p \wedge \Box q)$.

The formula $p \rightarrow \Box p$ defines the class of Kripke structures in which the valuation of p is closed under the accessibility relation.

The class of frames in which every state has a successor is defined by the formula $\Diamond\top$; the same formula defines the class of pointed frames $(\mathfrak{F}, w)$ in which w has a successor.

The formula $\Diamond p \rightarrow \Box p$ defines the class of frames $\mathcal{K}$ in which every state has at most one successor. It is straightforward to show that the formula is valid in every such frame. For the converse: if the formula fails at some state w of a Kripke structure over a frame $\mathfrak{F}$, then p is true at some successor of w. But since $\Box p$ is false at w, there must be another successor of w where p fails. Hence $\mathfrak{F}$ does not satisfy the defining property of $\mathcal{K}$.

Other standard examples of modally definable classes of frames include the classes of: reflexive frames, defined by $\Box p \rightarrow p$; transitive frames, defined by $\Box p \rightarrow \Box\Box p$; symmetric frames, defined by $\Diamond\Box p \rightarrow p$, etc. For more examples see [117, 75, 127, 128].

Proposition 5 implies that the definability of classes of (pointed) Kripke structures by modal formulae is a special case of first-order definability. Consequently, modal logic shares many basic model-theoretic results with first-order logic, such as compactness and Löwenheim–Skolem theorems (see [12, 68]). We will discuss the model theoretic aspects of modal logic as a fragment of first-order logic on Kripke structures in section 4.

On the other hand, Proposition 6 indicates that modal definability of (pointed) frames is a form of Π^1_1-definability, and the model-theoretic consequences of that fact will be discussed in section 8. In particular, we will see that it is indeed essentially second-order.

1.5 Polyadic modalities

In polyadic modal logics one considers modalities α of arbitrary arities $r(\alpha) \in \mathbb{N}$, which give rise to formulae $\langle\alpha\rangle(\varphi_1, \ldots, \varphi_n)$ if $n = r(\alpha)$. The interpretation of an n-ary modal operator α is given in terms of $(n+1)$-ary relations R_α in corresponding frames, and an n-ary operator on subsets of these frames, in such a way that the semantics is faithfully captured in the standard translation $\mathrm{ST}(\langle\alpha\rangle(\varphi_1, \ldots, \varphi_n; x_j)) := \exists y_1 \ldots \exists y_n (x_j R_\alpha y_1 \ldots y_n \wedge \bigwedge_{i=1}^n \mathrm{ST}(\varphi_i; y_i))$, where $y_1 \ldots y_n$ are the first n variables in $\mathrm{VAR} \setminus \{x_j\}$ (and $x_j R_\alpha y_1 \ldots y_n$ is just a notational variant for $R_\alpha x_j y_1 \ldots y_n$).

Polyadic modalities were first studied from an algebraic perspective, as normal and additive operators in Boolean algebras, by Jónsson and Tarski [78, 79]. All the essential model theoretic features of modal logic can be generalised to this more liberal setting, albeit with some care and sometimes unavoidable notational complications. In [41] Goguadze et al define and develop systematically an interpretation of polyadic languages into monadic ones, and simulations of polyadic by monadic logics, which transfer a number of important properties, such as frame completeness, finite model property, canonicity and first-order definability. On the other hand, so called *purely modal polyadic languages* are defined in [55], where all logical connectives except negation are treated as binary modalities, and modalities can be composed. Thus, all polyadic modal formulae are built from (composite) boxes and diamonds applied to literals, making their syntactic structure much simpler.

Throughout this chapter we will only treat monadic modalities explicitly.

2 BISIMULATION AND BASIC MODEL CONSTRUCTIONS

A major concern in model theory is the analysis of logical equivalence of structures in comparison with other natural notions of structural equivalence, in particular equivalences of a more combinatorial or algebraic nature. Bisimulation equivalences as studied below prove to be the algebraic/combinatorial counterparts to modal equivalence.

For first-order logic this combinatorial approach leads to the well-known characterisation of elementary equivalence via *Ehrenfeucht–Fraïssé games* (see [68, 108, 26, 25]). Variations of the basic Ehrenfeucht–Fraïssé idea apply to many other logics including modal logic. Modal equivalence can thus be put into the general Ehrenfeucht–Fraïssé framework. We shall sketch this connection in section 4. The very natural game associated with modal equivalence has, however, also been invented and studied independently and in its own right, with the notions of *zig-zag relation* (van Benthem) and *bisimulation equivalence* (Hennessy, Milner, Park). We therefore put an autonomous, modal treatment before the discussion of relationships with the general framework of Ehrenfeucht–Fraïssé and pebble games.

2.1 Bisimulation and invariance

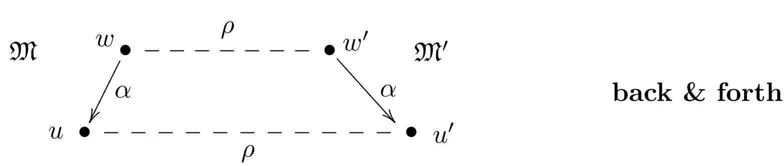
While the notion of logical equivalence is static, it can often be characterised in more dynamic, game-theoretic terms. The concept of bisimulation equivalence, which is closely related to corresponding games, is one of the most productive ideas in the model theory of modal logics, temporal logics, logics for concurrency, etc. Just as it has multiple roots in these various branches of logic, many variants have been employed to capture specific notions of "behavioural equivalence" between all kinds of transition systems that are interesting in their own right for various application areas – and not necessarily with any 'logic' in mind.

DEFINITION 11. Let $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$ and $\mathfrak{M}' = \langle W', \{R'_\alpha\}_{\alpha\in\tau}, V'\rangle$ be two Kripke τ-structures. A *bisimulation* between $\mathfrak{M}$ and $\mathfrak{M}'$ is a non-empty relation $\rho \subseteq W \times W'$ satisfying the following conditions for any $w\rho w'$:

Atom equivalence: w and w' satisfy the same atomic propositions, hereafter denoted by $w \simeq w'$.

Forth: For any $\alpha \in \tau$, if $wR_\alpha u$ for some $u \in W$, then there is some $u' \in W'$ such that $w'R'_\alpha u'$ and $u\rho u'$. (Any α-transition at w in $\mathfrak{M}$ can be matched at w' in $\mathfrak{M}'$.)

Back: Similarly, in the opposite direction: for any $\alpha \in \tau$, and $w'R'_\alpha u'$ there is some $u \in W$ such that $wR_\alpha u$ and $u\rho u'$. (Any α-transition at w' in $\mathfrak{M}'$ can be matched at w in $\mathfrak{M}$.)



That ρ is a bisimulation between $\mathfrak{M}$ and $\mathfrak{M}'$ is denoted as $\rho\colon \mathfrak{M} \rightleftarrows \mathfrak{M}'$. If, moreover, ρ is such that every element in $\mathfrak{M}$ is linked to some element of $\mathfrak{M}'$ and vice versa, we say that ρ is a *global bisimulation* and that $\mathfrak{M}$ and $\mathfrak{M}'$ are *globally bisimilar*.

DEFINITION 12. Two pointed Kripke structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ are *bisimilar* or *bisimulation equivalent*, denoted $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$, if there is a bisimulation ρ between $\mathfrak{M}$ and $\mathfrak{M}'$ such that $w\rho w'$.

Bisimulations between (pointed) frames can be defined likewise, by omitting *atom equivalence*. Thus, a relation ρ is a bisimulation between two frames $\mathfrak{F}$ and $\mathfrak{F}'$, iff it is a bisimulation between the respective Kripke structures $\langle\mathfrak{F}, V_\perp\rangle$ and $\langle\mathfrak{F}', V'_\perp\rangle$ where the valuations $V_\perp$ and $V'_\perp$ render every atomic proposition false at every state of the respective frame.

DEFINITION 13. Let $\mathcal{C}$ be a class of structures appropriate for the logical language $\mathcal{L}$ (e.g., pointed Kripke structures for ML). Let $\approx$ be an equivalence relation on $\mathcal{C}$. Then $\mathcal{L}$ is *preserved under* $\approx$ over $\mathcal{C}$, or $\mathcal{L}$ is $\approx$*-invariant* over $\mathcal{C}$, iff for any $\mathfrak{A} \approx \mathfrak{A}'$ in $\mathcal{C}$ and any $\varphi \in \mathcal{L}$: $\mathfrak{A} \models \varphi \;\Leftrightarrow\; \mathfrak{A}' \models \varphi$, i.e., $\mathfrak{A}$ and $\mathfrak{A}'$ are $\mathcal{L}$-equivalent. In other words: $\approx$ is a refinement of $\equiv_\mathcal{L}$, or $\approx\, \subseteq\, \equiv_\mathcal{L}$.

Invariance phenomena give insights into the semantics of the logic involved, and also often provide key tools for the model theoretic study of the logic (e.g., model constructions guided by $\approx$ equivalence). The relationship between modal logics and bisimulation equivalences provides an excellent example of such a fruitful companionship.

It would be straightforward to prove the following by induction on the structure of modal formulae, straight from the definition of bisimulations. However, this will also fall out as a corollary of the more instructive analysis of the associated bisimulation games. We therefore meanwhile only state the fact.

THEOREM 14 (bisimulation invariance).
$\mathrm{ML}(\tau)$ *is bisimulation invariant: if* $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$, *then* $(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')$.

Consequently, for every constant formula $\theta \in \mathrm{ML}(\tau)$ and pointed τ-frames $(\mathfrak{F}, w)$ and $(\mathfrak{F}', w')$: if $(\mathfrak{F}, w) \rightleftarrows (\mathfrak{F}', w')$, then $(\mathfrak{F}, w) \models \theta$ iff $(\mathfrak{F}', w') \models \theta$.

2.2 Classical truth-preserving constructions

Bisimulations induced by maps from one frame to another have classically been studied as *bounded morphisms* or *p-morphisms.* We state the corresponding back-and-forth conditions, which are slightly simpler in the case of such a functional relationship, and treat some particularly important special cases. The use of *generated and rooted substructures*, *bounded morphic images*, *tree unfoldings* and *disjoint unions* in connection with classical model constructions for modal logic is based on truth preservation for modal formulae. These constructions were introduced for basic modal logic [117, 7] before the notion of bisimulation was developed and its importance for modal logic realised. Via *duality theory*, which connects the relational semantics for modal logic with an algebraic semantics, bounded morphisms, generated subframes and disjoint unions correspond respectively to the fundamental universal algebraic notions of subalgebras, homomorphic images, and direct products. For details see Chapter 6 of this handbook, as well as [78, 43, 44, 114] and [5, Ch. 5].

The preservation results encountered in these special cases of a passage to bisimilar structures highlight to various degrees one of the key characteristic features of the semantics of modal logic: its *explicit locality* and *restricted nature of quantification.* Unlike first-order logic, whose global quantification over the entire universe makes truth generally dependent on the entire structure, the truth of a modal formula in a Kripke structure is evaluated relative to a 'current' state and admits access to the rest of the structure only along the edges of the accessibility relations.

Passage from a given structures to a bisimilar tree structure, obtained via a simple bounded morphism, shows for instance that any satisfiable formula of basic modal logic is satisfied at the root of a tree structure (tree model property, see Corollary 24; this can be further strengthened to a finite tree model property, see Lemma 35). Conversely, preservation results can be used to show that certain properties are not modally definable. We shall see some classical examples of this in section 2.3.

Bounded morphisms

DEFINITION 15. Let $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$ and $\mathfrak{M}' = \langle W', \{R'_\alpha\}_{\alpha\in\tau}, V'\rangle$ be Kripke structures. A function $\rho\colon W \to W'$ is a *bounded morphism* from $\mathfrak{M}$ to $\mathfrak{M}'$ if its graph is a bisimulation between $\mathfrak{M}$ and $\mathfrak{M}'$. We denote a bounded morphism as in $\rho\colon \mathfrak{M} \xrightarrow{\rightleftarrows} \mathfrak{M}'$.

Bounded morphisms between frames are similarly defined.

If ρ is onto, then $\mathfrak{M}'$ is a *bounded morphic image of* $\mathfrak{M}$ (and similarly for frames).

Thus, for each $u \in W$, a bounded morphism ρ uniquely singles out a bisimilar state $\rho(w)$ in W'. The bisimulation conditions for a bounded morphism between two Kripke structures correspondingly become:

Atom equivalence: $w \simeq \rho(w)$ for every $w \in W$.

Forth: For any $w \in W$ and $\alpha \in \tau$, if $wR_\alpha u$ for some $u \in W$, then $\rho(w)R'_\alpha\rho(u)$.

Back: For any $w \in W$ and $\alpha \in \tau$, if $\rho(w)R'_\alpha u'$ for some $u' \in W'$, then $u' = \rho(u)$ for some $u \in W$ such that $wR_\alpha u$.

Bisimulation invariance yields the following preservation results.

COROLLARY 16. *Bounded morphisms preserve truth and validity of modal formulae. More specifically, if* $\rho\colon \mathfrak{M} \overset{\rightleftarrows}{\longrightarrow} \mathfrak{M}'$ *is a bounded morphism and* $\varphi \in \mathrm{ML}(\tau)$*, then:*

(i) *for all* $u \in \mathrm{dom}(\mathfrak{F})$*:* $\mathfrak{M}, u \models \varphi$ *iff* $\mathfrak{M}', \rho(u) \models \varphi$.

(ii) *If* ρ *is onto, then* $\mathfrak{M} \models \varphi$ *iff* $\mathfrak{M}' \models \varphi$*, i.e.,* $\mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}) = \mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}')$.

(iii) *If* $\mathfrak{F}, u \models \varphi$*, then* $\mathfrak{F}', \rho(u) \models \varphi$.

(iv) *If* ρ *is onto, then* $\mathfrak{F} \models \varphi$ *implies* $\mathfrak{F}' \models \varphi$.

For the latter two claims one just has to note that each model $\mathfrak{M}' = \langle \mathfrak{F}', V' \rangle$ over the frame $\mathfrak{F}'$ can be pulled back to give a model $\mathfrak{M} = \langle \mathfrak{F}, V \rangle$ over the frame $\mathfrak{F}$ via $V(p) := \rho^{-1}[V'(p)] = \{w \in \mathrm{dom}(\mathfrak{F}) \mid \rho(w) \in V'(p)\}$. This turns ρ into a bounded morphism from $\mathfrak{M}$ to $\mathfrak{M}'$. Note, however, that not every model over $\mathfrak{F}$ is obtained in this manner.

We turn to several basic model constructions involving bounded morphisms: generated substructures, rooted substructures, tree unfoldings and disjoint unions.

Generated and rooted substructures

If $R \subseteq W^2$ is any binary relation over W, and $W' \subseteq W$, we write $R{\restriction}W'$ for the restriction of R to W', $R{\restriction}W' = R \cap (W' \times W')$. Similarly for a valuation V on W, $V{\restriction}W'$ stands for its restriction to W'.

DEFINITION 17. Let $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ be a frame, or $\mathfrak{M} = \langle \mathfrak{F}, V \rangle$ a Kripke structure over $\mathfrak{F}$, respectively, and $W' \subseteq W$.

(i) The induced *subframe of* $\mathfrak{F}$ *over* W' is the frame $\mathfrak{F}' := \mathfrak{F}{\restriction}W' = \langle W', \{R_\alpha{\restriction}W'\}_{\alpha\in\tau}\rangle$. The subframe relationship is denoted $\mathfrak{F}' \leq \mathfrak{F}$.

(ii) $\mathfrak{F}' = \mathfrak{F}{\restriction}W'$ is a *generated subframe of* $\mathfrak{F}$, denoted $\mathfrak{F}' \trianglelefteq \mathfrak{F}$, if W' is closed under all accessibility relations in the sense that $wR_\alpha u$ for $w \in W'$ implies $u \in W'$.

(iii) The induced *substructure of* $\mathfrak{M}$ *over* W' is the Kripke structure $\mathfrak{M}' = \mathfrak{M}{\restriction}W' = \langle \mathfrak{F}{\restriction}W', V{\restriction}W'\rangle$, denoted $\mathfrak{M}' \leq \mathfrak{M}$. If $\mathfrak{F}{\restriction}W' \trianglelefteq \mathfrak{F}$, then $\mathfrak{M}'$ is a *generated substructure of* $\mathfrak{M}$, denoted $\mathfrak{M}' \trianglelefteq \mathfrak{M}$.

Obviously, for $\mathfrak{M}' \trianglelefteq \mathfrak{M}$ the inclusion map $\rho\colon W' \to W$ is a bounded morphism. By bisimulation invariance, we therefore have the following.

PROPOSITION 18. *For all Kripke structures* $\mathfrak{M}' \trianglelefteq \mathfrak{M}$ *and for every formula* φ *of* $ML(\tau)$*:*

(i) *for every* $u \in \mathrm{dom}(\mathfrak{M}') : \mathfrak{M}, u \models \varphi$ *iff* $\mathfrak{M}', u \models \varphi$.

(ii) $\mathfrak{M} \models \varphi$ *implies* $\mathfrak{M}' \models \varphi$.

Likewise, for frames $\mathfrak{F}' \trianglelefteq \mathfrak{F}$ *and* $u \in \mathrm{dom}(\mathfrak{F}')$*:* $\mathfrak{F}, u \models \varphi$ *iff* $\mathfrak{F}', u \models \varphi$*, and* $\mathfrak{F} \models \varphi$ *implies* $\mathfrak{F}' \models \varphi$.

The latter claim holds since every Kripke structure over $\mathfrak{F}'$ is induced by a Kripke structure on $\mathfrak{F}$.

A particularly important case of generated subframes deals with the set of all states reachable from a fixed state. A *path* in a frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ is a sequence $\vec{w} = (w_0, \alpha_1, w_1, \ldots, \alpha_k, w_k)$, where $w_{i-1} R_{\alpha_i} w_i$ for $i = 1, \ldots, k$ (this path is *rooted* at w_0 and has *length* k). A path of length $k = 0$, $\vec{w} = (w_0)$, is identified with its root w_0. For $u \in W$, we denote the set of all paths rooted at u by $\vec{W}[u]$. For every path $\vec{w}$ as above we define the 'terminal state' function $f(\vec{w}) = w_k$ where k is the length of $\vec{w}$. Then

$$W[u] := \{f(\vec{w}) \mid \vec{w} \in \vec{W}[u]\}$$

is the set of all states in $\mathfrak{F}$ reachable from u (including u itself).

DEFINITION 19. Let $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ be a frame, $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$ a Kripke structure over $\mathfrak{F}$, and $u \in W$.

(i) The *subframe of* $\mathfrak{F}$ *rooted at* u is the frame $\mathfrak{F}[u] = \mathfrak{F}\restriction W[u]$.

(ii) The *substructure of* $\mathfrak{M}$ *rooted at* u is the Kripke structure $\mathfrak{M}[u] = \mathfrak{M}\restriction W[u]$.

(iii) $\mathfrak{F}$ (respectively $\mathfrak{M}$) is *rooted at* u if $W[u] = W$.

Clearly, for any $u \in W$: $\mathfrak{F}[u] \trianglelefteq \mathfrak{F}$ and $\mathfrak{M}[u] \trianglelefteq \mathfrak{M}$, respectively. Therefore, we obtain the following.

COROLLARY 20. *For every Kripke structure* $\mathfrak{M}' \trianglelefteq \mathfrak{M}$ *and formula* φ *of* $ML(\tau)$*:*

(i) *for all* $u \in W$*:* $\mathfrak{M}, u \models \varphi$ *iff* $\mathfrak{M}[u], u \models \varphi$.

(ii) $\mathfrak{M} \models \varphi$ *implies* $\mathfrak{M}[u] \models \varphi$.

(iii) *Likewise for (pointed) frames.*

Thus, any satisfiable formula is satisfiable at the root of a rooted Kripke structure.

Tree unfoldings

An important model construction based on a canonical bounded morphism is the *unfolding* or *tree unravelling* of a Kripke structure $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$ from some $u \in W$. This construction was introduced in [113], where the tree model property (cf. Corollary 24 below) was proved, too.

Recall the map $f\colon \vec{W}[u] \to W$, which maps the path $\vec{w} = (u = w_0, \alpha_1, w_1, \ldots, \alpha_k, w_k)$ to its terminal state $f(\vec{w}) = w_k$. The unfolding of $\vec{\mathfrak{M}}[u]$ of $\mathfrak{M}$ at u is based on the set $\vec{W}[u]$ of all paths rooted at u, with the natural definition of accessibility relations and a valuation that turns f into a bounded morphism.

DEFINITION 21. The *unfolding* (or, *unravelling*) of $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$ from some $u \in W$ is the rooted Kripke structure $\vec{\mathfrak{M}}[u] := \langle \vec{W}[u], \{\vec{R}_\alpha\}_{\alpha\in\tau}, \vec{V}\rangle$ with root $u = (u)$, where

$$\begin{array}{rcl} \vec{R}_\alpha & := & \{(\vec{w}, (\vec{w}, \alpha, w')) \mid \vec{w} \in \vec{W}[u], f(\vec{w}) R_\alpha w'\}, \\ \vec{V}(p) & := & f^{-1}[V(p)]. \end{array}$$

Indeed, $\vec{\mathfrak{M}}[u]$ is a tree structure with root $u = (u)$ in the sense of the following definition.

DEFINITION 22. A pointed frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ with distinguished state $u \in W$ is a *tree* with root u if $\mathfrak{F}$ is rooted at u and every state $w \in W$ is reachable from u by a unique path. Accordingly, every Kripke structure over $(\mathfrak{F}, u)$ is a tree structure.

OBSERVATION 23. For every pointed Kripke structure $(\mathfrak{M}, u)$ the terminal state map $f\colon \vec{W}[u] \to W[u]$ is a bounded morphism of the unfolding $\vec{\mathfrak{M}}[u]$ onto $\mathfrak{M}[u]$.

As $\vec{\mathfrak{M}}[u]$ is a tree structure with root $u = (u)$, we obtain the following. Also compare Lemma 35 below.

COROLLARY 24 (tree-model property). *Every satisfiable modal formula is satisfiable at the root of a tree.*

Disjoint unions

Disjoint unions are well known for relational structures: the component structures are put side by side without any relational links between the components. Assuming that the given family of Kripke structures or frames is based on universes that are pairwise disjoint, we may just take the set-theoretic union of the universes, accessibility relations, and valuations, respectively. If the given frames are not disjoint, they first need to be replaced by isomorphic copies over universes that are pairwise disjoint.

To be specific, define the *disjoint union* of an arbitrary family $\{W^i\}_{i\in I}$ of (not necessarily disjoint) sets as $\biguplus_{i\in I} W^i := \bigcup_{i\in I}(W^i \times \{i\})$. With this formalisation, we have the natural injection or embedding $\varepsilon_j\colon W^j \to \bigcup_{i\in I}(W^i \times \{i\})$ of each component set into the disjoint union, which maps $w \in W^j$ to $(w, j) \in \bigcup_{i\in I}(W^i \times \{i\})$.

DEFINITION 25. Consider a family of τ-frames $\{\mathfrak{F}^i = \langle W^i, \{R^i_\alpha\}_{\alpha\in\tau}\rangle\}_{i\in I}$ and a family of Kripke structures $\{\mathfrak{M}^i = \langle\mathfrak{F}^i, V^i\rangle\}_{i\in I}$ over these.

(i) The *disjoint union of* $\{\mathfrak{F}^i\}_{i\in I}$ is the frame $\biguplus_{i\in I}\mathfrak{F}^i = \langle\biguplus_{i\in I} W^i, \{R_\alpha\}_{\alpha\in\tau}\rangle$, where $(w_0, i_0)R_\alpha(w_1, i_1)$ iff $i_0 = i_1 = i$ and $w_0 R^i_\alpha w_1$.

(ii) The *disjoint union of* $\{\mathfrak{M}^i\}_{i\in I}$ is the Kripke τ-structure $\biguplus_{i\in I}\mathfrak{M}^i = \langle\biguplus_{i\in I}\mathfrak{F}^i, V\rangle$ where $V(p) = \biguplus_{i\in I} V^i(p)$.

It is immediate that the natural injection $\varepsilon_j\colon W^j \to \biguplus_{i\in I} W^i$ isomorphically embeds $\mathfrak{M}^j$ into $\biguplus_{i\in I}\mathfrak{M}^i$ and is indeed a bounded morphism with image $\epsilon_j[\mathfrak{M}^j] \simeq \mathfrak{M}^j$ and $\epsilon_j[\mathfrak{M}^j] \trianglelefteq \biguplus_{i\in I}\mathfrak{M}^i$. We therefore obtain the following, by bisimulation invariance and based on previous observations.

PROPOSITION 26. *Given a family of τ-frames $\{\mathfrak{F}^i = \langle W^i, \{R^i_\alpha\}_{\alpha\in\tau}\rangle\}_{i\in I}$, a family of Kripke structures $\{\mathfrak{M}^i = \langle\mathfrak{F}^i, V^i\rangle\}_{i\in I}$ over these frames, and $\varphi \in \mathrm{ML}(\tau)$:*

(i) *For every $j \in I$ and $w \in \mathrm{dom}(\mathfrak{M}^j)$: $\mathfrak{M}^j, w \models \varphi$ iff $\biguplus_{i\in I}\mathfrak{M}^i, (w, j) \models \varphi$.*

(ii) *For every $j \in I$ and $w \in \mathrm{dom}(\mathfrak{F}^j)$: $\mathfrak{F}^j, w \models \varphi$ iff $\biguplus_{i\in I}\mathfrak{F}^i, (w, j) \models \varphi$.*

(iii) *$\biguplus_{i\in I}\mathfrak{M}^i \models \varphi$ iff $\mathfrak{M}^i \models \varphi$ for every $i \in I$.*

(iv) *$\biguplus_{i\in I}\mathfrak{F}^i \models \varphi$ iff $\mathfrak{F}^i \models \varphi$ for every $i \in I$.*

The following structural observation [127] links some of the ideas explored in this section.

PROPOSITION 27. *Any Kripke structure is the bounded morphic image of a disjoint union of rooted Kripke structures, and indeed of tree structures.*

For a proof of the proposition, consider the families of the $\{\mathfrak{M}[u]\}_{u \in W}$ or $\{\vec{\mathfrak{M}}[u]\}_{u \in W}$. The desired bounded morphisms (from the disjoint unions of these families back onto $\mathfrak{M}$) are the unions of the projection and inclusion or terminal state maps defined on the components of these disjoint unions.

2.3 Proving non-definability

To show that a given property of structures is definable in a given logic, it suffices simply to find a defining formula. Showing that a property is *not* definable, however, is not so straightforward, and often requires elaborate arguments. A standard method for establishing non-definability of a property $\mathcal{P}$ (i.e., of the class of structures satisfying that property) in a logic $\mathcal{L}$ is to show that $\mathcal{P}$ is not closed under some construction preserving truth (validity) of all formulae of $\mathcal{L}$. Now that we have at hand constructions that preserve truth and validity of modal formulae, we can use them to show that various properties of frames and structures are not modally definable. Compare Definition 9 for the relevant notions of definability.

At the level of pointed Kripke structures, modal formulae capture only properties that are local in the sense that whether or not $\mathfrak{M}, w \models \varphi$ only depends on $(\mathfrak{M}[w], w)$. In other words, modal formulae are incapable of expressing any property of $(\mathfrak{M}, w)$ that involves points beyond $\mathfrak{M}[w]$. For instance, there is no $\varphi \in$ ML such that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M} \models p$. Indeed, one can always add to $\mathfrak{M}$ an extra point (as a disjoint union), not reachable from w, where p is false. The resulting pointed structure $(\mathfrak{M}', w)$ is bisimilar to $(\mathfrak{M}, w)$, whence φ would have to be equally true or false at w in both.

Likewise, at the level of Kripke structures, there is no $\varphi \in$ ML such that $\mathfrak{M} \models \varphi$ iff the accessibility relation of the underlying frame $\mathfrak{F}$ is reflexive. This follows for instance from the fact that the unfolding of any frame is irreflexive. If $\mathfrak{M}$ is reflexive, then so is the generated substructure $\mathfrak{M}[u]$, which however is also a bounded morphic image of the irreflexive $\vec{\mathfrak{M}}[u]$. Reflexivity, however, is well-known to be definable in terms of frame validity by the formula $\Box p \to p$. In other words, the class of reflexive frames is definable by the second-order sentence $\forall P \forall x(\forall y(Rxy \to Py) \to Px)$. Intuitively, in terms of truth in Kripke structures, modal formulae can make very little reference to the underlying frame.

We turn to properties of frames and non-definability in terms of frame validity, which is maybe the most interesting facet of modal expressiveness. One can show, for instance, that (unlike reflexivity) *irreflexivity* is not a modally definable frame property. This property is not preserved under surjective bounded morphisms, while surjective bounded morphisms preserve frame validity. One may consider unfoldings as above, or also the (irreflexive) frame $\mathfrak{F} = \langle \{w_1, w_2\}, \{(w_1, w_2), (w_2, w_1)\} \rangle$ and its bounded morphic image $\mathfrak{F}' = \langle \{w\}, \{(w, w)\} \rangle$, which is reflexive. Hence any φ valid in the former would also be valid in the latter.

Similarly, the class of non-reflexive frames (i.e., ones having at least one irreflexive point) is not definable in terms of validity of modal formulae, because it is not closed under passage to generated subframes. Likewise, the classes of finite frames, connected frames, or of frames with a universal accessibility relation ($R = W^2$), are not definable in terms of frame validity of modal formulae, as they are not closed under disjoint unions.

For another interesting example, consider the property of a frame to be a reflexive partial ordering. It is not modally definable, because anti-symmetry is not preserved under surjective bounded morphisms. Indeed, $\langle \mathbb{Z}, \leq \rangle$ is antisymmetric, but the mapping of it onto the symmetric frame $\mathfrak{F}$ above, sending all odd numbers to w_1 and all even ones to w_2, is a surjective bounded morphism (and remains so, even when we add an inverse or past modality, as in basic temporal logic).

However, the preservation results we have discussed so far are insufficient to capture frame non-definability. A witness is the following more subtle example: the property of *continuity,* or *Dedekind completeness* is not modally definable in modal logic, but to see that using a non-preservation argument is not easy. Ultimately, this follows from the fact that $\langle \mathbb{R}, \leq \rangle$ (which is continuous) and $\langle \mathbb{Q}, \leq \rangle$ (which is not) have the same *modal theory* (i.e., the same formulae of basic modal logic are valid in these frames); see [46].[3]

Finally, note that preservation under generated subframes, surjective bounded morphisms and disjoint unions is *not* sufficient to guarantee modal definability in terms of frame validity, even for first-order definable properties. For instance, the class of frames defined by the first-order sentence $\forall x \exists y (xRy \wedge yRy)$ (see [51, 128, 74]) is not modally definable, despite being closed under these three constructions. We will come back to this example in section 6.1.

For more examples of modal non-definability see [5, Section 3.3] and [128] where syntactic characterisations of the first-order properties preserved by each one of the three constructions mentioned above have been obtained.

3 BISIMULATION: A CLOSER LOOK

3.1 Bisimulation games

Bisimulation relations may be understood as descriptions of (non-deterministic) winning strategies for one player in corresponding model comparison games. We illustrate the concept in the case of bisimulations for basic modal logic – or Kripke structures with a single binary transition relation R – writing $\Diamond$ and $\Box$ for the associated modalities. All considerations admit canonical ramifications to the more general poly-modal setting (as well as to polyadic modalities).

Let $\mathfrak{M} = (W, R, V)$ and $\mathfrak{M}' = (W', R', V')$ be Kripke structures of this basic type. The *bisimulation game* over $\mathfrak{M}$ and $\mathfrak{M}$ is played by two players **I** and **II** with one pebble in $\mathfrak{M}$ and one in $\mathfrak{M}'$ to mark a single 'current' state in each structure. A configuration in the game consists of a current placement of the two pebbles and is described by the pair of pointed Kripke structures $(\mathfrak{M}, w; \mathfrak{M}', w')$, with distinguished w and w' for the current states (pebble positions).

A single *round* in the game is played as follows. The first player, **I**, or *challenger*, selects one of the two pebbles and moves it forward along an edge in the respective structure to a successor state. The second player, **II**, or *defender*, has to respond by similarly moving forward the pebble in the opposite structure.

[3] On the other hand, continuity is definable in temporal logic by the formula $\Box([P]p \to \langle F \rangle [P]p) \to ([P]p \to [F]p)$, where F and P are respectively the *future* and *past* modality, and $\Box\varphi = [P]\varphi \wedge \varphi \wedge [F]\varphi$ is the *always* modality. See [46].

During the game, **II** loses when no such response is possible or if the resulting new configuration fails to have the two pebbles in *atom equivalent* states (i.e., the new positions are distinguished by at least one atomic proposition, cf. Definition 29 (ii) below). **I** loses during the game if no further round can be played because both pebbles are in states without successors. An infinite run of the game, which continues through an infinite sequence of rounds played according to the above rules, is won by **II**.

We say that **II** has a *winning strategy* in the bisimulation game starting from configuration $(\mathfrak{M}, w; \mathfrak{M}', w')$, if she has responses to any challenges from the first player that guarantee her to win the game (either because **I** gets stuck, or because she can respond with good moves indefinitely).

Intuitively, we think of **I** as challenging the claim of bisimilarity in the current configuration, while **II** defends that bisimilarity claim. This is borne out by the following.

PROPOSITION 28. *Player* **II** *has a winning strategy in the bisimulation game starting from the initial configuration* $(\mathfrak{M}, w; \mathfrak{M}', w')$ *if, and only if,* $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$.

Indeed, an actual bisimulation $\rho\colon (\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$ *is* a non-deterministic winning strategy for **II**: she merely needs to select her responses so that the currently pebbled states remain linked by ρ. The atom equivalence condition on ρ guarantees that atom equivalence between pebbled states is maintained; the *forth* condition guarantees a matching response to challenges played by **I** in $\mathfrak{M}$; the *back* condition similarly guarantees a matching response to challenges played in $\mathfrak{M}'$.

Conversely, the set of pairs (u, u') in all configurations $(\mathfrak{M}, u; \mathfrak{M}', u')$ from which **II** has a winning strategy, if non-empty, is a bisimulation.

3.2 Finite bisimulations and characteristic formulae

The games view of a bisimulation suggest that we look at finite approximations corresponding to the existence of winning strategies for a fixed finite number of rounds. These approximations also hold the key to the connection between bisimulation equivalence and modal equivalence. Natural approximations to $\equiv_{\mathrm{ML}}$ are induced by the stratification of ML with respect to the nesting depth of modal formulae (cf. Definition 1), as follows.

DEFINITION 29. For two pointed Kripke τ-structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$:

(i) For $n \geq 0$, $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ are ML$_n$*-equivalent*, denoted $(\mathfrak{M}, w) \equiv^n_{\mathrm{ML}} (\mathfrak{M}', w')$, iff they satisfy exactly the same formulae of ML$_n$.

(ii) At the level of $\equiv^0_{\mathrm{ML}}$, we write $w \simeq w'$ instead of $(\mathfrak{M}, w) \equiv^0_{\mathrm{ML}} (\mathfrak{M}', w')$ and say that w and w' are *atom equivalent* (or, isomorphic when viewed as isolated states with atomic propositions according to V, V').

The n-round bisimulation game is played like the (unbounded) bisimulation game but terminates after n rounds (or beforehand if either player loses during one of these rounds). Now **II** also wins if the n-th round is completed without violating atom equivalence. The notion of a winning strategy is correspondingly adapted.

DEFINITION 30. Let $n \geq 0$. Two pointed Kripke structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ are

(i) *n-bisimilar*, or *n-bisimulation equivalent*, denoted $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w')$, if **II** has a winning strategy in the n-round bisimulation game starting from $(\mathfrak{M}, w; \mathfrak{M}', w')$.

(ii) *finitely bisimilar*, $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$, if $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w')$ for all $n \in \mathbb{N}$.

Note that 0-bisimulation equivalence *is* atom equivalence or modal equivalence $\equiv^0_{\mathrm{ML}}$, indistinguishability at the propositional level.

Clearly n-bisimulation equivalence implies m-bisimulation equivalence for any $m \leq n$; (full) bisimulation equivalence implies finite bisimulation equivalence; and finite bisimulation equivalence implies n-bisimulation equivalence for any n. We shall return to the interesting relationship between finite and full bisimulation equivalence below, in connection with the Hennessy–Milner Theorem (theorem 38 below).

A first connection between $\rightleftarrows_n$ and n-equivalence is made in the following.

LEMMA 31. $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w') \;\Rightarrow\; (\mathfrak{M}, w) \equiv^n_{\mathrm{ML}} (\mathfrak{M}', w')$.

Indeed, if $\mathfrak{M}, w \models \varphi$ and $\mathfrak{M}', w' \models \neg\varphi$ for some $\varphi \in \mathrm{ML}_n$, then **I** has a winning strategy in the n-round game from $(\mathfrak{M}, w; \mathfrak{M}', w')$. This is shown by induction on the nesting depth n of the distinguishing formula φ. At level $n = 0$, a distinction in ML_0 means atomic inequivalence – corresponding to a configuration in which **II** has lost.

In the induction step, assume that $(\mathfrak{M}, w)$ is distinguished from $(\mathfrak{M}', w')$ by a formula $\varphi \in \mathrm{ML}_{n+1}$. Propositional connectives in φ can be unravelled so that without loss of generality φ is of the form $\Diamond\psi$ for some $\psi \in \mathrm{ML}_n$. Suppose then that for instance $\mathfrak{M}', w' \models \neg\varphi$, while $\mathfrak{M}, w \models \varphi$. Let in that case **I** move the pebble in $\mathfrak{M}$ from w to some u, where $\mathfrak{M}, u \models \psi$. As $\mathfrak{M}', w' \models \neg\Diamond\psi$, any available response for **II** can only lead to a configuration $(\mathfrak{M}, u; \mathfrak{M}', u')$ in which $(\mathfrak{M}, u)$ and $(\mathfrak{M}', u')$ are distinguished by $\psi \in \mathrm{ML}_n$. Therefore, by the inductive hypothesis, **I** has a winning strategy for the remaining n rounds of the game.

Characteristic formulae

For the converse to the previous lemma, or for capturing the bounded bisimulation game in terms of modal logic, it is essential that the underlying vocabulary is finite: both τ and Φ need to be finite. We again stick with the case of a single binary accessibility relation R, but that restriction is purely for expository simplicity.

The crucial step in the transition from the bisimulation game to modal logic is the formalisation, as a formula $\chi^n_{[\mathfrak{M},w]} \in \mathrm{ML}_n$, of

"**II** has a winning strategy in the n-round game from $(\mathfrak{M}, w; \mathfrak{M}', w')$"

as a property of $(\mathfrak{M}', w')$, for fixed reference structure $(\mathfrak{M}, w)$ and depth n. In fact $\chi^n_{[\mathfrak{M},w]}$ may be constructed by induction on n, simultaneously for all $(\mathfrak{M}, w)$. Along with the induction one observes that $\rightleftarrows_n$ has finite index, and that, correspondingly, we generate only finitely many non-equivalent formulae $\chi^n_{[\mathfrak{M},w]}$ at level n (for finite τ and Φ!).

For $n = 0$, $\chi^0_{[\mathfrak{M},w]}$ is purely propositional and consists of the conjunction of all $p \in \Phi$ that are true in w and all $\neg p$ for those that are false at w. This fixes the atomic equivalence type, as it should.

Inductively, let

$$\chi^{n+1}_{[\mathfrak{M},w]} := \chi^0_{[\mathfrak{M},w]} \wedge \underbrace{\bigwedge_{(w,u)\in R} \Diamond\chi^n_{[\mathfrak{M},u]}}_{\textit{forth}} \quad\wedge\quad \underbrace{\Box \bigvee_{(w,u)\in R} \chi^n_{[\mathfrak{M},u]}}_{\textit{back}} .$$

Even for infinitely branching $\mathfrak{M}$, the conjunctions and disjunctions in this formula remain finite up to logical equivalence as there are only finitely many formulae of the respective kind.

Clearly $\mathfrak{M}, w \models \chi^{n+1}_{[\mathfrak{M},w]}$. But for arbitrary $(\mathfrak{M}', w')$, $\mathfrak{M}', w' \models \chi^{n+1}_{[\mathfrak{M},w]}$ indeed guarantees **II** a wining strategy in the $(n+1)$-round game from $(\mathfrak{M}, w; \mathfrak{M}', w')$. The conjunct $\chi^{0}_{[\mathfrak{M},w]}$ guarantees that the game is not lost already. The *back*-and-*forth* attributions in the two main conjuncts suggest how these are used to guarantee suitable responses, in the first round, to challenges from **I** played in either $\mathfrak{M}$ (*forth*) or $\mathfrak{M}'$ (*back*), respectively.

The *forth* part says that for all moves from w to some u in $\mathfrak{M}$, $\mathfrak{M}', w' \models \Diamond\chi^{n}_{[\mathfrak{M},u]}$, and any R'-successor u' of w' such that $\mathfrak{M}', u' \models \chi^{n}_{[\mathfrak{M},u]}$ provides a response for **II** that will allow her to succeed through another n rounds.

Similarly the *back* part says that for all moves from w' to some u' in $\mathfrak{M}$, $\mathfrak{M}', u' \models \chi^{n}_{[\mathfrak{M},u]}$ for some R-successor u of w in $\mathfrak{M}$ – a response that is good for another n rounds for **II**.

That failure of $\mathfrak{M}', w'$ to satisfy $\chi^{n}_{[\mathfrak{M},w]}$ affords **I** a win within n rounds follows from Lemma 31. Together, these observations yield the following tight connection between the bisimulation game and modal equivalence.

THEOREM 32. *Let* $(\mathfrak{M}, w)$ *and* $(\mathfrak{M}', w')$ *be pointed Kripke structures of the same finite type with finitely many atomic propositions. Then the following are equivalent:*

(i) $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w')$.

(ii) **II** *has a winning strategy in the n-round game from* $(\mathfrak{M}, w; \mathfrak{M}', w')$.

(iii) $\mathfrak{M}', w' \models \chi^{n}_{[\mathfrak{M},w]}$.

(iv) $(\mathfrak{M}, w) \equiv^{n}_{\mathrm{ML}} (\mathfrak{M}', w')$.

As corollaries we obtain a corresponding characterisation of full modal equivalence, and a normal form for ML formulae.

COROLLARY 33. *Over Kripke structures of finite type and with finitely many atomic propositions, finite bisimulation equivalence* $\rightleftarrows_\omega$ *coincides with modal equivalence.*

COROLLARY 34. *Any formula* $\varphi \in \mathrm{ML}_n$ *is logically equivalent to the disjunction* $\bigvee_{\mathfrak{M},w\models\varphi} \chi^{n}_{[\mathfrak{M},w]}$*, which is in fact finite as there are only finitely many such* χ^n *up to logical equivalence (in the vocabulary of* φ*).*

Similarly, for finite vocabularies, any class $\mathcal{C}$ *of pointed Kripke structures that is closed under n-bisimulation is definable in* ML_n *by the disjunction* $\bigvee_{(\mathfrak{M},w)\in\mathcal{C}} \chi^{n}_{[\mathfrak{M},w]}$.

Bisimulation-invariance of ML, Theorem 14, also becomes a simple corollary of the analysis of the game. Indeed, $\varphi \in \mathrm{ML}_n$ is even invariant under n-bisimulation equivalence $\rightleftarrows_n$, which of course implies invariance under (full) bisimulation.

3.3 Finite model property

A logic $\mathcal{L}$ has the *finite model property* (FMP) iff every satisfiable formula of $\mathcal{L}$ is satisfiable in a finite model, i.e., if satisfiability and satisfiability in finite structures coincide for $\mathcal{L}$.

For specific modal logics (e.g., normal extensions of basic modal logic) the implicit restriction to a prescribed class of admissible frames corresponds to a relativisation of the above criterion to the respective classes of (infinite or finite) admissible models. So

the finite model property for S5 say, states that any formula of ML that is satisfiable over some equivalence frame is also satisfiable over some finite equivalence frame.

The finite model property is a characteristic feature of many modal logics. For any modal logic with a recursive axiomatisation (such that it is recursively enumerable for validity) whose class of admissible finite frames is also recursively enumerable, the finite model property provides a standard method for proving decidability.[4] Here we briefly discuss the general *filtration method* for establishing the finite model property for modal logics. For basic modal logic we illustrate in section 3.3 that it even has a *finite tree model property*: every satisfiable formula has a finite tree model.[5]

Filtration

Filtration is the most widely used method for proving the finite model property in modal logics, particularly those determined by classes of frames with specific properties of the accessibility relation. This method is originally due to McKinsey who first applied an algebraic version of it in modal logic. Filtration was introduced in its present form by Lemmon and Scott [91] and further developed and applied by Segerberg [117]. Gabbay [31] introduced a different version, called *selective filtration*. Later, Fisher and Ladner [29] proved the finite model property of propositional dynamic logic PDL using filtration.

Given a formula φ of a modal logic L and a Kripke structure $\mathfrak{M}$ (of type appropriate for L) satisfying φ, we want to produce a *finite* Kripke structure $\tilde{\mathfrak{M}}$ (of appropriate type) satisfying φ. The method of filtration provides a transformation from models $\mathfrak{M}$ to finite models $\tilde{\mathfrak{M}}$ in a uniform manner with respect to φ and $\mathfrak{M}$. Before outlining the construction let us note that the satisfiability of a modal formula φ in a Kripke structure only depends on the truth of the (finitely many) subformulae of φ across that structure. Therefore, two states in a Kripke structure that satisfy the same subformulae of φ are *indistinguishable* from the viewpoint of φ. Sometimes it is necessary to extend the set of subformulae of φ to a wider but still finite set of formulae, called the *closure of* φ and denoted by $cl(\varphi)$. Thus, $cl(\varphi)$ partitions the model into *finitely many equivalence classes* of states, all states in each class satisfying the same subset of $cl(\varphi)$. The underlying idea of the filtration method is to collapse the infinite model to its finite quotient with respect to the equivalence relation generated by that partition, in a way that preserves the truth of all formulae in $cl(\varphi)$, and hence of φ itself.

The equivalence relation itself can be thought of as coarse-grained approximation to bisimulation equivalence that is specific to the given formula φ. It is meant to preserve φ but needs to do so at a coarser level than bisimulation to be of finite index. Note that n-bisimulation $\rightleftarrows_n$ can also serve as a finite index approximation but, because of its graded nature, does not lend itself to taking quotients in the desired global manner. This is because $\mathfrak{M}, u \rightleftarrows_n \mathfrak{M}, u'$ (i.e., that u and u' are of the same n-bisimulation type) does not imply that the same n-bisimulation types are accessible from u and u'.

Here are the formal details. Take any Kripke structure $\mathfrak{M} = \langle W, R, V \rangle$ and a set

[4] However, not every modal logic with the finite model property is decidable; see for instance $K \times K \times K$ in [35].

[5] In general, the finite model property and the tree model property are independent. While the tree model property can account for the decidability of the basic systems of modal logic and many of its extensions and variations (see section 5), it does not apply to axiomatic extensions which impose specific restrictions on the frames that are incompatible with tree-like structures like symmetry or confluence of the accessibility relation.

of formulae Γ, which is assumed to be closed under subformulae, single negation (i.e., if $\varphi \in \Gamma$ is not a negation itself, then $\neg\varphi \in \Gamma$) and under $\Box/\Diamond$ duality. Define an equivalence relation $\sim_\Gamma$ on W as follows:

$$u \sim_\Gamma w \text{ iff for every } \ \psi \in \Gamma : \mathfrak{M}, u \models \psi \Leftrightarrow \mathfrak{M}, w \models \psi.$$

Let $[w]_\Gamma$ be the equivalence class of w with respect to $\sim_\Gamma$ and $W_\Gamma = \{[w]_\Gamma \mid w \in W\}$. Note that if Γ is finite, then W_Γ is finite, too. Further, the valuation V is collapsed to a valuation V_Γ in W_Γ for all $p \in \Gamma$ canonically: $V_\Gamma(p) = \{[w]_\Gamma \mid w \in V(p)\}$; for all other variables q, V_Γ is defined arbitrarily, e.g., $V_\Gamma(q) = \emptyset$.

Now, we say that a Kripke structure $\tilde{\mathfrak{M}} = \langle W_\Gamma, \tilde{R}, V_\Gamma \rangle$ is a *filtration of M with respect to* Γ if for every $\psi \in \Gamma$ and $w \in W : \mathfrak{M}, w \models \psi$ iff $\tilde{\mathfrak{M}}, [w]_\Gamma \models \psi$. With a slight abuse of terminology, we also say that $\tilde{R}$ is a filtration of R with respect to Γ.

There are two simple conditions on the relation $\tilde{R}$ which guarantee that it is a filtration of R with respect to Γ. They give lower and upper bounds for that relation, respectively:

MIN. For every $u, w \in W$, if uRw, then $[u]_\Gamma \tilde{R} [w]_\Gamma$.

MAX. For every $[u]_\Gamma, [w]_\Gamma \in W_\Gamma$, if $[u]_\Gamma \tilde{R} [w]_\Gamma$, then for every $\Box\psi \in \Gamma$:
if $\mathfrak{M}, u \models \Box\psi$, then $\mathfrak{M}, w \models \psi$.[6]

By induction on ψ one can prove that for every $\tilde{R}$ satisfying these conditions, the structure $\tilde{\mathfrak{M}} = \langle W_\Gamma, \tilde{R}, V_\Gamma \rangle$ is indeed a filtration of $\mathfrak{M}$ with respect to Γ, and this claim is known as the *filtration lemma.* Often, the conditions *MIN* and *MAX* are adopted as the definition of a filtration of R, and the filtration lemma then claims that they imply that $\mathfrak{M}_\Gamma$ has the desired property.

Does every Kripke structure have a filtration with respect to any set of formulae Γ? Yes: converting the implication to equivalence in either of the conditions *MIN* and *MAX* defines a relation that satisfies the other condition, too, and hence renders a filtration:

- the *minimal filtration* $\mathfrak{M}_\Gamma^{\min} = \langle W_\Gamma, R_\Gamma^{\min}, V_\Gamma \rangle$, $R_\Gamma^{\min} = \{([u]_\Gamma, [w]_\Gamma) \mid (u, w) \in R\}$;
- the *maximal filtration* $\mathfrak{M}_\Gamma^{\max} = \langle W_\Gamma, R_\Gamma^{\max}, V_\Gamma \rangle$, where $[u]_\Gamma R_\Gamma^{\max} [w]_\Gamma$ holds iff for every $\Box\psi \in \Gamma$, $\mathfrak{M}, u \models \Box\psi$ implies $\mathfrak{M}, w \models \psi$.

Clearly, every relation $\tilde{R}$ such that $R_\Gamma^{\min} \subseteq \tilde{R} \subseteq R_\Gamma^{\max}$ is a filtration, too.

Now, given a formula φ and a pointed Kripke structure $(\mathfrak{M}, u)$ such that $\mathfrak{M}, u \models \varphi$, applying the filtration construction to $\Gamma = cl(\varphi)$ produces a finite pointed Kripke structure $(\tilde{\mathfrak{M}}, [u]_\Gamma)$ that satisfies φ, whence basic modal logic (modal logic K) has the finite model property.

This method can be refined to establish the finite model property for axiomatic extensions L of K, too, by adjusting the definition of $\tilde{R}$ so as to preserve the desired properties of the original structure $\mathfrak{M}$, such as transitivity, linearity etc., or to impose such properties on the resulting structure $\tilde{\mathfrak{M}}$ and thus to eventually guarantee that it is a model appropriate for the desired modal logic L. Examples of filtrations for a number of important modal and temporal logics, such as $T, K4, S4$, and the logics of various linear orderings can be found in [91, 117, 46]. A more general result, extending a theorem of Lewis [92], is [122, Theorem 2.6.8] stating that every modal logic axiomatised by a finite set of shallow formulae (see Section 8.2) admits filtration.

[6] This condition does not depend on the choice of representatives u and w, as $\psi, \Box\psi \in \Gamma$.

Finite tree model property

Before returning to the relationship between bisimulation and finite bisimulation in the next section, we apply the preservation result of Lemma 31 to an alternative, simple proof of the finite model property for basic modal logic, by establishing a stronger *finite tree model property*.

LEMMA 35 (finite tree model property). *For every $n \in \mathbb{N}$, every pointed Kripke structure of finite relational type is n-bisimilar to a finite tree structure. Consequently, any satisfiable formula of* ML *is satisfied at the root of a finite tree.*

Proof. According to section 2.2 the unfolding $\mathfrak{M}[u]$ of $(\mathfrak{M}, u)$ provides a bisimilar tree structure. As we only need n-bisimulation equivalence, we may cut off $\mathfrak{M}[u]$ at depth n from its root u, to obtain a tree structure $(\mathfrak{M}[u] \restriction U^n(u), u) \rightleftarrows_n (\mathfrak{M}, u)$ whose depth is bounded by n, where $U^n(u)$ stands for the set of nodes at distance up to n from u. This tree structure may still be infinite, due to infinite branching. In that case, however, we may prune successors at every node to retain at most one representative of each $\rightleftarrows_n$ equivalence class. As $\rightleftarrows_n$ has finite index (for finite vocabulary; see section 3.2), the resulting tree structure is finite. ❑

Finite branching, as well as a finite bound on the number of bisimulation types, are obvious for finite $\mathfrak{M}$, but a finite pointed Kripke structure $(\mathfrak{M}, u)$ in which a directed cycle is reachable from u cannot be bisimilar to a finite tree structure. Locally, however, this can be achieved in partial unfoldings.

LEMMA 36. *Let $n \in \mathbb{N}$. Every finite pointed Kripke structure $(\mathfrak{M}, u)$ is bisimilar to a finite pointed structure $(\hat{\mathfrak{M}}, \hat{u})$ whose restriction to depth n from the distinguished node $\hat{u}$ is a tree structure.*

Proof. Let $(\mathfrak{M}[u] \restriction U^n(u), u)$ be as in the proof of the last lemma (now finite). For each leaf node of this structure, take a new disjoint isomorphic copy of $\mathfrak{M}$ itself and identify the leaf node with its bisimilar partner node in that copy of $\mathfrak{M}$. The resulting structure is finite, bisimilar to $(\mathfrak{M}, u)$ and tree-like up to distance n from the distinguished node. ❑

Remarks. Results of this type can be carried much further. For instance, a more involved construction yields finite two-way bisimilar companions which are acyclic in restriction to the n-neighbourhood of any node [106, 107]. Such locally acyclic finite *bisimilar covers* are available also in restriction to various other non-elementary classes of frames, e.g., within the classes of all (finite) rooted frames or finite equivalence frames [17].

It is also interesting to note that finite and bisimilar $(\mathfrak{M}, u)$ and $(\mathfrak{M}', u')$ admit finite bisimilar companions $(\hat{\mathfrak{M}}, \hat{u})$ and $(\hat{\mathfrak{M}}', \hat{u}')$, respectively, whose restrictions to depth n from their distinguished nodes $\hat{u}$ and $\hat{u}'$ are even isomorphic tree structures. For this, we take $(\hat{\mathfrak{M}}, \hat{u})$ and $(\hat{\mathfrak{M}}', \hat{u}')$ as from the proof above and modify them by merely attaching extra isomorphic copies of substructures at nodes in the tree parts so as to achieve equal multiplicities for all bisimulation types at each node in the tree parts. It then follows that the tree parts are isomorphic.

3.4 Finite versus full bisimulation

For the relationship between finite and full bisimulation equivalence, we note that finite bisimulation equivalence can be strictly weaker in structures with infinite branching. A typical example of tree structures with $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$ but $(\mathfrak{M}, w) \not\rightleftarrows (\mathfrak{M}', w')$ is the following.

EXAMPLE 37. Let $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ be tree Kripke structures with trivial valuations, rooted at w and w', respectively. Let the roots have countably many distinct successors u_i, $i \geq 1$ in $\mathfrak{M}$ and u'_i, $i \geq 0$ in $\mathfrak{M}'$. For $i \geq 1$, we let each of u_i and u'_i be the starting point of a simple finite path of length i. We let the extra node u'_0 in $\mathfrak{M}'$ be the root of a simple infinite path. Then $(\mathfrak{M}, w) \not\rightleftarrows (\mathfrak{M}', w')$: let **I** move in $\mathfrak{M}'$ from w' to u'_0; the second player must move to one of the u_i for $i \geq 1$ in $\mathfrak{M}$; let then **I** lead the play in $\mathfrak{M}'$ along the infinite path: **II** gets stuck and loses in round $i+2$ when the end of the length i path from u_i has been reached. On the other hand, $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w')$ for every $n \in \mathbb{N}$, since any two paths of lengths greater than or equal to n look exactly the same in an n-round game.

However, infinite branching is essential to this phenomenon, as the following shows.

THEOREM 38 (Hennessy–Milner theorem). *Let $\mathfrak{M}$ and $\mathfrak{M}'$ both be finitely branching, i.e., every state in either structure has only finitely many immediate successors.*

Then $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$ implies $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$. Consequently, over finitely branching Kripke structures, modal equivalence coincides with bisimulation equivalence.

Proof. The argument is best given via the games. We claim that **II** can maintain $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$ indefinitely – which gives her a winning strategy for the infinite game. For instance, let **I** play in $\mathfrak{M}$ and move the pebble from w to u. Suppose that for all responses u' available to **II** in $\mathfrak{M}'$, $(\mathfrak{M}, u) \not\rightleftarrows_\omega (\mathfrak{M}', u')$. As there are only finitely many choices for u' due to finite branching, we can find a sufficiently large $n \in \mathbb{N}$ such that $(\mathfrak{M}, u) \not\rightleftarrows_n (\mathfrak{M}', u')$ for all u' with $(w', u') \in R'$. But this would imply $(\mathfrak{M}, w) \not\rightleftarrows_{n+1} (\mathfrak{M}', w')$, contradicting the assumption $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$. ❑

Unlike the Hennessy–Milner theorem, which is rather specific for bisimulation, the following observation rests on arguments from classical model theory, to do with saturation properties, and highlights a more general principle that applies to any finitary versus unbounded game equivalences of the Ehrenfeucht–Fraïssé variety; see for instance [108]. *Saturation* properties refer to the realisation of *types*. We think of a type as the formalisation of the properties of an element, through a set of formulae using constants for parameters from a given structure.

With a first-order language L and a set of parameters $A \subseteq W$ of the universe W of some structure $\mathfrak{M}$, associate the expansion of L_A of L with a constant name for each element of A; the corresponding expansion of $\mathfrak{M}$ is denoted $\mathfrak{M}_A$.

DEFINITION 39. An *element type with parameters in A* (in the first-order language L_A) is a set Σ of L_A-formulae in a single free element variable x. The type Σ is a *type of* $\mathfrak{M}_A$ if it is (finitely) *consistent* with the theory of $\mathfrak{M}_A$ in the sense that $\mathfrak{M}_A \models \exists x \bigwedge \Sigma_0$ for every finite $\Sigma_0 \subseteq \Sigma$. The type Σ is *realised* in $\mathfrak{M}_A$ if $\mathfrak{M}_A, w \models \Sigma$ for some element w.

A structure $\mathfrak{M}$ is ω-saturated if for every finite subset A every type of $\mathfrak{M}_A$ is realised in $\mathfrak{M}_A$.

Interesting properties are often expressible by types rather than by an individual formula. For instance, an R-successor of $w \in \mathfrak{M}$ from which there are arbitrarily long R-paths is described by the type $\Sigma_w := \{Rwx\} \cup \{\mathrm{ST}(\Diamond^n\top; x) \mid n \in \mathbb{N}\}$ with parameter w from $\mathfrak{M}$. Note that this is a type of $\mathfrak{M}$ iff there are arbitrarily long R-paths from $w \in \mathfrak{M}$. This does not imply that $\mathfrak{M}$ itself has a realisation of the type – a successor u of w that simultaneously satisfies all the requirements in Σ_w. By compactness, however, every structure $\mathfrak{M}$ has an ω-saturated elementary extension, cf. [12]. Let $\mathfrak{M}^*$ be such an elementary extension of $\mathfrak{M}$. For $w \in \mathfrak{M}$, Σ_w is a type of $\mathfrak{M}^*$ if it is a type of $\mathfrak{M}$. If Σ_w for $w \in \mathfrak{M}^*$ is a type of $\mathfrak{M}^*$, then there also is some R-successor u of w in $\mathfrak{M}^*$ such that $\mathfrak{M}^*, u \models \Diamond^n\top$ for all n; hence Σ_u will also be a type of $\mathfrak{M}^*$ and repeating the argument inductively we find that $\mathfrak{M}^*$ has an infinite path from w. In ω-saturated models, therefore, any element from which there are arbitrarily long paths, will also have an infinite path. Similar reasoning extends to provide responses for **II** in the infinite game over $\mathfrak{M}^*$ to meet any challenge from **I**, provided she has responses that are good for n rounds, for each n. In other words, playing over ω-saturated structures, **II** has a winning strategy in the infinite game whenever she has, for every n, a winning strategy for the n-round game. The proof is analogous to that given for Proposition 87 below; in the terminology to be introduced there, the class of ω-saturated structures has the *Hennessy–Milner property.*

REMARK 40. As shown in section 6.3, $\rightleftarrows_\omega$ coincides with $\rightleftarrows$ in restriction to ω-saturated structures.

In the bisimulation context weaker forms of saturation suffice, and in that sense the Hennessy–Milner theorem may be regarded as a special case. See section 6.3 for more on (modal) saturation.

Bisimulation and infinitary modal equivalence

Since, over infinitely branching structures, equivalence with respect to ordinary modal logic only reaches up to the level of finite bisimulation equivalence, $\rightleftarrows_\omega$, the question of the actual logical counterpart to full bisimulation equivalence arises. The situation is entirely similar to that in classical first-order logic, where it is clarified by Karp's theorem [82] (see also [68]). While the classical Ehrenfeucht–Fraïssé theorem associates finitary game equivalence (the back-and-forth notion of *finite isomorphism* between structures) with elementary equivalence, full infinitary game equivalence (the back-and-forth notion of *partial isomorphism* between structures) corresponds to equivalence with respect to the *infinitary logic* $\mathrm{L}_{\infty\omega}$ whose syntax allows for disjunctions and conjunctions over arbitrary sets of formulae, [68, 108]. In order to extend modal logic ML to its infinitary variant ML_∞, we put the following additional clause for formula formation. If Ψ is any set of formulae of ML_∞, then $\bigwedge\Psi$ and $\bigvee\Psi$ are formulae of ML_∞. These formulae have an ordinal-valued nesting depth, based on the usual rules for the finitary constructors of ML (see Definition 1) together with the extra stipulation that the nesting depth of an infinitary conjunction or disjunction is the supremum of the nesting depths of the constituent formulae. The semantics of the infinite conjunctions and disjunctions is the natural one; with, e.g., $\mathfrak{M}, w \models \bigvee\Psi$ iff $\mathfrak{M}, w \models \psi$ for some $\psi \in \Psi$.

Completely analogous to the treatment of the finitary game in relation to finitary modal logic, we then get the following. (As a side effect of the availability of infinitary conjunctions and disjunctions, we need not restrict the underlying vocabularies to be

finite.) Comparison with the classical version of Karp's theorem highlights the observation that bisimulation is for modal model theory what partial isomorphism is for classical model theory.

THEOREM 41 (Karp's theorem for modal logic). *Let $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ be Kripke structures of the same type. Then the following are equivalent:*

(i) $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$.

(ii) **II** *has a winning strategy in the infinite bisimulation game from* $(\mathfrak{M}, w; \mathfrak{M}', w')$.

(iii) $(\mathfrak{M}, w) \equiv_{\mathrm{ML}_\infty} (\mathfrak{M}', w')$.

Proof. (i) $\Leftrightarrow$ (ii) is obvious. For (ii) $\Rightarrow$ (iii) compare Lemma 31: similar to there, if $(\mathfrak{M}, w)$ is distinguished from $(\mathfrak{M}', w')$ by a formula of nesting depth α, then one can find a move for **I** which will force a successor configuration in which the positions are distinguished at some nesting depth $\beta < \alpha$. By well-foundedness this gives **I** a winning strategy. For (iii) $\Rightarrow$ (ii) one observes that **II** can maintain ML_∞ equivalence indefinitely. ❑

Remark. Characteristic formulae $\chi^\alpha_{[\mathfrak{M},u]}$ with an ordinal parameter α for their nesting depth, can still be defined inductively in a canonical way. (The analogous infinitary formulae for the infinite first-order Ehrenfeucht–Fraïssé game are known as Scott formulae, see for instance [68].) For the infinite game over infinitely branching $\mathfrak{M}$, a position in which players may have infinitely many non-equivalent choices for a next move, is adequately described by an infinite conjunction $\bigwedge \Diamond\varphi_i$ in conjunction with $\Box \bigvee \varphi_i$, where each φ_i describes the bisimulation type of one potential successor in the game over $\mathfrak{M}$, at a nesting depth level that typically needs to be an infinite ordinal. A sufficiently high nesting depth that can be used uniformly across a given $\mathfrak{M}[u]$ is the least ordinal α such that any two states in $\mathfrak{M}[u]$ that are equivalent at nesting depth α in ML_∞ are equivalent at nesting depth $\alpha + 1$. For this α, equivalence at nesting depth α implies equivalence at any nesting depth, i.e., full ML_∞ equivalence, and hence bisimilarity. (The minimal such α is the *closure ordinal* of the co-inductive definition of the bisimulation relation over $\mathfrak{M}[u]$, also compare section 3.5.)

That a given α has this property for $\mathfrak{M}[u]$ is itself expressible in ML_∞. The defining property of α is equivalent to the assertion that, for all $v \in \mathfrak{M}[u]$, $\mathfrak{M}[u] \models \chi^\alpha_{[\mathfrak{M},v]} \rightarrow \chi^{\alpha+1}_{[\mathfrak{M},v]}$. Let ψ^α be the conjunction of all formulae

$$\Box^n \bigwedge_{v \in \mathfrak{M}[u]} \big(\chi^\alpha_{[\mathfrak{M},v]} \rightarrow \chi^{\alpha+1}_{[\mathfrak{M},v]}\big).$$

Then $\mathfrak{M}, u \models \psi^\alpha$ iff within $\mathfrak{M}[u]$, the ML_∞ type at nesting depth $\alpha+1$ is fully determined by the type at nesting depth α. The conjunction $\chi_{[\mathfrak{M},u]} := \psi^\alpha \wedge \chi^\alpha_{[\mathfrak{M},u]}$ for suitable α, characterises $(\mathfrak{M}, u)$ up to bisimulation, thus providing a canonical characteristic formula in ML_∞.

Unlike the definability assertion of Corollary 34, however, bisimulation closure of a class $\mathcal{C}$ of Kripke structures on its own does not guarantee definability in ML_∞. In the example of Observation 42 below, the relevant disjunction of characteristic formulae would be class-sized, and hence not in ML_∞. However, definability of $\mathcal{C}$ in ML_∞ does follow, for instance, if $\mathcal{C}$ comprises only set-many different bisimulation types (which

is in particular the case for the setting of finite model theory, or in restriction to any other class of bounded cardinality). This is sufficient to ensure that $\mathcal{C}$ is definable by a disjunction over characteristic formulae analogous to Corollary 34.

OBSERVATION 42. Well-foundedness, or the class of all pointed Kripke structures $(\mathfrak{M}, u)$ in which there is no infinite path from u, is not definable in infinitary modal logic ML_∞.

This class is definable by the modal μ-calculus L_μ formula $\mu X.\Box X$ (see section 5.2) and hence in monadic second-order logic MSO.[7] On the other hand, well-foundedness is not even definable in infinitary first-order logic $L_{\infty\omega}$, [95]. We sketch a direct proof of non-definability in ML_∞.

For an ordinal α consider the Kripke structure $\mathfrak{M}_\alpha = \langle \{\beta \mid \beta \leq \alpha\}, R\rangle$ with $R = \{(\beta, \beta') \mid \beta' < \beta \leq \alpha\}$ the inverse of the order relation on these ordinals, and its modification $\mathfrak{M}'_\alpha$ with R replaced by $R' = R \cup \{(\alpha, \alpha)\}$. We show by induction on the ordinal γ that $(\mathfrak{M}'_\alpha, \alpha) \equiv_\gamma (\mathfrak{M}_\alpha, \beta)$ (equivalence in ML_∞ up to nesting depth γ) for all $\alpha \geq \beta \geq \gamma$. It follows that no formula of ML_∞ can separate the well-founded $(\mathfrak{M}_\alpha, \alpha)$ from the non-wellfounded $(\mathfrak{M}'_\alpha, \alpha)$ for all α.

The claim is obvious for $\gamma = 0$; also the limit steps are trivial. For the successor step, from γ to $\gamma + 1$, consider $\alpha \geq \beta \geq \gamma + 1$; it suffices to show that then even $\mathfrak{M}'_\alpha, \alpha \models \Diamond\psi \;\Leftrightarrow \mathfrak{M}_\alpha, \beta \models \Diamond\psi$ for ψ of nesting depth γ. The only non-trivial instance of this assertion is when $\mathfrak{M}'_\alpha, \alpha \models \Diamond\psi$ because $\mathfrak{M}'_\alpha, \alpha \models \psi$. But then $\mathfrak{M}_\alpha, \gamma \models \psi$ by the inductive hypothesis. It follows that $\mathfrak{M}_\alpha, \beta \models \Diamond\psi$ as $\beta \geq \gamma + 1$ implies that $(\beta, \gamma) \in R$.

3.5 Largest bisimulations as greatest fixed points

The union of all bisimulation relations between two given Kripke structures is again a bisimulation relation, and hence a maximal bisimulation in the sense of set inclusion. Such *largest bisimulations* can also be defined co-inductively, and be understood as the greatest fixed-point of suitable monotone operators. Again, and purely for expository purposes, we sketch this approach in the simple case of a single accessibility relation R.

Let $X \subseteq W \times W'$, and let $w \in W$ and $w' \in W'$ be atom equivalent ($w \simeq w'$). Let us say that the pair (w, w') has the *back-and-forth property w.r.t.* X iff player **II** has a single round strategy to lead the bisimulation game from $(\mathfrak{M}, w; \mathfrak{M}', w')$ to a configuration $(\mathfrak{M}, u; \mathfrak{M}', u')$ such that $(u, u') \in X$. (Note that the *back*-and-*forth* conditions for a bisimulation relation say that each of its pairs has the *back*-and-*forth* property w.r.t. the relation itself.)

Consider the following operator F on subsets $X \subseteq W \times W'$:

$$F(X) := \big\{(w, w') \in X \mid (w, w') \text{ has the } \textit{back}\text{-and-}\textit{forth} \text{ property w.r.t. } X\big\}.$$

The operator F is monotone in the sense that $X \subseteq Y \Rightarrow F(X) \subseteq F(Y)$. It therefore has a unique greatest fixed point in restriction to any subset of $W \times W'$. We are interested in the greatest fixed point of F that respects atom equivalence, and therefore consider the restriction F_0 of F to $X_0 := \{(u, u') \in W \times W' \mid u \simeq u'\}$. Let $\rho := \mathrm{gfp}(F_0) \subseteq X_0$ be this greatest fixed point. Being a fixed point of F within X_0, ρ respects atom equivalence;

[7] Note that this is definability in the sense of (local) Kripke structure semantics, albeit in a logic which is itself of a second-order nature, and should not be confused with the modal definability of the class of transitive well-founded frames.

being a fixed point of F, ρ has the *back*-and-*forth* property. So ρ is a bisimulation. As any bisimulation between $\mathfrak{M}$ and $\mathfrak{M}'$ must also be a fixed-point of F_0, ρ is the largest such.

REMARK 43. The stages of the evaluation of $\mathrm{gfp}(F_0)$ produce a monotone decreasing ordinal-indexed sequence of subsets $X_\alpha \subseteq W \times W'$ according to

$$\begin{array}{rcll} X_0 & = & \{(u,u') \in W \times W' \mid u \simeq u'\} & \\ X_{\alpha+1} & = & F_0(X_\alpha) & \text{(successor stage)} \\ X_\lambda & = & \bigcap_{\alpha<\lambda} X_\alpha & \text{(limit stage)} \end{array}$$

which is eventually constant with value $\mathrm{gfp}(F_0)$. The least ordinal α such that $X_{\alpha+1} = X_\alpha$ is called the *closure ordinal* of this greatest fixed point evaluation over $\mathfrak{M}$ and $\mathfrak{M}'$. This closure ordinal is bounded by the number of bisimulation types realised in $\mathfrak{M}$ and $\mathfrak{M}'$. For cardinality reasons it is in particular strictly less than the successor cardinal of $|W| + |W'|$.

Over finite Kripke structures in particular, the limit $\mathrm{gfp}(F_0)$ is reached within a number of iterations bounded by $|W| + |W'|$, whence the largest bisimulation is polynomial time computable.

One verifies by induction that, for $n \in \mathbb{N}$, X_n is the subset

$$X_n = \big\{(u,u') \in W \times W' \mid (\mathfrak{M}, u) \rightleftarrows_n (\mathfrak{M}', u')\big\}$$

and correspondingly that

$$X_\omega = \big\{(u,u') \in W \times W' \mid (\mathfrak{M}, u) \rightleftarrows_\omega (\mathfrak{M}', u')\big\}.$$

Closure within $m := |W| + |W'|$ steps for finite Kripke structures, implies that, in restriction to $\mathfrak{M}$ and $\mathfrak{M}'$, m-bisimulation equivalence $\rightleftarrows_m$ and hence equivalence in ML_m coincide with full bisimulation equivalence $\rightleftarrows$ and equivalence in ML. This quantitative analysis provides a direct proof of the Hennessy–Milner theorem (with additional a priori bounds) in the special case of finite (rather than just finitely branching) Kripke structures.

3.6 Bisimulation quotients and canonical representatives

Bisimulation quotients provide canonical minimal bisimilar companions, in which every bisimulation type is realised only once. They thus form succinct representations of the overall bisimulation type of a structure $\mathfrak{M}$. There is an analogy with filtrations (compare section 3.3), but here the quotient is taken with respect to the largest bisimulation within the given structure, rather than with respect to some coarser equivalence induced by some set of modal formulae. Passage to bisimulation quotients is often desirable for complexity reasons, for instance for model checking of bisimulation invariant properties. Bisimulation quotients of finite structures are polynomial time computable, as the largest bisimulation is polynomial time computable over finite structures as a greatest fixed point.

For a Kripke structure $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$, consider the largest bisimulation within $\mathfrak{M}$ itself, $\rho^{\mathfrak{M}} = \{(u,u') \mid (\mathfrak{M}, u) \rightleftarrows (\mathfrak{M}, u')\} \subseteq W^2$, as an equivalence relation on W. Let us write $[u]_\rho$ for the equivalence class of $u \in W$. Note that $\rho^{\mathfrak{M}}$ is a congruence w.r.t. the valuation V (by atom equivalence). Therefore V induces a natural quotient valuation $V/\rho^{\mathfrak{M}}$ on the quotient $W/\rho^{\mathfrak{M}}$. While $\rho^{\mathfrak{M}}$ is not in general a congruence w.r.t. the R_α, clearly $(w,u) \in R_\alpha$ implies that for any $w' \in [w]_\rho$ there is $u' \in [u]_\rho$ such that

$(w', u') \in R_\alpha$ (by the back and forth conditions). A natural quotient interpretation for the R_α over $W/\rho^{\mathfrak{M}}$ therefore is

$$R_\alpha/\rho^{\mathfrak{M}} := \{([w]_\rho, [u]_\rho) \in (W/\rho^{\mathfrak{M}})^2 \mid (w, u) \in R_\alpha^{\mathfrak{M}}\}.$$

DEFINITION 44. The *bisimulation quotient* $\mathfrak{M}/\rho^{\mathfrak{M}}$ is the Kripke structure with universe $W/\rho^{\mathfrak{M}} = \{[u]_\rho \mid u \in W\}$, accessibility relations $R_\alpha/\rho^{\mathfrak{M}}$ and valuation $V/\rho^{\mathfrak{M}}$.

LEMMA 45. *The canonical projection* $\pi\colon W \to W/\rho^{\mathfrak{M}}$ *from* $\mathfrak{M}$ *onto its bisimulation quotient* $\mathfrak{M}/\rho^{\mathfrak{M}}$ *is a surjective bounded morphism.*

$\mathfrak{M}/\rho^{\mathfrak{M}}$ is minimal among all globally bisimilar companion structures of $\mathfrak{M}$, as any other such must also have at least one representative of each bisimulation type realised in $\mathfrak{M}$. Moreover, any global bisimulation between two such quotient structures is uniquely determined by bisimulation types and is necessarily an isomorphism. The analogue for ordinary (rather than global) bisimulation equivalence of pointed Kripke structures $(\mathfrak{M}, u)$ needs to be based on quotients $\mathfrak{M}[u]/\rho^{\mathfrak{M}}$ taken after restriction to the generated substructure rooted at u. The bisimulation quotient associated with a (pointed) Kripke structure thus provides a *canonical representative* of its bisimulation type, 'canonical' in the sense of being uniquely determined up to isomorphism.

COROLLARY 46. *Kripke structures* $\mathfrak{M}$ *and* $\mathfrak{M}'$ *are globally bisimilar iff their bisimulation quotients are isomorphic. Pointed Kripke structures* $(\mathfrak{M}, u)$ *and* $(\mathfrak{M}', u')$ *are bisimilar iff the bisimulation quotients* $(\mathfrak{M}[u]/\rho^{\mathfrak{M}}, [u]_\rho^{\mathfrak{M}})$ *and* $(\mathfrak{M}'[u']/\rho^{\mathfrak{M}'}, [u']_\rho^{\mathfrak{M}'})$ *are isomorphic.*

For other kinds of canonical representatives of the bisimulation type of a pointed Kripke structure we may look to trees. Via tree unfoldings any pointed Kripke structure is bisimilar to a tree structure. In order to associate a companion tree structure which is uniquely determined up to isomorphism, though, one needs to impose conditions on the multiplicities among bisimilar siblings in the tree. For countably branching Kripke structures, for instance, in which every state has at most countably many immediate successors, *ω-branching tree unfoldings* $\vec{\mathfrak{M}}^{\omega}[u]$ may be used. These are defined in complete analogy with ordinary tree unfoldings, cf. Definition 21, but based on the set of all ω-labelled paths rooted at u. An ω-labelled path in $\mathfrak{M}$ is a sequence $\vec{w} = (w_0, \alpha_1, m_1, w_1, \ldots, \alpha_k, m_k, w_k)$, where $\vec{w} = (w_0, \alpha_1, w_1, \ldots, \alpha_k, w_k)$ is a path in $\mathfrak{M}$ in the usual sense, and with labels $m_i \in \mathbb{N}$. Two ω-labelled paths $\vec{w}$, $\vec{w}'$ are linked by an R_α-edge in $\vec{\mathfrak{M}}^{\omega}[u]$ if $\vec{w}'$ is an α-extension of $\vec{w}$: $\vec{w}' = (\vec{w}, \alpha, m, w')$ for some $m \in \mathbb{N}$. Through the ω-labelling, the multiplicity of each bisimulation type in each successor set w.r.t. R_α is countably infinite. It is then easy to see that any two bisimilar ω-branching tree unfoldings of countably branching Kripke structures are isomorphic.

This observation may be extended in a straightforward manner to κ-tree unfoldings $\vec{\mathfrak{M}}^{\kappa}[u]$ based on κ-labelled paths, for any infinite cardinal κ.

COROLLARY 47. *For any infinite cardinal* κ*, and pointed Kripke structures* $(\mathfrak{M}, u)$ *and* $(\mathfrak{M}', u')$ *whose branching degree is bounded by* κ*:* $(\mathfrak{M}, u) \rightleftarrows (\mathfrak{M}', u')$ *if, and only if,* $(\vec{\mathfrak{M}}^{\kappa}[u], u) \simeq (\vec{\mathfrak{M}}'^{\kappa}[u'], u')$.

3.7 *Robinson consistency, local interpolation, and Beth definability*

We illustrate the usefulness of the canonicity property expressed in Corollary 47 with a proof of the following analogue of the Robinson joint consistency property [12] for poly-modal logic.

PROPOSITION 48 (Robinson consistency). *For $i = 1, 2$ let $\tau^{(i)}$ be modal similarity types; $\Phi^{(i)}$ sets of atomic propositions; and $\Gamma^{(i)} \subseteq \mathrm{ML}[\tau^{(i)}, \Phi^{(i)}]$. If $\Gamma^{(1)} \cap \Gamma^{(2)}$ is a complete modal theory (in the local sense), and if both $\Gamma^{(1)}$ and $\Gamma^{(2)}$ are consistent, then $\Gamma = \Gamma^{(1)} \cup \Gamma^{(2)}$ is also consistent.*

Proof. Let $\tau^{(0)} := \tau^{(1)} \cap \tau^{(2)}$, $\Phi^{(0)} := \Phi^{(1)} \cap \Phi^{(2)}$, $\Gamma^{(0)} := \Gamma^{(1)} \cap \Gamma^{(2)}$.

Let $\mathfrak{M}, u \models \Gamma^{(1)}$ and $\mathfrak{N}, v \models \Gamma^{(2)}$. Without loss of generality assume that both structures are ω-saturated, which implies that also their $(\tau^{(0)}, \Phi^{(0)})$ reducts $\mathfrak{M}^{(0)}$ and $\mathfrak{N}^{(0)}$ are ω-saturated. Then $(\mathfrak{M}^{(0)}, u) \equiv_{\mathrm{ML}} (\mathfrak{N}^{(0)}, v)$, as both satisfy the complete theory $\Gamma^{(0)}$. By the Hennessy–Milner property for ω-saturated structures: $(\mathfrak{M}^{(0)}, u) \rightleftarrows (\mathfrak{N}^{(0)}, v)$ (cf. Remark 40).

Let $\kappa \geq |\mathfrak{M}|, |\mathfrak{N}|$ and consider the κ-tree unfoldings $\hat{\mathfrak{M}} := \vec{\mathfrak{M}}^{\kappa}[u]$ and $\hat{\mathfrak{N}} := \vec{\mathfrak{N}}^{\kappa}[v]$. The generated $(\tau^{(0)}, \Phi^{(0)})$-subtrees of $(\hat{\mathfrak{M}}, u)$ and $(\hat{\mathfrak{N}}, v)$ are themselves κ-tree unfoldings of corresponding generated $(\tau^{(0)}, \Phi^{(0)})$-substructures of $\mathfrak{M}$ and $\mathfrak{N}$. So they are isomorphic as $(\tau^{(0)}, \Phi^{(0)})$-trees. We may assume that $(\hat{\mathfrak{M}}, u)$ and $(\hat{\mathfrak{N}}, v)$ intersect precisely in these isomorphic subtrees. Let then $\mathfrak{K} := \hat{\mathfrak{M}} \cup \hat{\mathfrak{N}}$ be their union (note that $u = v$). The component structures $(\hat{\mathfrak{M}}, u)$ and $(\hat{\mathfrak{N}}, v)$ are the generated $(\tau^{(i)}, \Phi^{(i)})$-subtrees for $i = 1$ and $i = 2$, respectively. By bisimulation invariance, $\mathfrak{K}, u \models \Gamma^{(i)}$ for $i = 1, 2$. Therefore Γ is satisfiable. ❑

Consistency properties can usually be directly related to interpolation [12]. Here we obtain the *local interpolation* theorem for poly-modal logic as a corollary. For modal similarity types and sets of atomic propositions as above: let $\models \varphi \to \psi$ be a valid (local) consequence, $\varphi \in \mathrm{ML}[\tau^{(1)}, \Phi^{(1)}]$, $\psi \in \mathrm{ML}[\tau^{(2)}, \Phi^{(2)}]$. We want to show that there is an interpolant $\chi \in \mathrm{ML}[\tau^{(0)}, \Phi^{(0)}]$ (i.e., in the common language):

$$\models (\varphi \to \chi) \wedge (\chi \to \psi).$$

Assume there was no interpolant. One can then find a complete theory $\Gamma^{(0)}$ in the common vocabulary for which both $\Gamma^{(1)} := \Gamma^{(0)} \cup \{\varphi\}$ and $\Gamma^{(2)} := \Gamma^{(0)} \cup \{\neg\psi\}$ are consistent (see below). With the consistency property established above, however, this would show that $\varphi \wedge \neg\psi$ is satisfiable, invalidating the implication $\varphi \to \psi$. Assuming without loss of generality that the common language $\mathrm{ML}[\tau^{(0)}, \Phi^{(0)}]$ is countable, one generates $\Gamma^{(0)}$ inductively as a union of an increasing chain of finite sets $\Gamma^{(0)}_n$. The sets $\Gamma^{(0)}_n$ are inductively augmented towards completion, by adding one formula or its negation at a time, guided by the condition that there be no interpolant χ with $\Gamma^{(0)}_n \models (\varphi \to \chi) \wedge (\chi \to \psi)$.

COROLLARY 49. *Poly-modal logic satisfies the interpolation theorem for local consequence.*

The interpolation property can be relativised to particular modal logics or classes of frames. We mention one general result of this kind. Following [122], a subframe $\mathfrak{F}$ of the direct product $\prod_{i \in I} \mathfrak{F}_i$ (see section 6.2) is said to be a *bisimulation product* of the family of frames $\{\mathfrak{F}_i\}_{i \in I}$ if the canonical projection $\pi_i : \mathfrak{F} \to \mathfrak{F}_i$ is a surjective bounded morphism, for each $i \in I$. The following has been established in [122, Thm 2.5.3].

PROPOSITION 50. *Let $\mathcal{K}$ be an elementary class of frames closed under generated subframes and bisimulation products. Then modal logic over $\mathcal{K}$ has interpolation.*

The interpolation property is intimately related to the *Beth definability property* which links *implicit* with *explicit* definability.

Consider a fixed (poly-)modal language $\mathrm{ML}[\tau,\Phi]$. For any list of propositional variables $\mathbf{q}$ from Φ, we denote by $\mathrm{ML}[\mathbf{q}]$ the sublanguage of $\mathrm{ML}[\tau,\Phi]$ restricted to the propositional variables listed in $\mathbf{q}$. Let $p \in \Phi$ be a propositional variable not in $\mathbf{q}$, and $\Gamma = \Gamma(p,\mathbf{q}) \subseteq \mathrm{ML}[p,\mathbf{q}]$ a modal theory. Intuitively, Γ defines p implicitly if it uniquely determines the valuation of p relative to the rest. Formally, let p' be a propositional variable not occurring in $\Gamma(p,\mathbf{q})$ and $\Gamma' = \Gamma(p',\mathbf{q})$ the result of substituting p' for p throughout Γ. Γ *defines p implicitly* if the following is valid (in the sense of local consequence):

$$\Gamma \cup \Gamma' \vDash p \leftrightarrow p'.$$

On the other hand, p is said to be *explicitly definable* relative to Γ if for some $\varphi(\mathbf{q}) \in \mathrm{ML}[\mathbf{q}]$ (thus, not containing p):

$$\Gamma \vDash p \leftrightarrow \varphi(\mathbf{q}).$$

Such φ is then called an *explicit definition* of p relative to Γ.

Clearly, explicit definability entails implicit definability. *Beth's definability theorem* (proved in the early 1950s for first-order logic) states the converse: *implicit definability entails explicit definability.* A standard proof technique is by reduction to interpolation.

Let $\Gamma(p,\mathbf{q}) \cup \Gamma(p',\mathbf{q}) \vDash p \leftrightarrow p'$. By compactness, $\gamma(p,\mathbf{q}) \wedge \gamma(p',\mathbf{q}) \vDash p \leftrightarrow p'$ for some formula γ from Γ (assuming Γ closed under $\wedge$). This implies the validity of

$$\vDash \big(\gamma(p,\mathbf{q}) \wedge p\big) \to \big(\gamma(p',\mathbf{q}) \to p'\big).$$

Local interpolation yields an interpolant $\varphi \in \mathrm{ML}[\mathbf{q}]$ in the common language and thus not containing p or p', such that both $\vDash (\gamma(p,\mathbf{q}) \wedge p) \to \varphi$ and $\vDash \varphi \to (\gamma(p',\mathbf{q}) \to p')$. Together these two establish that φ explicitly defines p relative to γ and hence relative to Γ. We have thus obtained the following.

COROLLARY 51. *Modal logic satisfies Beth's definability theorem for local consequence.*

The notions of interpolation, implicit and explicit definability, and the Beth definability property admit *global* versions, with respect to the global consequence relation (i.e., with respect to validity in Kripke structures). Beth's definability theorem for global consequence can be proved just like the local one above, by noting that Γ implies ψ globally iff $\Box^*\Gamma \vDash \psi$, where $\Box^*\Gamma = \{\Box^n\gamma \mid n \in \mathbb{N}, \gamma \in \Gamma\}$.

Semantically, global implicit definability means that, in any Kripke structure $\mathfrak{M}$ for $\mathrm{ML}(\mathbf{q})$, there is at most one valuation for p such that the resulting expansion $\mathfrak{M}^p$ satisfies $\Gamma(p,\mathbf{q})$. Thus, in order to show that Γ does *not* define p implicitly it suffices to find two models of $\Gamma(p,\mathbf{q})$ that differ in the valuation of p but are otherwise identical. This is the idea of *Padoa's method* for disproving definability in classical logic.

As for global explicit definability in modal logic, Conradie [13] has shown that it can be characterised semantically as follows. p is explicitly globally definable relative to $\Gamma(p,\mathbf{q})$ iff for every two Kripke structures $\mathfrak{M}_1$ and $\mathfrak{M}_2$ satisfying $\Gamma(p,\mathbf{q})$: $\mathfrak{M}_1 \equiv_{\mathrm{ML}[\mathbf{q}]} \mathfrak{M}_2 \;\Rightarrow\; \mathfrak{M}_1 \equiv_{\mathrm{ML}[p,\mathbf{q}]} \mathfrak{M}_2$. Here $\equiv_{\mathrm{ML}[\mathbf{q}]}$ denotes equivalence in $\mathrm{ML}[\mathbf{q}]$. In fact, $\equiv_{\mathrm{ML}[\mathbf{q}]}$ may be replaced for this condition by the corresponding bisimulation relation $\rightleftarrows_{\mathrm{ML}[\mathbf{q}]}$.

For more on interpolation and Beth definability in modal logic, see Chapter 8 of this handbook, [98, 10, 73], as well as [15] for uniform interpolation in the modal mu-calculus, [122] for results on interpolation in extended modal languages, and [36] for a comprehensive exposition of the state of the art on interpolation and definability.

3.8 Bisimulation-safe modal operators

It is easy to find examples of bisimilar pointed Kripke structures $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$, over the modal similarity type with a single modality associated with an accessibility relation R say, such that the corresponding expansions with new accessibility relations interpreted by the converse relations $R^{-1} := \{(u, v) \mid (v, u) \in R\}$ are not bisimilar. On the other hand, $\rho\colon (\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$ for pointed (poly-modal) Kripke structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ implies that the same ρ also is a bisimulation for the expansions by accessibility relations generated from the R_α by the constructors provided in propositional dynamic logic PDL: union, composition, star, as well as test (compare Lemma 70). Thus, the question arises: which operations on relations are 'safe for bisimulations', i.e., preserve bisimulations which hold for their arguments? This question was raised and analysed by van Benthem. In particular, he answered that question completely for the case of *first-order definable* operations on binary relations (see [130, Section 5.3], also [5, Section 2.7]). The operation $\sim$ of *domain-complementation* is defined as an operation on binary relations according to ${\sim}R := \{(x, x) \mid \neg\exists z Rxz\}$.

THEOREM 52. *A first-order definable operation $O(R_1, \ldots, R_n)$ on binary relations is safe for bisimulation iff it can be constructed from $R_1, \ldots, R_n$ using atomic tests $p?$, unions, compositions and the operation of domain-complementation.*

This characterisation was extended in [131] to operations definable in infinitary languages, by allowing infinite unions, too. Since the star operation or iteration, *, is definable as an infinite union of compositions, this accounts for the bisimulation safety of PDL as stated above. The notion of bisimulation-safety and the results above were further extended by Hollenberg [72].

4 MODAL LOGIC AS A FRAGMENT OF FIRST-ORDER LOGIC

The embedding of modal logics into a fragment of first-order logic via the standard translation makes results and techniques for that fragment directly available to the analysis of the modal logic. In this section we discuss further aspects of the relationship between modal and first-order logic.

4.1 Finite variable fragments of first-order logic

DEFINITION 53. Over a purely relational vocabulary and for $k \geq 1$ let *k-variable first-order logic* be the syntactic fragment $\mathrm{FO}^k \subseteq \mathrm{FO}$ consisting of those FO formulae that only use k distinct variable symbols, say $x_0, \ldots, x_{k-1}$, free or bound.

Gabbay [32] first observed that the standard translation, with thrifty re-use of variables as presented in section 1.3, embeds basic modal logic ML into FO^2, the two-variable fragment of first-order logic. (For polyadic modalities of arities up to m, one similarly gets an embedding into the $(m + 1)$-variable fragment.)

LEMMA 54. *The standard translation based on* $\mathrm{ST}(\_;x_0)$ *and* $\mathrm{ST}(\_;x_1)$ *embeds* ML *into* FO^2.

For instance, for ML with a single unary modality $\Diamond$ associated with the binary accessibility relation R, the standard translation operates with an alternate use of two variables, x_0 and x_1, as in

$$\mathrm{ST}\big(\Diamond\Box\Diamond p; x_0\big) = \exists x_1\big(Rx_0x_1 \wedge \forall x_0\big(Rx_1x_0 \rightarrow \exists x_1\big(Rx_0x_1 \wedge Px_1\big)\big)\big).$$

It should be noted that this re-use of variable symbols is at odds for instance with a prenex formalisation in first-order logic. It has several other benefits, however, to be discussed below. And even though the embedding into the guarded fragment of first-order logic which has emerged more recently (see section 4.3 below) may have greater explanatory power for some characteristic features of modal logics, the straightforward embedding into finite variable fragments has also been put to good use.

Consider the embedding of basic modal logic into FO^2. By results of Scott [116] (valid for FO^2 without equality) and Mortimer [102] (with equality), FO^2 has the finite model property. In fact FO^2 has an exponential bound on small models [59]. Therefore, the finite model property for basic modal logic and decidability for satisfiability may be inferred via the translation into FO^2. The complexity and small model bounds obtained in this way, however, are not optimal.

The fact that ML embeds into a finite-variable fragment also provides upper bounds on its model checking complexity. Consider the so-called combined complexity of checking whether $\mathfrak{M}, w \models \varphi$, with both the finite structure $\mathfrak{M}$ and the formula φ as input. The standard translation of modal logic into FO is itself linear time computable. While the combined model checking complexity for FO over finite relational structures is complete for Pspace, it becomes Ptime for FO^k. Moreover, even for FO^2 and basic modal logic the problem is Ptime-hard. For FO^2 one also obtains a bound of $\mathcal{O}(|\varphi||\mathfrak{M}|)$, linear in both input components.[8] FO^2 thus constitutes a natural syntactic fragment of classical first-order logic which matches the finite model property, the decidability and model checking complexity of basic modal logic. These parallels and their limitations are further discussed in [60, 135, 57].

Remark. At the level of FO^3 and higher, which becomes relevant for instance for polyadic modalities, the target logic FO^k fails to have the finite model property and is just as undecidable for satisfiability as full first-order logic, and also does not have linear time model checking. For many purposes, including satisfiability and model checking, however, natural reductions from polyadic into unary modal logics are available that still make the special status of the two-variable fragment available for polyadic modal logics. See for instance [41].

The k-variable fragments of FO play an interesting role in finite model theory and for algorithmic issues, primarily because they give rise to natural and algorithmically manageable *pebble games*. The k-pebble game is precisely the variant of the classical (first-order) Ehrenfeucht–Fraïssé game associated with the restriction to k variable symbols. Bisimulation games in their turn may be regarded as restrictions of these k-pebble games.

[8] This bound refers to a random access model of computation and a succinct representations of the binary accessibility relations R_α through adjacency lists. The input size for the structure is then linear in the number of states plus the number of accessibility edges.

Just as the ordinary n-round Ehrenfeucht–Fraïssé game captures elementary equivalence up to quantifier rank n [26, 68, 108], and just as the n-round bisimulation game captures modal equivalence in ML_n, so the n-round k-pebble game captures equivalence in FO^k up to quantifier rank n.

In the classical (variable-unconstrained) Ehrenfeucht–Fraïssé game for FO over two relational structures $\mathfrak{A}$ versus $\mathfrak{A}'$, the players, **I** and **II**, mark finite configurations of elements in these structures with matching pebbles. A configuration in the game is specified by two tuples of marked elements $\mathbf{a}$ in $\mathfrak{A}$ and $\mathbf{a}'$ in $\mathfrak{A}'$, denoted $(\mathfrak{A}, \mathbf{a}; \mathfrak{A}', \mathbf{a}')$. In each round, **I** chooses one of the structures, and places another marker on one of the elements of that structure; **II** has to respond by marking an element in the opposite structure. In one round the game thus proceeds from a configuration $(\mathfrak{A}, \mathbf{a}; \mathfrak{A}', \mathbf{a}')$ to some configuration $(\mathfrak{A}, \mathbf{a}, a; \mathfrak{A}', \mathbf{a}', a')$ with newly pebbled elements a and a'. **II** loses as soon as the partial map induced by the correspondence between pebbled elements $f\colon \mathbf{a} \mapsto \mathbf{a}'$ is not a local isomorphism. The existence of a winning strategy for **II** in the n-round game then precisely captures elementary equivalence up to quantifier rank n.

The variant for FO^k is obtained by changing the rules in such a manner that no more than k elements of each structure are ever pebbled simultaneously; the game is restricted to configurations $\mathfrak{A}, \mathbf{a}; \mathfrak{A}', \mathbf{a}'$ with tuples $\mathbf{a}$ and $\mathbf{a}'$ of lengths up to k. In any round starting from a configuration of full length k, **I** first removes one of the pebbles and then repositions that same pebble in its structure, and **II** has to do likewise with the matching pebble in the opposite structure. This game then captures levels of equivalence in FO^k, [25].

It is an obvious consequence of Lemma 54 that equivalence in FO^2 implies equivalence with respect to basic modal logic with unary modalities. However, this may also be inferred directly at the level of the games. One observes that the relevant bisimulation game can be emulated by the 2-pebble game in the sense that

- any challenge available to player **I** in the modal game is also available in the 2-pebble game.
- any responses for **II** that are good for the 2-pebble game are good in the modal game, too.

A move along an R-edge in the bisimulation game is emulated in the two-pebble game by means of a placement of the second pebble in the target node. The formerly active pebble now only plays the auxiliary role to guarantee that the right kind of edge is used in an admissible manner also in the response by **II**. But, clearly a strategy in the two-pebble game guarantees more than just bisimulation equivalence, illustrating the gap in expressive power between modal logic and the two-variable fragment of first-order logic into which it can be embedded.

Consider the expressive power of basic (poly-modal) ML over corresponding Kripke structures $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, \{P_i\}\rangle$. Unlike ML, FO^2 formulae generally define binary predicates over Kripke structures. However, the expressive power of FO is also very limited in this respect. As can be inferred from the 2-pebble game, any FO^2-formula $\varphi(x_0, x_1)$ is logically equivalent to a Boolean combination of quantifier free formulae of FO^2 (atomic formulae, including equality) and FO^2 formulae in a single free variable $\psi(x_i)$, $i = 0, 1$. In other words, the expressive power of FO^2, too, is essentially governed by its expressive power in terms of unary relations (properties of single elements in Kripke structures, state properties in process logics). Comparing the expressive power

of basic modal logic ML with that of FO^2 for defining properties of elements and the discriminating powers of bisimulation versus two-pebble game equivalence, basic modal logic is lacking

(i) relativised quantification along backward R_α-edges.

(ii) quantification relativised by (positive or arbitrary) boolean combinations of accessibility relations (including equality).

(iii) unrelativised, global first-order quantification in one variable.

Corresponding features can be added to basic modal logic, as for instance through extensions via *inverse modalities* (in temporal settings: past modalities) interpreted w.r.t. to the converses $R_\alpha^- = \{(v,u) \mid (u,v) \in R_\alpha\}$; a *global modality* interpreted w.r.t. to the full binary relation $U = W \times W$ over universe W; or other constructors for derived accessibilities.[9] An extension of basic modal logic that provides a minimal set of constructs in the above vein so as to precisely capture the expressive power of FO^2, is provided in [96]. A comparison of the satisfiability problems of these two logics shows that there is no polynomial time translation from FO^2 into its modal counterpart, under suitable complexity assumptions. Furthermore, on certain classes of frames extended modal logics can reach the full expressiveness of first-order logic. The most prominent example is Kamp's result in [80] that the temporal language with Since and Until is expressively complete for all first-order definable connectives on the class of Dedekind complete linear orders. This line of work was further developed by others, including Stavi, Gabbay, Venema, Reynolds. For further details see [32, 34], as well as Chapter 11 of this handbook.

4.2 The van Benthem–Rosen characterisation theorem

The fundamental observation that modal logics are embedded into (fragments of) first-order logic via the standard translation immediately calls for the following question. Given an arbitrary first-order formula (in an appropriate vocabulary of Kripke structures), under which conditions is it equivalently expressible in modal logic? In other words, precisely which first-order properties of pointed Kripke structures are expressible in modal logic? Bisimulation invariance is obviously a necessary condition; van Benthem's Theorem says that it is sufficient as well.

Another point of view is also illuminating. Take bisimulation invariance as the fundamentally important semantic notion. It deserves this status for many non-logical reasons, since it is *the* natural notion of process equivalence (thinking of Kripke structures as transition systems), game equivalence (transition systems for games), knowledge equivalence (Kripke structures for knowledge representation), et cetera. From the perspective of first-order logic, then, one would want to isolate the bisimulation invariant properties because just these conform with the underlying semantic intuition. For instance, a first-order property of transition systems captures a property of processes if, and only if, it does not distinguish between bisimulation equivalent transition systems.

Bisimulation invariance is not a decidable property of first-order formulae, as can be seen through reduction of the satisfiability problem. For $\varphi \in \mathrm{FO}(\tau_\Phi \setminus \{R\})$, the formula $\hat{\varphi}(x) := \varphi \wedge Rxx$ is bisimulation invariant iff φ is unsatisfiable. The syntactic subset consisting of those first-order formulae that happen to be bisimulation invariant is

[9] An example of that is the union (*or*) on program formulae in PDL, which, however, is reducible to plain ML in this context, since, for instance $[\alpha \cup \beta]\varphi \equiv [\alpha]\varphi \wedge [\beta]\varphi$ and $\langle \alpha \cup \beta \rangle\varphi \equiv \langle\alpha\rangle\varphi \vee \langle\beta\rangle\varphi$.

therefore *not* the syntax of a reasonable logic. But the characterisation theorem says that modal logic precisely fills this gap. ML, or its translation into FO, provides decidable syntax for just the bisimulation invariant first-order properties; ML is the first-order logic for bisimulation respecting properties.

THEOREM 55 (van Benthem). *Let $\varphi(x) \in \mathrm{FO}$ be in a vocabulary of Kripke structures. Then the following are equivalent:*

(i) *φ is bisimulation invariant: $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$ implies $\mathfrak{M}, w \models \varphi \Leftrightarrow \mathfrak{M}', w' \models \varphi$.*

(ii) *$\varphi(x)$ is logically equivalent to a formula $\tilde{\varphi} \in \mathrm{ML}$.*

Note that (ii) $\Rightarrow$ (i) is just Theorem 14 again. The crucial point here is *expressive completeness* of ML for *all* bisimulation invariant first-order properties. The core idea for that is to establish the following – which is reminiscent of a compactness property.

LEMMA 56. *If $\varphi(x) \in \mathrm{FO}$ is bisimulation invariant, then it is invariant under n-bisimulation for some $n \in \mathbb{N}$.*

The lemma implies (i) $\Rightarrow$ (ii) in the theorem, as any n-bisimulation invariant property is clearly definable in ML_n. Indeed, by Corollary 34, φ is then equivalent to a disjunction of characteristic formulae for n-bisimulation equivalence classes. For the lemma, we sketch a version of the classical proof and an alternative argument more closely based on the games.

Via classical model theory. Assume to the contrary that φ was not invariant under n-bisimulation for any $n \in \mathbb{N}$, and hence not equivalent to any modal formula. Enumerate all modal formulae of the appropriate type as $(\psi_i)_{i\in\mathbb{N}}$. Successively choose one of ψ_i or $\neg\psi_i$ to obtain a maximally consistent set T of modal formulae consistent with both φ and $\neg\varphi$. By compactness one obtains pointed Kripke structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ such that both satisfy T, while $\mathfrak{M}, w \models \varphi$ and $\mathfrak{M}', w' \models \neg\varphi$. As $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ satisfy the same complete modal theory, $(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')$ and therefore $(\mathfrak{M}, w) \rightleftarrows_\omega (\mathfrak{M}', w')$. Passage to ω-saturated (or modally saturated, see section 6.3) elementary extensions of $(\tilde{\mathfrak{M}}, w)$ and $(\tilde{\mathfrak{M}}', w')$ would then give us structures $(\tilde{\mathfrak{M}}, w) \rightleftarrows (\tilde{\mathfrak{M}}', w')$ (cf. Remark 40), which are still distinguished by φ, contradicting bisimulation invariance of φ.

Via games. This alternative proof of the crucial step towards the characterisation theorem admits ramifications that persist where the classical argument fails, in particular in finite model theory. In its present form this argument is based on [105, 107] building on ideas from Rosen's finite model theory version of the characterisation theorem [112], as further discussed below (Theorem 61) and in section 9. The *n-neighbourhood* of an element u in a Kripke structure $\mathfrak{M}$ consists of all elements whose *Gaifman distance* from u is at most n. Here Gaifman distance is graph theoretic distance in the undirected graph induced by the symmetrised accessibility relation. We write $\mathfrak{M} \restriction U^n(u)$ for the induced substructure on the n-neighbourhood of u in $\mathfrak{M}$.

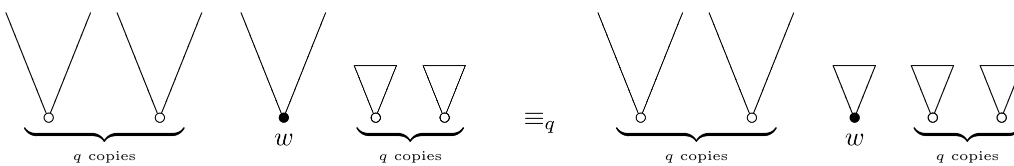
DEFINITION 57. A formula $\varphi(x)$ is *n-local* if for any two pointed tree Kripke structures $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ that are isomorphic in restriction to the n-neighbourhoods of their distinguished nodes, $\mathfrak{M}, w \models \varphi \Leftrightarrow \mathfrak{M}', w' \models \varphi$.

It is easy to see that, if $\varphi(x)$ is bisimulation invariant and n-local, then it is n-bisimulation invariant. In fact, this is obvious for trees and then extends to arbitrary pointed Kripke structures through their unfoldings into trees (see section 2.2). See [105, 106] for the following.

LEMMA 58. *Let $\varphi(x) \in \mathrm{FO}$ have quantifier rank q. If φ is bisimulation invariant, then it is n-local, and hence invariant under n-bisimulation, for $n = 2^q - 1$.*

The first-order locality argument is in fact a ramification of the much more general *Gaifman locality* property of first-order logic [38], which is a useful tool in classical as well as finite model theory [25]. In the context of bisimulation invariant properties, locality together with the exponential bound may however also be derived from a straightforward and self-contained analysis based on first-order Ehrenfeucht–Fraïssé games. In fact, the lemma holds for any $\varphi(x)$ that is invariant under disjoint unions, which itself is an easy consequence of bisimulation invariance (see section 2.2). Let $\varphi(x) \in \mathrm{FO}$ have quantifier rank q. Consider a pointed Kripke structure $(\mathfrak{M}, w)$ or, because it may be conceptually easier though not necessary for the argument, without loss of generality a pointed tree structure $(\mathfrak{M}, w)$ with root w. Let $\mathfrak{M}' = \mathfrak{M} \restriction U^n(w)$ be the substructure induced on the n-neighbourhood of w. It suffices to show that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}', w \models \varphi$.

Let $\mathfrak{N}$ be the disjoint union of q copies of $\mathfrak{M}$ and $\mathfrak{M}'$ each. Using invariance under disjoint unions, it suffices to show that $\mathfrak{N} \uplus \mathfrak{M}, w \models \varphi$ iff $\mathfrak{N} \uplus \mathfrak{M}', w \models \varphi$.



It is not hard to exhibit a winning strategy for **II** in the ordinary q-round Ehrenfeucht–Fraïssé game on these structures. **II** merely needs to respect, in round m of the game, the critical distance $d_m = 2^{q-m}$: if **I**'s move in round m goes to within distance d_m of an already pebbled element, **II** plays according to a local isomorphism in the d_m-neighbourhoods of previously pebbled elements; if **I**'s move goes to an element further away from *all* previously pebbled elements, **II** responds in a fresh isomorphic copy of type $\mathfrak{M}$ or $\mathfrak{M}'$, correspondingly.

The exponential bound expressed in the lemma is actually optimal. For a bisimulation invariant property expressible in FO_q but not in ML_n for any $n < 2^q - 1$ consider the property that a state in which p holds is reachable on a path of length less than 2^q. It should be noted that the classical proof of van Benthem's theorem provides no corresponding quantitative information.

COROLLARY 59. *For $\varphi(x) \in \mathrm{FO}$ of quantifier rank q, the following are equivalent for $n = 2^q - 1$:*

(i) *φ is bisimulation invariant.*

(ii) *φ is invariant under n-bisimulation and equivalently expressible in ML_n.*

The exponential bound on the modal nesting depth is sharp: FO *is exponentially more succinct than* ML *for expressing bisimulation invariant properties.*

Some of the underlying ideas of these results are very robust and extend to various ramified settings, some of which are to be discussed in section 5. The classical proof of the characterisation theorem, in particular, carries through for many natural extensions

of basic modal logic associated with refined notions of basic bisimulation equivalence; we mention in particular the corresponding characterisation theorem for the guarded fragment of first-order logic [1] (see Theorem 65 here). But also the game based approach extends to a wide range of settings. One of its main strengths is that it goes through in the setting of finite model theory, as explained below. Another variation that comes naturally from the game based proof is its relativisation to arbitrary bisimulation closed classes [105]. The classical proof, on the other hand, clearly relativises to elementary classes of structures.

COROLLARY 60. *Let $\mathcal{C}$ be a class of Kripke structures that is closed under bisimulation. Then $\varphi(x) \in \mathrm{FO}$ is bisimulation invariant in restriction to $\mathcal{C}$ iff it is equivalent to a formula $\tilde{\varphi} \in \mathrm{ML}$ in restriction to $\mathcal{C}$. Similarly for any elementary class $\mathcal{C}$.*

Theorem 55 characterises the elementary properties of pointed Kripke structures which are definable by single modal formulae. In section 6.4 we will obtain more general preservation results, characterising properties and classes of Kripke structures which are definable by finite or infinite sets of modal formulae, by employing constructions and results from classical model theory.

Ramifications of the characterisation theorem

We sketch a version of the game and locality based proof of van Benthem's characterisation theorem given above, which applies in finite model theory as well as classically. We thus get the finite model theory version due to Rosen [112], even with the same tight exponential bound on succinctness as in Corollary 59.

THEOREM 61. *For $\varphi(x) \in \mathrm{FO}$ of quantifier rank q, the following are equivalent:*

(i) *φ is bisimulation invariant over finite Kripke structures.*

(ii) *φ is equivalent to a formula of ML_n over finite Kripke structures, for $n = 2^q - 1$.*

Proof. We merely need to adapt the proof outlined above in minor ways to avoid passage through infinite structures. For that we may replace bisimilar companion tree structures by the finite, local versions provided by Lemma 36 rather than full unfoldings. For the proof of n-locality of φ (cf. Lemma 58) no modifications are necessary in the game argument, as it applies to arbitrary relational structures exactly as for trees. In fact we only need to use partial tree unfoldings to argue that n-locality and bisimulation invariance together imply n-bisimulation invariance also in restriction to finite structures, as follows.

Let $\varphi(x)$ be bisimulation invariant and n-local over finite structures. Consider finite structures $(\mathfrak{M}, w) \rightleftarrows_n (\mathfrak{M}', w')$. We need to show that $\mathfrak{M}, w \models \varphi$ iff $\mathfrak{M}', w' \models \varphi$. As φ is bisimulation invariant, we may replace $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ by bisimilar finite companion structures whose restrictions to $U^n(w)$ and $U^n(w')$ are trees, by Lemma 36. As φ is n-local, these structures may further be replaced by their restrictions to the n-neighbourhoods of w and w', which are n-bisimilar tree structures of depth n, hence bisimilar. So φ is true in w iff it is true in w'. ❑

Compare section 9 for further discussion of the finite model theory context; for further ramifications concerning modal logics based on refined notions of bisimulation also compare section 5; for relativisations to other non-elementary classes of frames, see in particular [17].

4.3 Guarded fragments of first-order logic

The standard translation (see section 1.3) immediately suggested finite variable fragments as an appropriate framework for the study of modal logic within first-order logic. In some ways, however, the finite variables feature fails to give satisfactory insights into the model theoretic behaviour of modal logics. The comparatively smooth finite model theory (see section 9) of modal logics and most notably also their decidability properties (considering robustness under extensions [135]; see section 5.2) are not reflected by the finite variable fragments or even FO^2 in particular [61, 60].

Guarded fragments of first-order logic were introduced by Andréka, van Benthem and Németi in [1]. Compared to the finite variable fragments, the *guarded fragment* GF of first-order logic is much closer to the qualitative characteristics of modal logics. It has greater explanatory power as a framework for the study of modal logics within first-order. For instance, GF and some of its further extensions mirror the decidability as well as finite and tree model properties of modal logics. Crucially, there is a natural notion of *guarded bisimulation* at the root of some of these features. On the other hand guarded logics considerably extend the expressive power of standard modal logics, and in particular still encompass many of their important extensions. Guarded logics have thus come to play an important role in the quest for more expressive fragments of first-order logic that share many of the model theoretic and algorithmic properties that make modal logics so useful for various applications. GF and its relatives extend the scope of essentially modal model theory, including algorithmic and finite model theory aspects, in the direction of first-order.

The guarded fragment GF of FO generalises the *relativised nature* of modal quantification. Let $\alpha(\mathbf{x},\mathbf{y})$ be an atomic first-order formula in variable tuples as displayed, and consider existential and universal quantification over variables $\mathbf{y}$ where the range of quantification is restricted to those $\mathbf{y}$ that satisfy $\alpha(\mathbf{x},\mathbf{y})$ in relation to $\mathbf{x}$ (α is called the *guard* of the quantification). The following shorthand syntax is useful for this α-relativised quantification:

$$(\exists \mathbf{y}.\alpha)\varphi \;:=\; \exists \mathbf{y}\big(\alpha(\mathbf{x},\mathbf{y}) \wedge \varphi(\mathbf{x},\mathbf{y})\big), \text{ and its dual } (\forall \mathbf{y}.\alpha)\varphi \;:=\; \forall \mathbf{y}\big(\alpha(\mathbf{x},\mathbf{y}) \rightarrow \varphi(\mathbf{x},\mathbf{y})\big).$$

Modal quantification (or its standard translation into first-order) displays just this kind of relativisation, where the guards are the atoms $R_\alpha xy$ for accessibility relations R_α.[10] GF admits relativised quantification of this kind, for any atom α, provided that the variables that occur in α comprise *all* the free variables in the formula φ that is being quantified. The standard translation of modal logics (section 1.3) clearly obeys these restrictions.

DEFINITION 62. For an arbitrary relational vocabulary τ, the formulae of $\mathrm{GF}(\tau) \subset \mathrm{FO}(\tau)$, the guarded fragment, are generated from the atomic formulae by closure under boolean connectives and *guarded quantification*; i.e., if $\varphi(\mathbf{x},\mathbf{y}) \in \mathrm{GF}(\tau)$ and if $\alpha(\mathbf{x},\mathbf{y})$ is a τ-atom (also allowing equality) such that $\mathrm{free}(\varphi) \subseteq \mathrm{var}(\alpha)$, then $\big(\forall \mathbf{y}.\alpha\big)\varphi(\mathbf{x},\mathbf{y})$ and $\big(\exists \mathbf{y}.\alpha\big)\varphi(\mathbf{x},\mathbf{y})$ are also in $\mathrm{GF}(\tau)$.

The atom α in these last formulae is called the *guard* of the (universal or existential) quantification. The *nesting depth* is declared for formulae of GF similar to the first-order

[10] This is good also in the polyadic case, where an n-ary modality α associated with an $(n+1)$-ary relation R_α gives rise to quantification with guard $R_\alpha(x,\mathbf{y})$.

quantifier rank, with the only exception that it increases by just 1 with every guarded quantification (rather than by the number of quantified variables in $\mathbf{y}$). The semantics of GF is just that of first-order logic. It makes sense, however, to look at the crucial restriction with a view to a semantic understanding.

DEFINITION 63. Let $\mathfrak{A}$ be a τ-structure. A subset $s \subseteq A$ is *guarded* if s is a singleton set or if $s = \{a_1, \ldots, a_k\}$ for some tuple $(a_1, \ldots, a_k) \in R^{\mathfrak{A}}$ for some relation $R \in \tau$. A tuple $\mathbf{a}$ over $\mathfrak{A}$ is *guarded* if its components are elements of some common guarded subset.

Guarded quantification essentially is quantification over guarded tuples. Intuitively, only the elements of guarded subsets are simultaneously visible in the guarded perspective; this intuition is borne out in the concept of guarded bisimulation (see Definition 64 below).

Clearly the standard translation embeds ML into GF, and actually into the two-variable fragment of GF, $\mathrm{GF} \cap \mathrm{FO}^2$, which is strictly between ML and FO^2 in expressive power, comprising some but not all the features that separate ML from FO^2 as discussed at the end of section 4.1 above. GF naturally comprises

(i) inverse (or past) modalities, as guardedness is non-directional.

(ii) positive Boolean operations on accessibilities (including equality), as for instance in $[\alpha \cap \beta]\varphi \equiv \big(\forall y.(R_\alpha xy \wedge R_\beta xy)\big)\varphi(y) \equiv (\forall y.R_\alpha xy)(R_\beta xy \rightarrow \varphi(y))$.

(iii) a global modality, or universal/existential quantification over a single free variable, as any singleton set is guarded.

Moreover, it should be noted that GF is genuinely polyadic in the sense of representing no restriction on the arities of definable predicates, whereas even polyadic modal logics are still monadic in that sense. But GF indirectly also has a finite variable nature to it. Note that guarded sets are bounded in size by the width (maximal arity) of the available relation symbols. It is not hard to show that any formula in $\mathrm{GF}(\tau)$, for τ of width k, is equivalent to a boolean combination of atomic formulae and formulae that are in $\mathrm{GF} \cap \mathrm{FO}^k$ (up to a possible renaming of variables).

Guarded bisimulations form the backbone of the model theory of GF, playing the same role for GF that ordinary bisimulations play for modal logics. In essence a guarded bisimulation is a back-and-forth equivalence based on local isomorphisms between guarded subsets.

DEFINITION 64. A *guarded bisimulation* between τ-structures $\mathfrak{A}$ and $\mathfrak{B}$ is a non-empty set Z of local (partial) isomorphisms between $\mathfrak{A}$ and $\mathfrak{B}$ such that

(i) for every $\rho \in Z$, the domain and image of ρ are guarded subsets of $\mathfrak{A}$ and $\mathfrak{B}$, respectively.

(ii) Z satisfies the following back-and-forth conditions w.r.t. guarded subsets:
forth: for every $\rho \in Z$ with domain s and every guarded subset s' of $\mathfrak{A}$, there is some $\rho' \in Z$ with domain s' such that ρ and ρ' agree on $s \cap s'$.
back: analogously, w.r.t. to the inverse maps ρ^{-1} and for guarded subsets of $\mathfrak{B}$.

Guarded bisimulations preserve the semantics of GF just as bisimulations preserve the semantics of ML. Moreover, bounded guarded bisimulations – best defined in terms of the restriction of corresponding guarded bisimulation games to a fixed finite number of rounds – precisely capture the levels of equivalence w.r.t. guarded formulae of corresponding nesting depth. Finally, GF is semantically characterised as a fragment of

FO precisely through guarded bisimulation invariance. This analogue of van Benthem's characterisation of modal logic is due to Andréka, van Benthem and Németi [1].

THEOREM 65. *For any first-order formula* $\varphi \in \mathrm{FO}(\tau)$ *the following are equivalent:*

(i) φ *is invariant under guarded bisimulation.*

(ii) φ *is logically equivalent to a formula* $\tilde{\varphi} \in \mathrm{GF}(\tau)$*.*

It is interesting to note that the full analogue of this characterisation theorem in finite model theory is currently still open. For relational vocabularies of width up to two (essentially coloured directed graphs), the analogue is proved in [106].

Perhaps the most important model theoretic consequence of an analysis of GF w.r.t. guarded bisimulations is a corresponding generalisation of the tree model property. For arbitrary relational structures one obtains guarded bisimilar companion structures through a process of *guarded unravelling* or *unfolding*. These relational structures are close to trees in being *tree-decomposable* by means of guarded subsets. Tree decompositions provide a representation of the underlying relational structure by a tree. This notion from graph and hypergraph theory (see for instance [4]) has been fruitfully employed in relational structures also in applications to relational databases [3]. Tree representations based on guarded subsets work with tree structures whose nodes describe all the guarded substructures of the given structure. Guarded unravellings [56, 58] provide tree decompositions by guarded subsets. As the size of guarded subsets in τ-structures is bounded by the width of τ (the maximal arity of relations in τ), one automatically obtains a bound on the tree width. The resulting *generalised tree model property* from [56] is the following.

THEOREM 66. *Any satisfiable formula* $\varphi \in \mathrm{GF}(\tau)$ *has a model which is tree decomposable in terms of its guarded subsets and consequently of tree width* $m-1$*, where* m *is the width of* τ*.*

Such a generalised tree model property can be of eminent model theoretic importance, especially with a view to algorithmic questions, because properties of tree decomposed models may be determined in terms of their tree representations. Using classical model theoretic tools for trees, and in particular automata theoretic methods, the generalised tree model property has strong consequences for decidability and complexity issues. For instance, GF and some of its extensions beyond first-order logic that are invariant under guarded bisimulation and hence satisfy the generalised tree model property, can be decided for satisfiability via reductions to the monadic second-order theory of trees (Rabin's theorem). A direct reduction to emptiness problems for suitable tree automata moreover typically yields optimal complexity bounds. Even finite models for formulae of GF can be built from infinite tree-like models, using finite saturation arguments based on Herwig's extension theorem for partial isomorphisms [67], thus providing an elegant proof of the finite model property for GF [56].

THEOREM 67. *Any satisfiable formula of* GF *has a finite model:* GF *has the finite model property.*

The *clique guarded fragment* pushes the basic idea of guarded quantification a bit further by relaxing the notion of guarded subsets. A subset s of a relational structure is *clique guarded* if any pair of elements from the set is guarded (the subset forms a clique in the Gaifman graph). In the clique guarded fragment, quantification is restricted to

clique guarded rather than guarded subsets. The resulting logic naturally embeds the first-order translation of the Until operator of temporal logic:

$$(\varphi \,\mathsf{Until}\, \psi)(x) \equiv \exists y\big(x \leq y \wedge \psi(y) \wedge \forall z\big((x \leq z \wedge z < y) \rightarrow \varphi(z)\big)\big),$$

because the relevant x, y, z triples form cliques w.r.t. comparability under $\leq$. The clique guarded fragment is no longer restricted to finite variables as clique guarded subsets can have any size. (The Until operator, which crucially requires three variables, is expressible in terms of clique guarded triples w.r.t. a binary relation.)

Despite the increase in expressiveness, the clique guarded fragment is still decidable for satisfiability [56] and it also satisfies the finite model property [69, 70] (with links between clique guardedness and extension theorems for partial isomorphisms).

5 VARIATIONS, EXTENSIONS, AND COMPARISONS OF MODAL LOGICS

There is a considerable body of work on ramifications of the familiar classical modal logics. At the level of ordinary semantics in (pointed) Kripke structures or transition systems, many variations and extensions have been proposed. These largely aim at preserving some of the key model theoretic features of basic modal logics while adapting or boosting the expressive power – either for the purposes of a systematic investigation or for the modelling of situations that cannot be captured by the standard modal languages. The many application areas of modal logics contribute to interesting ramifications and continue to trigger new developments. We give but a few examples. Variants of basic modal languages for the purposes of description logics, as treated in depth in Chapter 13 of this handbook, naturally use for instance inverse modalities (for inverse roles) or graded modalities (for number constraints). Various constructors for new modalities based on composite accessibility relations (e.g., relational composition or transitive closures) have long been studied in temporal and process logics (see Chapters 11 and 12 among others). More recently similar extensions have been employed in formalisms developed for the navigation and retrieval of information in data formats like XML (see [100]).

While a more comprehensive concept of a generalised modal model theory may lead to further consolidation of the big picture, we can here only attempt to exemplify some simple model theoretic ideas in this direction. For a tentative framework, let us regard the underlying notion of bisimulation invariance as the key feature of a specifically modal model theory (at the level of Kripke semantics). We may then tentatively explore this theme along two axes: *variations* in the sense of variations of the underlying notion of bisimulation; and *extensions* of expressive power subject to the requirement of invariance w.r.t. the given notion of bisimulation.

For two typical examples of these orthogonal directions consider, on the one hand, the addition of past modalities (backward moves in the bisimulation game), and, on the other hand, the extension by path quantification (as for reachability assertions or unbounded iteration of $\Diamond$).

For this largely informal sketch we limit ourselves to just a few logics that play a prominent role in connection with transition systems and the behaviour of processes. Some of these and many others are treated at much greater depth in other chapters of this handbook, in particular Chapters 11, 12 and 17 of this handbook and several others in Parts 3 and 4. As criteria for the model theoretic character of the logics

under consideration, over and above their expressive power, we look in particular at the corresponding bisimulation games and model theoretic characterisation theorems, at the tree model property and the finite model property, and at satisfiability issues, which are particularly relevant in many applications (compare Chapters 3 and 17 of this handbook).

5.1 Variations through refined notions of bisimulation

A refinement of bisimulation equivalence ought to be matched, on the logic side, by a more expressive logic. We thus encounter extensions of basic modal logic to more expressive fragments of first-order logic, like those considered in sections 4.1 and 4.3.

In terms of the bisimulation game (or the back-and-forth conditions) over Kripke structures with binary accessibility relations one can introduce a variety of additional moves, in order to capture the expressiveness of some natural extensions of basic modal logic, for instance:

- unconstrained moves to arbitrary states (global bisimulation). This corresponds to the addition of a universal modality (or $\forall/\exists$ quantification) to basic ML, which also allows for an explicit transition between global and local semantics (see, e.g., [54, 22]).
- backward moves along edges (two-way bisimulation). This corresponds to the addition of past or inverse modalities to basic ML.
- counting moves, in which the number of available responses is controlled (counting or locally bijective bisimulation). This corresponds to the extension of basic ML by graded or counting modalities (see [21]).

(Also compare [88] for bisimulations for a hierarchy of description logic languages).

In terms of further reaching variations that also involve the format of the underlying structures and game positions, we discussed in section 4.3 guarded bisimulations for arbitrary relational structures – corresponding to guarded rather than ordinary modal quantification and guarded fragments of first-order logic as important intermediaries between modal and first-order logics.

As indicated, these variations typically correspond to natural extensions of ML. These correspondences manifest themselves in terms of

(i) Ehrenfeucht–Fraïssé relationships: equivalence in the extended logic is characterised by the existence of winning strategies for player **II** in the corresponding, refined bisimulation games.

(ii) characterisation theorems in the style of Theorems 55 or 65 that characterise the respective logic as a fragment of first-order logic, in terms of invariance under the refined notion of bisimulation.

For instance, the *global bisimulation game* gives player **I** the option to switch, for an individual round, to moves in which both players are allowed to move the pebbles to any element of the respective structure rather than just along accessibility edges. This is the Ehrenfeucht–Fraïssé game for the extension ML[$\forall$] of basic ML, in which a global modality is available (corresponding to unrestricted universal first-order quantification in the standard translations). Then **II** has a winning strategy for the n-round game on $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ iff $(\mathfrak{M}, w)$ and $(\mathfrak{M}', w')$ satisfy exactly the same formulae in ML[$\forall$] of

quantifier rank up to n. Also the classical proof pattern for the characterisation theorem (compare the classical proof argument for Lemma 56) goes through. This uses compactness and ω-saturated or modally saturated extensions and the analogue of Remark 40, which is good also for this refined bisimulation game. So we have obtained the following.

PROPOSITION 68. *A first-order formula $\varphi(x)$ is invariant under* global bisimulation *iff it is equivalent to a formula of* ML[∀].

This proposition may serve as a representative for a whole family of similar characterisation results for many other variants of basic modal logic. In fact, these game techniques are not at all even restricted to the modal setting. Analogous Ehrenfeucht–Fraïssé and characterisation theorems hold for instance also for the finite variable fragments FO^k in relation to k-pebble game equivalence. Interestingly, as far as the characterisation theorems are concerned, the picture becomes more varied when we shift attention to the finite model theory versions (cf. section 9, in particular Theorem 130).

5.2 *Extensions beyond first-order*

Extensions induced by variations of the underlying notion of bisimulation in the first instance all lead to modal logics of (pointed) Kripke structures that are still fragments of first-order logic. There is the orthogonal direction of extension that adds expressiveness through stronger constructors in the logic while still adhering to invariance under the given notion of bisimulation. These extensions address some of the expressive deficiencies inherent in first-order, in particular its restriction to essentially local properties (in the sense of Gaifman's locality theorem). Major process logics, aimed at formalising dynamic properties of processes in terms of Kripke structures as transition systems, need to express fundamental properties – like reachability or well-foundedness – that are non-local and hence not expressible in FO.

The process logics discussed below specifically aim for the formalisation of properties of programs or processes, based on the modelling of states and state transitions in Kripke structures as *transition systems*: atomic propositions model atomic *state properties*, and accessibility relations between states model atomic state transformers or *atomic programs*. This setting calls for logics of a fundamentally modal nature – especially since the intended processes are captured by transition systems only up to bisimulation equivalence. Bisimilar transition systems describe exactly the same processes in the sense that there is a complete correspondence of possible runs at the level of individual transitions and in terms of mutual step-wise simulation (*bi-simulation*).

We fix a finite similarity type with modalities α corresponding to binary predicates R_α (transition relations for atomic programs α) and a set of atomic propositions p corresponding to unary predicates P interpreted as the set of states satisfying p. The framework of basic modal logic ML provides modalities for the atomic programs α for assertions about the possible results of single-step state transformations. Various additional constructors have been proposed for the formalisation of dynamic, non-local properties, involving for instance unbounded iterations of transitions. We illustrate the examples of PDL, CTL^* and L_μ. For one simple concrete example of a dynamic, non-local property, we consider the following (at a state):

(χ) in any possible future state of the system, there will be a reachable state in that state's future where p holds.

Propositional dynamic logic

Propositional dynamic logic PDL [29] is based on a dual perspective involving both states and transitions as primary objects of its semantics. Correspondingly, PDL distinguishes two kinds of formulae, *state formulae* and *program formulae*. State formulae, like the familiar modal formulae are evaluated at the states of a transition system and thus define unary predicates on the universe; program formulae on the other hand are evaluated on pairs of states and define binary predicates on the state space, i.e., derived transition relations. Here we work with the following definition; for more on PDL see Chapter 12 of this handbook. We use $\varphi, \psi, \ldots$ for state formulae, $\eta, \zeta, \ldots$ for program formulae.

DEFINITION 69. State and program formulae of PDL are generated by mutual induction.
State formulae: the Boolean closure of atomic propositions p, and modal quantification of the form $\langle\eta\rangle\varphi$ and $[\eta]\varphi$ for program formulae η and state formulae φ.
Program formulae: the closure of the atomic program formulae α and of all formulae $\varphi?$ ("test" operator on state formulae φ) under union $(\eta \cup \zeta)$, composition $(\eta;\zeta)$ and star or iteration, (η^*).

The semantics of state formulae is the natural one based on the semantics of the corresponding program formulae that define modalities η in terms of new transition relations R_η. For those, the specific constructors are defined in relational terms: atomic program formulae α refer to the given transition relations R_α; the union operator is set union: $R_{\eta\cup\zeta} = R_\eta \cup R_\zeta$; composition is relational composition: $R_{\eta;\zeta} = R_\eta \circ R_\zeta = \{(u,w) \mid (u,v) \in R_\eta, (v,w) \in R_\zeta \text{ for some } v\}$; the star operation corresponds to the reflexive transitive closure: $R_{\eta^*} = \bigcup_{n\geq 0}(R_\eta)^n$; finally, the test operator defines a loop relation according to $R_{\varphi?} = \{(u,u) \mid \mathfrak{M}, u \models \varphi\}$.

The PDL state formula $\langle\eta^*\rangle\varphi$, for instance, expresses reachability on an η-path of a state that satisfies φ. Note that this is not expressible in FO, even for atomic η and φ. (χ) of the example above is expressible in PDL using $\eta := \bigcup_{\alpha\in\tau}\alpha$, as $\chi = [\eta^*]\langle\eta^*\rangle p$.

We turn to bisimulation invariance. While the standard notion refers to state formulae, the constructors for PDL program formulae also respect bisimulation equivalence, in the sense of bisimulation safety (see section 3.8).

LEMMA 70. *For Kripke structures* $\mathfrak{M}$, *let* $\mathfrak{M}^*$ *denote the expansion with all the accessibility relations defined by* PDL *program formulae. Then any bisimulation* $\rho\colon \mathfrak{M} \rightleftarrows \mathfrak{M}'$ *is also a bisimulation between these expansions,* $\rho\colon\ \mathfrak{M}^* \rightleftarrows \mathfrak{M}'^*$.

Bisimulation invariance for state formulae is then straightforward. In fact it falls out of the inductive proof of the claim of the lemma, which is best understood in terms of the underlying games. Consider the operations of union, composition and star on accessibility operations. For moves along $R_{\eta\cup\zeta} = R_\eta \cup R_\zeta$, the responses of **II** merely need no longer respect η/ζ individually; moves along $R_{\eta;\zeta}$ can be responded to as if they came as individual moves in two consecutive rounds; similarly, a move along an R_{η^*}-edge corresponds to a finite sequence of moves along R_η-edges, which is similarly covered by **II**'s strategy. If, for some state formula φ, $(u,u') \in \rho$ implies that $\mathfrak{M}, u \models \varphi$ iff $\mathfrak{M}', u' \models \varphi$, then it follows that play according to ρ guarantees that (stationary) $R_{\varphi?}$-moves are available in $\mathfrak{M}$ iff they are available in $\mathfrak{M}'$.

COROLLARY 71. *Any state formula of* PDL *is invariant under bisimulation.*

Computation tree logic

For computation tree logic CTL*, the emphasis is on branching time temporal behaviour rather than process algebra. It is customary to study CTL* over transition systems with a single binary transition relation R (corresponding to a single unary modality $\Diamond$) which moreover is required to have no terminal nodes, i.e., we assume $\mathfrak{M} \models \Diamond\top$.

The intuitive idea in CTL* is to associate the runs from a state u of a transitions system $\mathfrak{M}$ with the tree structure $\vec{\mathfrak{M}}[u]$ (the unfolding or tree unravelling, as defined in section 2.2). The infinite branches of the tree $\vec{\mathfrak{M}}[u]$ are the *computation paths* of $\mathfrak{M}$ at u. Besides state formulae, which define properties of states as usual, CTL* has *path formulae* that define properties of such computation paths. Here a *path* at u is an infinite R-path rooted at u in the usual graph theoretic sense; we write $\sigma = u_0, u_1, \dots$ for a path at $u = u_0$.

DEFINITION 72. State and path formulae of CTL* are generated by mutual induction.
State formulae: Boolean closure of atomic propositions p and formulae $\mathsf{E}\gamma$ and $\mathsf{A}\gamma$ for path formulae γ (existential and universal path quantification).
Path formulae: Boolean closure of all state formulae φ and formulae $\mathsf{Next}\,\gamma$ (temporal "next" operator) and $\gamma\,\mathsf{Until}\,\delta$ (temporal until operator) for path formulae γ, δ.

The semantics of atomic propositions (as state formulae) and of the Boolean connectives is the natural one. We just highlight the specific constructors for state and path formulae. The semantics of a state formula φ is given in terms of a state $u \in \mathfrak{M}$, the semantics of path formulae γ, δ in terms of a path $\sigma = u_0, u_1, \dots$ in $\mathfrak{M}$, whose suffixes we denote as in $\sigma^j = u_j, u_{j+1}, \dots$:

$\mathfrak{M}, u \models \mathsf{E}\gamma$ iff there is a path σ at u such that $\mathfrak{M}, \sigma \models \gamma$, similarly for the dual A.

$\mathfrak{M}, \sigma \models \varphi$ iff $\mathfrak{M}, u_0 \models \varphi$.

$\mathfrak{M}, \sigma \models \mathsf{Next}\,\gamma$ iff $\mathfrak{M}, \sigma^1 \models \varphi$.

$\mathfrak{M}, \sigma \models \gamma\,\mathsf{Until}\,\delta$ iff for some $j \geq 0$: $\mathfrak{M}, \sigma^j \models \delta$ and for $0 \leq i < j$, $\mathfrak{M}, \sigma^i \models \gamma$.

Reachability of a state satisfying φ, for instance, becomes expressible as $\mathsf{E}(\top\,\mathsf{Until}\,\varphi)$. The formula $\top\,\mathsf{Until}\,\varphi$ is also abbreviated $\mathsf{F}\,\varphi$, "eventually φ". Using this abbreviation, our sample property (χ) is expressible as $\chi = \neg\,\mathsf{EF}\,\neg\,\mathsf{EF}\,p$.

PROPOSITION 73. *Any state formula of* CTL* *is invariant under bisimulation.*

This is a straightforward consequence of the fact that any bisimulation $\rho\colon \mathfrak{M} \rightleftarrows \mathfrak{M}'$ preserves paths in the sense that for $(u, u') \in \rho$, every path $\sigma = u_0, u_1, \dots$ at $u_0 = u$ in $\mathfrak{M}$ has a bisimilar companion path $\sigma' = u'_0, u'_1, \dots$ at $u'_0 = u'$ in $\mathfrak{M}'$, which is bisimilar in the sense that $(u_i, u'_i) \in \rho$ for all i.

Interestingly, CTL* admits a characterisation as the bisimulation invariant fragment of monadic path logic, that fragment of monadic second-order logic (over trees) in which second-order quantifiers range over paths. In the light of Theorem 76 below, this characterisation also clarifies the relationship between CTL* and the much more expressive modal μ-calculus. The following is due to [101] over arbitrary tree models and to [65] over the binary tree.

THEOREM 74. *State formulae of* CTL* *precisely define those state properties that are bisimulation invariant and definable in monadic path logic.*

Modal μ-calculus

The modal μ-calculus L_μ is a particularly natural and powerful extension of basic modal logic, which encompasses both PDL and CTL*. In many ways it may be regarded as *the* extension of modal logic for the purposes of temporal reasoning about processes and corresponding model checking applications. Its theory is well developed, ranging from more classical model theoretic issues to computational and in particular automata theoretic analysis; see Chapter 12 of this handbook for a thorough treatment. Here, we only very selectively comment on some aspects of L_μ and essentially restrict ourselves to its role as an extension of ML in our bisimulation-oriented perspective on modal model theory.

L_μ is the canonical fixed point extension of basic modal logic. Least (and dually, greatest) fixed points of monotone operators capture natural forms of recursion closely related to inductive (and dually, co-inductive) definitions. In L_μ basic modal logic is augmented by the means to define, as fixed points, the results of recursions based on definable monotone operators.

Consider basic modal logic with free monadic-second order variables $X, Y, \ldots$ (treated like monadic predicate letters or variables for propositions). A formula $\psi = \psi(X)$ is *positive* in X if X only appears within the scope of an even number of negations in ψ. Positivity in X ensures that, for each structure $\mathfrak{M}$ that interprets all the remaining variables, the following operation on the power set $\mathcal{P}(W)$ of the universe W of $\mathfrak{M}$ is monotone (in the sense that $X \subseteq X'$ implies $\psi[X] \subseteq \psi[X']$):

$$\begin{array}{rcl} \psi^{\mathfrak{M}} \colon \mathcal{P}(W) & \longrightarrow & \mathcal{P}(W) \\ X & \longmapsto & \psi^{\mathfrak{M}}[X] := \{w \in W \mid \mathfrak{M}, X, w \models \psi\}. \end{array}$$

This operation therefore has unique $\subseteq$-minimal and -maximal fixed points, the least and greatest fixed points of $\psi(X)$, respectively.

DEFINITION 75. The syntax of L_μ is based on basic modal logic ML with free monadic second-order variables, plus closure under the least and greatest fixed point constructors: if $\psi \in \mathrm{L}_\mu$ is positive in X, then $\mu X.\psi$ and $\nu X.\psi$ are also formulae of L_μ (in which X is bound).

The semantics of formulae $\varphi \in \mathrm{L}_\mu$ is inductively defined in terms of Kripke structures $\mathfrak{M}$ with interpretations for the free second-order variables; $\mathfrak{M}, u \models \mu X.\psi$ (respectively $\nu X.\psi$) if u is in the least (respectively greatest) fixed point of the operator associated with ψ over $\mathfrak{M}$.

The least fixed point $\mu X.\psi(X)$ in $\mathfrak{M}$ is also definable as the limit of stages X^α generated by induction over the ordinal α, where $X^0 = \emptyset$, $X^{\alpha+1} = \psi^{\mathfrak{M}}[X^\alpha]$ for successor steps, and $X^\lambda = \bigcup_{\alpha<\lambda} X^\alpha$ for limits λ. By monotonicity, the sequence of the X^α is increasing. Over each $\mathfrak{M}$ it eventually must become constant for cardinality reasons. Then the least fixed point of $\psi^{\mathfrak{M}}$ is $X^\infty = \bigcup_\alpha X^\alpha = X^\gamma$ for the minimal γ such that $X^{\gamma+1} = X^\gamma$. (This γ is the closure ordinal of the fixed point over $\mathfrak{M}$.)

The L_μ formula $\mu X.\psi(X)$ for $\psi(X) = \varphi \vee \Diamond X$, for instance, expresses reachability of a state satisfying φ. The monotone operator $\psi^{\mathfrak{M}}$ maps $X \subseteq W$ to the union of $\varphi^{\mathfrak{M}}$ with $\Diamond(X)$. Stage X^n consists of those states from which a state satisfying φ is reachable on an R-path of length less than n. The least fixed point is reached within ω stages over any $\mathfrak{M}$, with $X^\infty = X^\omega$ being the set of states satisfying $\langle R^*\rangle\varphi$. Similarly, well-foundedness

of the converse of R, i.e., non-existence of infinite R-paths from a state, is captured by the least fixed point of the operator defined by the formula $\psi(X) = \Box X$.

Our sample property (χ) is expressible as $\chi = \nu Y.\big(\Box Y \wedge \mu X.(p \vee \Diamond X)\big)$.

Least and greatest fixed points as provided in L_μ admit straightforward explicit definitions in monadic second-order logic MSO, and L_μ may be regarded as a fragment of MSO via a corresponding translation. The following theorem of Janin and Walukiewicz [77] characterises L_μ as the bisimulation invariant fragment of MSO. This is entirely similar in spirit to Theorem 55 for basic modal logic at the first-order level. Covering a far more expressive setting, its proof is also entirely different and based on a sophisticated use of tree automata that recognise corresponding classes of tree models.

THEOREM 76 (Janin–Walukiewicz). *For any* MSO *formula* $\varphi = \varphi(x)$ *the following are equivalent:*

(i) *φ is bisimulation invariant.*

(ii) *φ is logically equivalent to a formula of* L_μ.

We note that, in a similar modal spirit, fixed point extensions have been explored under variations of the underlying notion of bisimulation. In particular, the so-called full μ-calculus with inverse modalities, as related to two-way bisimulation, is studied in [136]; guarded fixed point logic μGF, [62], is the natural extension of the guarded fragment GF by fixed points. For the latter, an analogue of the above characterisation theorem has also been obtained, with a stronger fragment of second-order logic, guarded second-order logic, in place of MSO, [58].

Infinitary modal logics

We encountered ML_∞, the extension of basic modal logic ML by conjunctions and disjunctions over arbitrary *sets* of formulae, in section 3.4. Theorem 41 characterises bisimulation equivalence as equivalence in ML_∞. The restriction to set-size (rather than class-size) disjunctions (or unions) is crucial. Remarkably, L_μ (and CTL*) cannot be embedded into ML_∞: the well-foundedness property expressed by $\mu X.\Box X \in \mathrm{L}_\mu$, for instance, is not globally definable in ML_∞ (see Observation 42). In fact, L_μ (or CTL*) and ML_∞ are incomparable in expressive power.

On the other hand, the individual stages in the generation of any modal least or greatest fixed point are globally definable in ML_∞. In the example of $\mu X.\Box X$, the stages X^α are definable by formulae $\varphi_\alpha \in \mathrm{ML}_\infty$ according to $\varphi_0 = \bot$, $\varphi_{\alpha+1} = \Box\varphi_\alpha$ and $\varphi_\lambda = \bigvee_{\alpha<\lambda} \varphi_\alpha$. The reason that the fixed point X^∞ is not ML_∞ definable is that there is no bound on the closure ordinal of this induction. For many natural (restricted) settings, however, ML_∞ is a maximal bisimulation-invariant logic. For the following compare the remark on characteristic formulae below Theorem 41.

OBSERVATION 77. Over any class of structures that intersects only set-many bisimulation equivalence classes, every bisimulation closed state property is definable in ML_∞.

Several extended logics, including PDL as an important fragment of L_μ, also admit direct translations into ML_∞, though. For PDL this is a consequence of the fact that the closure ordinal of the fixed points needed to capture PDL constructs is uniformly bounded by ω. In fact, PDL therefore embeds into that fragment of ML_∞ in which disjunctions and conjunctions over countable, rather than arbitrary, sets of formulae are

admitted, $\mathrm{ML}_{\omega_1} \subset \mathrm{ML}_\infty$. The PDL reachability assertion $\langle \alpha^* \rangle \varphi$, for instance, globally translates into $\bigvee_{n\in\omega} \langle \alpha \rangle^n \varphi$, where $\langle \alpha \rangle^n$ is the n-fold iteration of the diamond operator.

ML_{ω_1} may be studied as a fragment of the corresponding infinitary extension of first-order logic, $L_{\omega_1\omega}$, which itself has a well developed classical model theory [83]. Similar to $L_{\omega_1\omega}$, ML_{ω_1} also admits a complete proof system (including infinitary rules) and even satisfies (Craig and Lyndon type) interpolation theorems. Characterisation, completeness, and preservation theorems for ML_{ω_1} and some of its fragments have been obtained along such lines by Radev [110] and Sturm [119, 120].

5.3 Model theoretic criteria

We briefly discuss three particularly relevant model theoretic properties in the light of some of the variations and extensions mentioned above. These may serve as examples that among others could contribute to a framework for a more comprehensive comparative model theory of modal logics.

Finite model property (FMP). As noted in section 3.3, the basic modal logic itself has the finite model property, as do many of its variations and extensions. The variations of ML discussed in section 5.1 above, by inverse and global modalities, as well as the guarded fragment GF, have the FMP. For the extensions beyond FO the finite model property for L_μ, due to Streett and Emerson [118], implies FMP for all of its sub-logics, like CTL* and PDL.[11] The *full μ-calculus*, L_μ with inverse modalities, on the other hand lacks the FMP [136]. The following counterexample illustrates this. The formula $\nu X.(\langle R \rangle X \wedge \mu Y. \left[R^{-1}\right] Y)$ requires an infinite (forward) R-path along which every node is well-founded w.r.t. R (does not admit an infinite backward R-path). This implies that the infinite path cannot fold back onto itself; the formula therefore only admits infinite models.

Tree model property. Recall that a logic has the tree model property if every satisfiable formula is satisfied in a tree model. Basic modal logic has the (finite) tree model property (cf. Lemma 35). In fact any bisimulation invariant logic has the tree model property, based on the existence of bisimilar tree unfoldings (cf. section 2.2). In this sense the tree model property, more than the finite model property, is a hallmark of modal model theory. Moreover, many important variations, even though no longer invariant under ordinary bisimulations, still retain (variant) tree model properties. This phenomenon carries particularly far in the case of GF (see Theorem 66, which also generalises to any guarded bisimulation invariant logic).

Decidability. Decidability and complexity of the satisfiability problem provides one measure for the comparison of the variations and extensions discussed above. Basic modal logic may be seen to be decidable for a number of distinct reasons, as it were. Firstly, as FO is recursively enumerable for validity, ML is decidable as a fragment of FO that is recursively enumerable for satisfiability due to its finite model property. More specifically, however, the finite (tree) model property for basic modal logic (cf. Lemma 35) may be strengthened by effective bounds on depth and branching degree of the candidate tree models – indeed, a Pspace (or alternating Ptime) procedure for satisfiability can be

[11] The finite model property of many variations and extensions of modal logic, such as PDL and CTL, can be obtained by filtration, see [46]. However, this method does not work for some of the more complex systems such as CTL* and L_μ, where tableau-like and automata-based methods are applied instead.

extracted (cf. Chapter 3 of this handbook). Alternatively, decidability of ML may be attributed to just its tree model property and the fact that its tree models are recognised by tree automata, for which emptiness is decidable (cf. Chapters 3 and 17). In view of the extensions that go beyond FO this second line of reasoning carries much further. Extensions that are 'modal' in the sense of being bisimulation invariant share the tree model property. Allowing for the appropriate variations of bisimulation, this approach covers not only L_μ, but even the full μ-calculus [136] or the fixed point extension of the guarded fragment [62], which fail to have the FMP. See [57, 135] in this connection for a discussion of the robustness of decidability of modal logics, with a focus on tree models and the accompanying automata theoretic techniques; also see Chapter 17 of this handbook. A comparison between FO^2 and ML in relation to their extensions by natural constructs (e.g., counting, path quantification, transitive closures, fixed points) has also highlighted the special status of modal logic in regard to decidability of such extensions: even comparatively weak extensions of FO^2 along these lines are highly undecidable [61].

6 FURTHER MODEL-THEORETIC CONSTRUCTIONS

One of the traditional directions of development for model theory of a given logic is to identify a sufficiently rich collection of constructions on models, preserving truth in the logic, so that the fundamental concepts of logical definability and logical equivalence can be characterised in terms of these constructions.

In section 2 we introduced the basic model-theoretic notions of generated substructures, bounded morphisms and disjoint unions of Kripke structures and frames, and established corresponding preservation results. These constructions, however, are not sufficient for a complete description of the modal definability of properties or modal equivalence of structures. In this section we introduce and study two more advanced constructions: *ultrafilter extensions* and *ultraproducts*. The former, stemming from the Jónsson–Tarski representation theorem for Boolean algebras with operators in [78], was introduced in modal logic by Goldblatt [43, 44] and used for model-theoretic characterisations of modal definability in [51, 126, 28]. See also section 8. The latter comes from first-order logic, as the most characteristic construction preserving first-order validity (see [12]). Since modal logic on Kripke structures is a fragment of first-order logic, it is a natural truth-preserving construction here, too, and features in the model-theoretic characterisations of modal definability in Kripke structures in section 6.4. Later in this section we indicate how ultrafilter extensions and ultraproducts are linked with each other, and how they relate modal equivalence between Kripke structures with bisimulations, through the notion of saturation.

6.1 Ultrafilter extensions

Let $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ be a τ-frame and let $\mathbf{U}(W)$ be the set of all ultrafilters over W. For every $w \in W$, $\mathsf{u}[w] = \{X \subseteq W \mid w \in X\}$ is the principal ultrafilter generated by w. Further, for every $X \subseteq W$ we define $\mathsf{u}(X) := \{\mathsf{u} \in \mathbf{U}(W) \mid X \in \mathsf{u}\}$.

For each $\alpha \in \tau$ we define a binary relation $R^{\mathfrak{ue}}_\alpha$ on $\mathbf{U}(W)$ as follows. For $\mathsf{u}, \mathsf{w} \in \mathbf{U}(W)$:

$$\mathsf{u} R^{\mathfrak{ue}}_\alpha \mathsf{w} \text{ iff } \langle R_\alpha\rangle (X) \in \mathsf{u} \text{ for every } X \in \mathsf{w}.$$

In particular, note that for every $\alpha \in \tau$, and $x, y \in W$, $xR_\alpha y$ iff $\mathsf{u}[x]R^{\mathfrak{ue}}_\alpha\mathsf{u}[y]$.

DEFINITION 78. Given a τ-frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$:

(i) The *ultrafilter extension of* $\mathfrak{F}$ is the τ-frame $\mathfrak{ue}(\mathfrak{F}) := \langle \mathbf{U}(W), \{R_\alpha^{\mathfrak{ue}}\}_{\alpha\in\tau}\rangle$.

(ii) For every Kripke τ-structure $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$, the *ultrafilter extension of* $\mathfrak{M}$ is the Kripke τ-structure $\mathfrak{ue}(\mathfrak{M}) := \langle \mathfrak{ue}(\mathfrak{F}), V^{\mathfrak{ue}}\rangle$ where $V^{\mathfrak{ue}}(p) = \mathsf{u}(V(p))$ for each $p \in \Phi$.

Thus, the subframe of $\mathfrak{ue}(\mathfrak{F})$ consisting of the principal ultrafilters on $\mathfrak{F}$ is isomorphic to $\mathfrak{F}$ but in general, it is *not* a generated subframe of $\mathfrak{ue}(\mathfrak{F})$ (see [5, Example 2.58]). However, every finite frame is isomorphic to its ultrafilter extension. For a proof, see e.g. [5, Proposition 2.59].

Here are two concrete examples of ultrafilter extensions from [129]; also compare [129] for a detailed study of ultrafilter extensions and their use in characterising modal definability in some special classes of frames.

- $\mathfrak{ue}(\langle \mathbb{Z}, <\rangle)$, where $\langle \mathbb{Z}, <\rangle$ is the linearly ordered set of integers, comprises an isomorphic copy of $\langle \mathbb{Z}, <\rangle$ represented by the principal ultrafilters, and two infinite clusters of free ultrafilters, one consisting of elements less than all 'standard' integers, and the other of elements greater than all 'standard' integers. All ultrafilters in each cluster are $<^{\mathfrak{ue}}$-related.

- $\mathfrak{ue}(\langle \mathbb{Q}, <\rangle)$, where $\langle \mathbb{Q}, <\rangle$ is the linearly ordered set of rationals, looks similar. It consists of a copy of the rationals, with infinite clusters on each end, but, since every real number can be approximated from either side by a sequence of rationals, it also has for every *real* number a pair of 'infinitesimally' close clusters, one on either side.

LEMMA 79. *For every Kripke τ-structure $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$ and any formula φ of* ML(τ)*: $V^{\mathfrak{ue}}(\varphi) = \mathsf{u}(V(\varphi))$, i.e., $\mathfrak{ue}(\mathfrak{M}), \mathsf{u} \models \varphi$ iff $V(\varphi) \in \mathsf{u}$.*

This lemma shows that the notion of ultrafilter extension is *canonical*: a state, being an ultrafilter, contains precisely the valuations of those formulae which are true at that state.

COROLLARY 80. *For every Kripke τ-structure $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$, $w \in \mathrm{dom}(\mathfrak{F})$, and any formula φ of* ML(τ)*:*

(i) $\mathfrak{M}, w \models \varphi$ *iff* $\mathfrak{ue}(\mathfrak{M}), \mathsf{u}[w] \models \varphi$.

(ii) *If* $\mathfrak{ue}(\mathfrak{M}) \models \varphi$, *then* $\mathfrak{M} \models \varphi$.

(iii) *If* $\mathfrak{ue}(\mathfrak{F}), \mathsf{u}[w] \models \varphi$, *then* $\mathfrak{F}, w \models \varphi$.

(iv) *If* $\mathfrak{ue}(\mathfrak{F}) \models \varphi$, *then* $\mathfrak{F} \models \varphi$.

We say that a class of τ-frames $\mathcal{C}$ *reflects ultrafilter extensions* if a τ-frame $\mathfrak{F}$ belongs to $\mathcal{C}$ whenever $\mathfrak{ue}(\mathfrak{F}) \in \mathcal{C}$. Thus, FR($\Gamma$) reflects ultrafilter extensions for every set of modal formulae Γ.

That the converses of the latter 3 claims above do not hold can be seen from the following example. The modal formulae preserved in ultrafilter extensions will be characterised in Proposition 114.

EXAMPLE 81. By Proposition 114, the Gödel–Löb formula: $\Box(\Box p \to p) \to \Box p$ is not preserved in ultrafilter extensions because it is not canonical (see [75]).

Non-reflection of ultrafilter extensions can be used to prove modal non-definability in frames in cases where the other truth preserving constructions introduced earlier may not

work. Going back to the example at the end of section 2.3: the sentence $\delta = \forall x \exists y (xRy \wedge yRy)$ is not captured by frame validity of any ML formula, despite being preserved under generated subframes, surjective bounded morphisms and disjoint unions, because it does not reflect ultrafilter extensions. Indeed, $\langle \mathbb{N}, < \rangle \not\models_{\mathrm{FO}} \delta$ while $\mathfrak{ue}(\langle \mathbb{N}, < \rangle) \models_{\mathrm{FO}} \delta$ because every free ultrafilter is a maximal element with respect to the quasi-order $<^{\mathfrak{ue}}$ (see [128] or [5, Example 2.58] for details).

6.2 Ultraproducts

The constructions of direct products and ultraproducts of first-order structures can be applied to frames, considered as $\mathrm{FO}(\tau)$-structures, and to Kripke structures, considered as $\mathrm{FO}(\tau_\Phi)$-structures.

DEFINITION 82. Let $\{W^i\}_{i\in I}$ be a family of sets indexed by a set I.

(i) The *direct product of* $\{W^i\}_{i\in I}$ is the set $\prod_{i\in I} W^i = \{g : I \to \bigcup_{i\in I} W^i \mid g(i) \in W^i \text{ for all } i \in I\}$.

(ii) For any ultrafilter $\mathbf{U}$ on I, the *ultraproduct of* $\{W^i\}_{i\in I}$ *over* $\mathbf{U}$, $\prod^{\mathbf{U}}_{i\in I} W^i$, is the quotient of $\prod_{i\in I} W^i$ w.r.t. the equivalence relation $\sim_{\mathbf{U}}$ defined by $g \sim_{\mathbf{U}} g'$ iff $\{i \in I \mid g(i) = g'(i)\} \in \mathbf{U}$. We write $g^{\mathbf{U}}$ for the $\sim_{\mathbf{U}}$ equivalence class of g.

(iii) For any family $\{X^i \subseteq W^i\}_{i\in I}$, $\prod^{\mathbf{U}}_{i\in I} X^i = \{g^{\mathbf{U}} \in \prod^{\mathbf{U}}_{i\in I} W^i \mid \{i \in I \mid g(i) \in X^i\} \in \mathbf{U}\}$.

DEFINITION 83. Let $\{\mathfrak{F}^i = \langle W^i, \{R^i_\alpha\}_{\alpha\in\tau}\rangle\}_{i\in I}$ be a family of τ-frames indexed by a set I, and $\{\mathfrak{M}^i = \langle \mathfrak{F}^i, V^i\rangle\}_{i\in I}$ be a family of Kripke τ-structures over these frames.

(i) The *direct product of* $\{\mathfrak{F}^i\}_{i\in I}$ is the τ-frame $\prod_{i\in I} \mathfrak{F}^i := \langle \prod_{i\in I} W^i, \{R_\alpha\}_{\alpha\in\tau}\rangle$, where for $\alpha \in \tau$: $g_0 R_\alpha g_1$ iff $g_0(i) R^i_\alpha g_1(i)$ for every $i \in I$.

(ii) The *direct product of* $\{\mathfrak{M}^i\}_{i\in I}$ is the Kripke τ-structure $\prod_{i\in I} \mathfrak{M}^i := \langle \prod_{i\in I} \mathfrak{F}^i, V\rangle$, where $V(p) := \prod_{i\in I} V^i(p)$ for each $p \in \Phi$.

If, further, $\mathbf{U}$ is an ultrafilter on I:

(iii) The *ultraproduct of* $\{\mathfrak{F}^i\}_{i\in I}$ *over* $\mathbf{U}$ is the τ-frame $\prod^{\mathbf{U}}_{i\in I} \mathfrak{F}^i := \langle \prod^{\mathbf{U}}_{i\in I} W^i, \{R^{\mathbf{U}}_\alpha\}_{\alpha\in\tau}\rangle$, where for $\alpha \in \tau$: $g_0^{\mathbf{U}} R^{\mathbf{U}}_\alpha g_1^{\mathbf{U}}$ iff $\{i \in I \mid g_0(i) R^i_\alpha g_1(i)\} \in \mathbf{U}$.

(iv) The *ultraproduct of* $\{\mathfrak{M}^i\}_{i\in I}$ *over* $\mathbf{U}$ is the Kripke τ-structure $\prod^{\mathbf{U}}_{i\in I} \mathfrak{M}^i := \langle \prod^{\mathbf{U}}_{i\in I} \mathfrak{F}^i, V^{\mathbf{U}}\rangle$ such that for each $p \in \Phi$, $V^{\mathbf{U}}(p) := \prod^{\mathbf{U}}_{i\in I} V^i(p)$.

If $\mathfrak{F}^i = \mathfrak{F}$ for every $i \in I$, the ultraproduct is called an *ultrapower of* $\mathfrak{F}$, denoted $\prod^{\mathbf{U}}_I \mathfrak{F}$; similarly for Kripke structures, where the ultrapower is denoted $\prod^{\mathbf{U}}_I \mathfrak{M}$.

By the fundamental theorem of Łoś (see, e.g., [12, 68]), every first-order definable property holds in an ultraproduct iff it holds in a 'large' (i.e., in the ultrafilter) set of component structures. Moreover, every Σ^1_1-definable property is preserved by ultraproducts [12, Corollary 4.1.14]. Therefore, validity of modal formulae in (pointed) frames, being a Π^1_1-definable property in terms of the standard translation, is reflected (i.e., its negation is preserved) by ultraproducts. Using these, we obtain the following preservation results.

PROPOSITION 84. *For every family of Kripke τ-structures $\{\mathfrak{M}^i = \langle \mathfrak{F}^i, V^i\rangle\}_{i\in I}$, ultrafilter $\mathbf{U}$ on I, $g^{\mathbf{U}} \in \prod^{\mathbf{U}}_{i\in I} \mathfrak{F}^i$, and formula φ of* $\mathrm{ML}(\tau)$*:*

(i) $\prod_{i\in}^{\mathbf{U}} \mathfrak{M}^i, g^{\mathbf{U}} \models \varphi$ *iff* $\{j \in I \mid \mathfrak{M}^j, g(j) \models \varphi\} \in \mathbf{U}$.

(ii) $\prod_{i\in I}^{\mathbf{U}} \mathfrak{M}^i \models \varphi$ *iff* $\{j \in I \mid \mathfrak{M}^j \models \varphi\} \in \mathbf{U}$.

(iii) *If* $\prod_{i\in I}^{\mathbf{U}} \mathfrak{F}^i, g^{\mathbf{U}} \models \varphi$, *then* $\{j \in I \mid \mathfrak{F}^j, g(j) \models \varphi\} \in \mathbf{U}$.

(iv) *If* $\prod_{i\in I}^{\mathbf{U}} \mathfrak{F}^i \models \varphi$, *then* $\{j \in I \mid \mathfrak{F}^j \models \varphi\} \in \mathbf{U}$.

Since, however, not every valuation in an ultraproduct of frames can be obtained as an ultraproduct of valuations in the components, the converse of the latter two claims above does not hold.

The following observation due to Goldblatt [44, 47] blends first-order and modal constructions.

PROPOSITION 85. *For any family* $\{\mathfrak{F}^i\}_{i\in I}$ *of* τ*-frames and any ultrafilter* $\mathbf{U}$ *on* I, $\prod_{i\in I}^{\mathbf{U}} \mathfrak{F}^i$ *is embeddable as a generated subframe into* $\prod^{\mathbf{U}} \left(\biguplus_{i\in I} \mathfrak{F}^i\right)$.

The embedding is defined canonically as $g^{\mathbf{U}} \mapsto g^{\mathbf{U},+}$, where $g^{\mathbf{U},+} := (w(i), i)$ for each $i \in I$. Furthermore, as shown in [129], any ultraproduct of frames $\prod_{i\in I}^{\mathbf{U}} \mathfrak{F}^i$ is embeddable as a subframe of $\mathfrak{ue}\left(\biguplus_{i\in I} \mathfrak{F}^i\right)$.

6.3 Modal saturation and bisimulations

A class of (pointed) Kripke structures $\mathcal{C}$ is said to have the *Hennessy–Milner property* if modal equivalence between structures in $\mathcal{C}$ implies (and hence is equivalent to) bisimulation equivalence. For instance, as noted in Theorem 38 the class of all finite structures has the Hennessy–Milner property. Compare Definition 39 for first-order types and ω-saturation. The following weaker notion of saturation is more specific to modal logic.

DEFINITION 86. A Kripke τ-structure $\mathfrak{M} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, V\rangle$ is *modally saturated at a state* $w \in W$ if for every $\alpha \in \tau$ and set of modal formulae Γ, the following saturation condition holds:
if $\mathfrak{M}, w \models \langle\alpha\rangle \bigwedge \Gamma_0$ for all finite $\Gamma_0 \subseteq \Gamma$, then there is some $u \in W$ such that $wR_\alpha u$ and $\mathfrak{M}, u \models \Gamma$.
$\mathfrak{M}$ is *modally saturated* if it is modally saturated at each of its states.

It is clear from Definition 39 that ω-saturated Kripke structures are modally saturated.

PROPOSITION 87. *The class of modally saturated Kripke structures has the Hennessy–Milner property.*

Proof. If $\mathfrak{M}$ and $\mathfrak{M}'$ are modally saturated, then $\rho := \{(w, w') \in W \times W' \mid (\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')\}$ is a bisimulation between $\mathfrak{M}$ and $\mathfrak{M}'$. Atom equivalence is obvious. Consider for instance the *forth* condition. Let $(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')$ and let $(w, u) \in R_\alpha$. Put $\Gamma := \mathrm{Th}_{\mathrm{ML}}(\mathfrak{M}, u)$. For finite $\Gamma_0 \subseteq \Gamma$, $\mathfrak{M}, w \models \langle\alpha\rangle \bigwedge \Gamma_0$ and hence also $\mathfrak{M}', w' \models \langle\alpha\rangle \bigwedge \Gamma_0$. By modal saturation of $\mathfrak{M}'$ at w' therefore, there is some u' such that $(w', u') \in R_\alpha$ and $\mathfrak{M}', u' \models \Gamma$. But this means that $(\mathfrak{M}, u) \equiv_{\mathrm{ML}} (\mathfrak{M}', u')$, and u' is as desired for the forth requirement. ❑

COROLLARY 88. *The class of* ω*-saturated Kripke structures has the Hennessy–Milner property.*

It is well-known from classical model theory [12, Corollary 4.3.14] that the ultrapower of any (pointed) Kripke structure w.r.t. a regular ultrafilter is an ω-saturated elementary

extension of that structure. Furthermore, two (pointed) Kripke structures are modally equivalent iff any pair of their ω-saturated ultrapowers are modally equivalent, and hence, by Corollary 88, bisimilar. Thus, we obtain the following characterisation of modal equivalence between Kripke structures from [20], as a corollary of the above.

THEOREM 89. *Two (pointed) Kripke structures are modally equivalent iff any pair of their ω-saturated ultrapowers are bisimilar.*

A parallel with first-order logic can be drawn here if we think of bisimulations as the modal analogue of partial isomorphisms between Kripke structures, and note that elementary equivalence on ω-saturated structures coincides with partial isomorphism between them (see [108, 68, 23]). Then Theorem 91 below completes the match. Before getting there, we need the following result, due to van Benthem [126], building on a construction of Fine [28].

THEOREM 90. *For every Kripke τ-structure $\mathfrak{M}$, $\mathfrak{ue}(\mathfrak{M})$ is a bounded morphic image of an ω-saturated ultrapower of $\mathfrak{M}$.*

Proof. Let $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$ where $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$.
The structure $\mathfrak{F}^\times = \langle W, \{R_\alpha\}_{\alpha\in\tau}, \{X \mid X \subseteq W\}\rangle$ has in particular every $V(\varphi)$ as a distinguished predicate. Take an ω-saturated ultrapower $\mathfrak{F}^* = \prod_I^{\mathbf{U}} \mathfrak{F}^\times$ and for each $f^{\mathbf{U}} \in \prod_I^{\mathbf{U}} W$ define $v(f^{\mathbf{U}}) = \{X \subseteq W \mid f^{\mathbf{U}} \in \prod_I^{\mathbf{U}} X\}$. It is immediate to check that $v(f^{\mathbf{U}}) \in \mathbf{U}(W)$. Considering v as a mapping from $\prod_I^{\mathbf{U}} \mathfrak{M}$ onto $\mathfrak{ue}(\mathfrak{M})$ one can show that it is a bounded morphism. The most difficult step (proved in [126] for the case of one unary modality, see also the proof of [5, Proposition 2.61]) is to prove the *back* condition, which uses the saturation of $\mathfrak{F}^\times$. ❑

Using this theorem we can now obtain a strengthening of the model-theoretic characterisation of modal equivalence, first proved by Hollenberg [71]. See also [138] and [5, Theorem 2.62].

THEOREM 91. *For any pointed Kripke structures* $(\mathfrak{M}, w)$ *and* $(\mathfrak{M}', w')$,

$$(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w') \;\; \textit{iff} \;\; (\mathfrak{ue}(\mathfrak{M}), \mathsf{u}[w]) \rightleftarrows (\mathfrak{ue}(\mathfrak{M}'), \mathsf{u}[w']).$$

Proof. The direction from right to left is immediate from Lemma 79 and bisimulation invariance, Theorem 14. For the converse direction, suppose $(\mathfrak{M}, w) \equiv_{\mathrm{ML}} (\mathfrak{M}', w')$. Then, by Theorem 89, $(\prod_I^{\mathbf{U}} \mathfrak{M}, g_w^{\mathbf{U}}) \rightleftarrows (\prod_I^{\mathbf{U}} \mathfrak{M}', g_{w'}^{\mathbf{U}})$ for the ω-saturated ultrapowers defined in the proof above, where $g_w(i) = w$ for each $i \in I$, and likewise for $g_{w'}$. Note that $v(g_w^{\mathbf{U}}) = \mathsf{u}[w]$ and $v(g_{w'}^{\mathbf{U}}) = \mathsf{u}[w']$. Composing this bisimulation with the surjective bounded morphisms $v : (\prod_I^{\mathbf{U}} \mathfrak{M}, g_w^{\mathbf{U}}) \xrightarrow{\rightleftarrows} (\mathfrak{ue}(\mathfrak{M}), \mathsf{u}[w])$ and $v' : (\prod_I^{\mathbf{U}} \mathfrak{M}', g_{w'}^{\mathbf{U}}) \xrightarrow{\rightleftarrows} (\mathfrak{ue}(\mathfrak{M}'), \mathsf{u}[w'])$, we obtain a bisimulation between the ultrafilter extensions. ❑

The following observation is immediate from the definitions.

LEMMA 92. *Bisimulations preserve modal saturation at a state: if $(\mathfrak{M}, w) \rightleftarrows (\mathfrak{M}', w')$, then $\mathfrak{M}$ is modally saturated at w iff $\mathfrak{M}'$ is modally saturated at w'. Consequently, global bisimulations preserve modal saturation of models.*

From this lemma and Theorem 90, since surjective bounded morphisms are global bisimulations, we obtain the following result from [48], (see also [5, Proposition 2.61])

COROLLARY 93. *The ultrafilter extension of every Kripke structure is modally saturated.*

As Venema argues quite aptly in [138], this result along with Theorem 91 indicates that, for modal logics, ultrafilter extensions can play the role that ultrapowers play in first-order logic for the construction of saturated extensions of structures.

6.4 Modal definability of properties of Kripke structures

Kripke structures serve to give model theoretic semantics to modal logic. Conversely, focusing on Kripke structures in their own right, we regard modal logic as a language for defining classes of Kripke structures. We may ask the natural model-theoretic questions from this angle, like, for instance: what classes/properties of (pointed) Kripke structures are definable by (sets of) modal formulae? A definitive answer to that question was given in the case of elementary properties of pointed Kripke structures defined by single modal formulae, by Theorem 55. Here we address the general question by using classical model-theoretic tools and the constructions introduced earlier in this section.

Since modal formulae express first-order conditions on (pointed) Kripke structures, these are special cases of *first-order definable* (by a single first-order sentence), respectively *elementary* (definable by any set of first-order sentences) classes and properties. Keisler's theorem [12, Theorem 4.1.12] characterising elementary and first-order definable classes is therefore relevant here: a class of first-order structures is elementary iff it is closed under elementary equivalence and ultraproducts; it is first-order definable iff both the class and its complement are elementary. Since modal formulae cover only a fragment of the first-order language $\mathrm{FO}(\tau_\Phi)$, these results give necessary but not sufficient conditions for modal definability of classes of (pointed) Kripke structures. But 'elementary equivalence' for modal logic is modal equivalence. Would that adjustment of Keisler's theorem suffice to guarantee modal definability? The answer is 'yes' in both cases. The following is from [22].

THEOREM 94. *A class $\mathcal{K}$ of (pointed) Kripke structures is definable by a set of modal formulae iff it is closed under modal equivalence and ultraproducts; $\mathcal{K}$ is definable by a single modal formula iff both $\mathcal{K}$ and its complement are definable by a set of modal formulae.*

Proof. These can be proved by adapting the proof of Keisler's theorem. Alternatively, we may invoke a corollary of the Keisler–Shelah theorem (cf. Corollary 6.1.16 and Theorem 6.1.15 in [12]) which states that a class of first-order structures is elementary iff it is closed under isomorphism and ultraproducts while its complement is closed under ultrapowers. The latter condition here follows from closure under modal equivalence. Once $\mathcal{K}$ has been shown to be elementary, a general argument can be applied that works not only for modal formulae but for any other natural fragment Δ of first-order logic (see [12, Lemma 3.2.1]): if $\Delta \subseteq \mathrm{FO}$ is closed under negation and disjunction, then an elementary class is axiomatisable with formulae from Δ iff it is closed under Δ-equivalence.

For definability by a single formula, one may use compactness for ML just as for FO to show that whenever both the given class and it complement are definable by a set of formulae, then the class (and its complement) are definable by a single formula. Alternatively, one may first establish first-order definability of $\mathcal{K}$, and then use Theorem 55 and

bisimulation invariance to see that the defining formula must be equivalent to a modal formula. ❑

Note that, as an immediate consequence of (the classical proof of) Theorem 55, an elementary class of (pointed) Kripke structures is closed under modal equivalence iff it is closed under bisimulations. Therefore, we can strengthen somewhat the results above, by replacing closure under modal equivalence by bisimulation closure, but at the expense of demanding closure of the complement under ultrapowers. See [22] and [5, Theorems 2.75, 2.76] for the following.

THEOREM 95. *For any class $\mathcal{K}$ of pointed Kripke structures:*

(i) *$\mathcal{K}$ is definable by a set of modal formulae iff it is closed under bisimulation and ultraproducts, while its complement is closed under ultrapowers.*

(ii) *$\mathcal{K}$ is definable by a single modal formula iff it is closed under bisimulation, while both it and its complement are closed under ultraproducts.*

Proof. For the non-trivial part of (i): assuming the closure conditions for $\mathcal{K}$ and its complement, we consider the modal theory $\mathrm{Th}_{\mathrm{ML}}(\mathcal{K})$ and show that it defines $\mathcal{K}$, i.e., every model of it is in $\mathcal{K}$. For details see [22], [5, Theorem 2.75]. Alternatively, we can take a shortcut: by Theorem 89 the closure conditions imply that $\mathcal{K}$ is closed under modal equivalence, and hence Theorem 94 applies.

For the non-trivial part of (ii) we may use (i) and a standard compactness argument as in the proof of Keisler's theorem (see [22] and [5, Theorems 2.76]), or use Theorem 94 again. ❑

Similar results can be obtained for classes of Kripke structures; we leave these to the reader.

Finally, we mention the following results of Venema [138] which characterise modal definability of classes of (pointed) Kripke structures in purely modal terms, i.e., without involving the typical constructions from classical logic. In what follows, a bisimulation $\rho\colon \mathfrak{M} \rightleftarrows \mathfrak{M}'$ is *surjective* if every state in $\mathfrak{M}'$ has a bisimilar one in $\mathfrak{M}$; an *ultrafilter union* of a family of pointed Kripke structures $\left\{\mathfrak{M}^i, w^i\right\}_{i\in I}$ is a pointed Kripke structure $\left(\mathfrak{ue}\left(\biguplus_{i\in I}\mathfrak{M}^i\right), \mathsf{w}\right)$, where w is an ultrafilter containing every co-finite subset of $\{w_i \mid i \in I\}$.

THEOREM 96. *A class of Kripke structures is modally definable iff it is closed under disjoint unions, surjective bisimulations, and ultrafilter extensions, while it reflects ultrafilter extensions.*

A class of pointed Kripke structures is modally definable iff it is closed under bisimulations and ultrafilter unions, and reflects ultrafilter extensions.

To summarise: model theory of modal logic over Kripke structures essentially derives from first-order model theory, with the crucial extra feature of bisimulation invariance. The additional requirement of bisimulation invariance leads us from classical model theory to modal model theory and allows us to develop the analogy between them further.

7 GENERAL FRAMES

Neither of the two kinds of semantic structures we have considered so far, viz. Kripke frames and Kripke structures, provides a completely satisfactory framework for the se-

mantics for modal logic. On the one hand, truth and validity in Kripke structures, with its crucial dependency on given valuations, does not reflect the richer semantics in terms of validity in frames. On the other hand, validity in frames, being an essentially second-order notion, is in general deductively intractable. As a consequence, frame-incomplete modal logics are the rule, rather than the exception (see Chapter 7 of this handbook). It is therefore necessary to look for a new type of semantic structures, 'hybrids' between Kripke structures and frames, combining the expressive richness of the frame-based semantics with the flexibility and good deductive behaviour of the one based on Kripke structures.

Such structures, called *general frames*, were introduced in modal logic by Thomason in [124], with precursors in [97] and [28]. General frames are analogues to Henkin's 'general models' for second-order logic, extending first-order structures with a family of 'admissible sets', and restricting the second-order quantification to such sets only. Independently, general frames essentially arose from the seminal study by Jónsson and Tarski [78] of Boolean algebras with operators (see also Chapter 6 of this handbook), since they appear as the 'concrete', set-theoretic counterparts of modal algebras, arising in the Jónsson–Tarski representation theorem, and thus providing the link between the algebraic and relational semantics.

In this section we introduce the modal semantics based on general frames, develop the basic model theory of general frames and briefly mention the *duality theory* which relates them to algebras. We then discuss the relevance and use of general frames to the model theory of the frame-based modal semantics, in terms of *persistence* of modal formulae with respect to various important classes of general frames.

7.1 General frames as semantic structures in modal logic

Note that the operators $\langle R\rangle$ and $[R]$ defined in section 1.2 are monotone. Besides, the operators $\langle R\rangle$ are *normal* (preserving falsum) and *additive* (distributive over disjunctions); see Chapter 6 of this handbook. Hence every structure $\langle \mathcal{P}(W); \cap, -, \varnothing, \{\langle R_\alpha\rangle\}_{\alpha\in\tau}\rangle$ is a (complete and atomic) Boolean algebra with operators in the terms of [78] (see also Chapter 6), called a *modal τ-algebra.*

DEFINITION 97. Given a τ-frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$, a *general τ-frame over* $\mathfrak{F}$ is a structure $\langle \mathfrak{F}, \mathbb{W}\rangle$ expanding $\mathfrak{F}$ with a τ-algebra of *admissible subsets* of $\mathcal{P}(W)$, closed under boolean operations and the operators $\{\langle R_\alpha\rangle\}_{\alpha\in\tau}$, i.e., $\mathbb{W}$ is a τ-subalgebra of $\langle \mathcal{P}(W); \cap, -, \varnothing, \{\langle R_\alpha\rangle\}_{\alpha\in\tau}\rangle$.

Given a general τ-frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W}\rangle$ we denote $\mathfrak{F}$ by $\mathfrak{G}_\#$ and the τ-algebra $\mathbb{W}$ by $\mathfrak{G}^+$.

EXAMPLE 98. For every Kripke structure $\mathfrak{M} = \langle \mathfrak{F}, V\rangle$, $\langle \mathfrak{F}, \{V(\varphi) \mid \varphi \in \mathrm{ML}(\tau)\}\rangle$ is a general τ-frame over $\mathfrak{F}$, *generated by* $\mathfrak{M}$. In particular, the general τ-frame $\mathfrak{G}_L$ generated by the canonical Kripke structure $\mathfrak{M}_L$ (see Chapter 7 of this handbook) of a normal modal logic L is called the *canonical general frame of* L.

Among the general frames over $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ there is a least one, viz. $\mathfrak{F}_{\min} = \langle \mathfrak{F}, \mathbb{W}_{\min}\rangle$ generated from the Kripke structure $\mathfrak{M}_{\min} = \langle \mathfrak{F}, V_{\min}\rangle$ where $V_{\min}(p) = \emptyset$ for every $p \in \Phi$, and a greatest one, viz. the *full general τ-frame* $\mathfrak{F}_{\max} = \langle \mathfrak{F}, \mathcal{P}(W)\rangle$. Clearly, local (as well as global) validity in $\mathfrak{F}$ and $\mathfrak{F}_{\max}$ coincide. So we can safely identify the τ-frame $\mathfrak{F}$ with $\mathfrak{F}_{\max}$. Furthermore, the family of all general frames over a τ-frame $\mathfrak{F} = \langle W, \{R_\alpha\}_{\alpha\in\tau}\rangle$ forms a complete lattice.

DEFINITION 99. Given a general τ-frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle$, a *valuation over* $\mathfrak{G}$ is any valuation $V : \Phi \to \mathbb{W}$. A Kripke structure $\langle \mathfrak{F}, V \rangle$ where V is a valuation over $\mathfrak{G}$ is a *Kripke structure over* $\mathfrak{G}$, also denoted by $\langle \mathfrak{G}, V \rangle$ or $\langle \mathfrak{F}, \mathbb{W}, V \rangle$.

It follows by a routine induction that if $\mathfrak{M} = \langle \mathfrak{F}, \mathbb{W}, V \rangle$, then $V(\varphi) \in \mathbb{W}$ for every $\varphi \in \mathrm{ML}(\tau)$.

DEFINITION 100. Given a formula $\varphi \in \mathrm{ML}(\tau)$, a general τ-frame $\mathfrak{G}$, and $w \in W$, we say that *φ is (locally) valid at w in* $\mathfrak{G}$, denoted $\mathfrak{G}, w \models \varphi$, if φ is true at w in every Kripke structure over $\mathfrak{G}$. *φ is valid in* $\mathfrak{G}$, denoted $\mathfrak{G} \models \varphi$, if φ is valid in $\mathfrak{G}$ at every $w \in W$, i.e., φ is valid in every Kripke structure over $\mathfrak{G}$.

Note that local validity of modal formulae in a general τ-frame is preserved under the rule Modus Ponens and under taking uniform substitutions, while validity is also preserved under Necessitation.

All general frames generated from Kripke structures have an at most countable algebra of admissible sets, so not every general frame is of that type. On the other hand, every general frame *can* be generated from a Kripke structure in an extended language with an appropriately large cardinality of the set of atomic propositions. This observation is sufficient to transfer various results and constructions from Kripke structures to general frames.

However, as semantic structures for modal logic, general frames match most closely modal algebras. Indeed, as already noted, every general τ-frame $\mathfrak{G}$ generates a '*complex τ-algebra*' $\mathfrak{G}^+$. Conversely, every τ-algebra $\mathfrak{A}$ determines a general frame $\mathfrak{A}_+$ based on the *ultrafilter frame* of that algebra (see section 7.2), and is moreover embedded in $(\mathfrak{A}_+)^+$ in a way extending the Stone representation for Boolean algebras. That embedding is the subject of the celebrated *Jónsson–Tarski representation theorem* (see [78], [5, Section 5.3], or Chapter 6 of this handbook). Furthermore, there exists an algebraic-categorial *duality* between general frames and modal algebras, systematically developed by Goldblatt in [43, 44, 47] and later, from a topological perspective by [114] (see also [5, Section 5.4]), discussed in detail in Chapter 6 of this handbook.

7.2 Constructions and truth preservation results on general frames

Bisimulations and special cases

DEFINITION 101. Let $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle$ and $\mathfrak{G}' = \langle \mathfrak{F}', \mathbb{W}' \rangle$ be two general τ-frames. A bisimulation ρ between $\mathfrak{F}$ and $\mathfrak{F}'$ is a *bisimulation between* $\mathfrak{G}$ *and* $\mathfrak{G}'$ if for every valuation V over $\mathfrak{G}$ there is a valuation V' over $\mathfrak{G}'$ such that $\rho\colon \langle \mathfrak{G}, V \rangle \rightleftarrows \langle \mathfrak{G}', V' \rangle$, and vice versa.

A bisimulation between pointed general frames is defined likewise.

Note that not every bisimulation between Kripke frames is a bisimulation between them as full general frames, because not every valuation over one of them must have a matching valuation satisfying *atom equivalence.*

COROLLARY 102. *If $\rho\colon (\mathfrak{G}, w) \rightleftarrows (\mathfrak{G}', w')$ is a bisimulation between pointed general τ-frames $(\mathfrak{G}, w)$ and $(\mathfrak{G}', w')$ then $(\mathfrak{G}, w) \equiv_{\mathrm{ML}} (\mathfrak{G}', w')$. Likewise, if $\rho\colon \mathfrak{G} \rightleftarrows \mathfrak{G}'$, then $\mathfrak{G} \equiv_{\mathrm{ML}} \mathfrak{G}'$.*

The definitions of generated subframes, bounded morphisms, and disjoint unions can be extended to general frames.

DEFINITION 103. Given a general τ-frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle$, a *generated subframe of* $\mathfrak{G}$ is any general τ-frame $\mathfrak{G}' = \langle \mathfrak{F}', \mathbb{W}' \rangle$ where $\mathfrak{F}' \trianglelefteq \mathfrak{F}$ and $\mathbb{W}' = \{X \cap \mathrm{dom}(\mathfrak{F}') \mid X \in \mathbb{W}\}$.

DEFINITION 104. Let $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle$ and $\mathfrak{G}' = \langle \mathfrak{F}', \mathbb{W}' \rangle$ be two general τ-frames and $\rho \colon \mathfrak{F} \xrightarrow{\rightleftarrows} \mathfrak{F}'$ a bounded morphism. Then ρ is a *bounded morphism* from $\mathfrak{G}$ to $\mathfrak{G}'$ if for every $Y \in \mathbb{W}'$, $\rho^{-1}[Y] \in \mathbb{W}$; ρ is a *bounded strong morphism* from $\mathfrak{G}$ to $\mathfrak{G}'$ if it is a bounded morphism from $\mathfrak{G}$ to $\mathfrak{G}'$ and for every $X \in \mathbb{W}$, $\rho[X] \in \mathbb{W}'$ and $X = \rho^{-1}[\rho[X]]$.

DEFINITION 105. The *disjoint union* of the family $\left\{\mathfrak{G}^i = \left\langle \mathfrak{F}^i, \mathbb{W}^i \right\rangle\right\}_{i \in I}$ of general τ-frames is $\biguplus^i_{i \in I} \mathfrak{G}^i = \left\langle \biguplus_{i \in I} \mathfrak{F}^i, \mathbb{W} \right\rangle$, where $\mathbb{W} = \left\{\biguplus_{i \in I} X^i \mid X^i \in \mathbb{W}^i \text{ for each } i \in I\right\}$.

We leave it to the reader to check that generated subframes and disjoint unions of general frames produce general frames indeed, and to see that they, as well as bounded strong morphisms, are particular cases of general frame bisimulations. The associated preservation results are immediate, and are left to the reader, too. As for bounded morphisms of general frames, in general they are not general frame bisimulations and only preserve validity in the forward direction.

Ultrafilter extensions and ultraproducts

The construction of ultrafilter extensions of frames can be generalised to the Stone representation of modal algebras (see Chapter 6 of this handbook), which in turn are essentially general frames, thus defining ultrafilter extensions of general frames. More precisely, given a general τ-frame $\mathfrak{G} = \langle W, \{R_\alpha\}_{\alpha \in \tau}, \mathbb{W} \rangle$ over a frame $\mathfrak{F}$, let $\mathbf{U}(\mathbb{W})$ be the set of all ultrafilters over the algebra $\mathfrak{G}^+$. For each $\alpha \in \tau$ we define a binary relation $R^{\mathbb{W}}_\alpha$ on $\mathbf{U}(\mathbb{W})$ just like $R^{\mathfrak{ue}}_\alpha$ in $\mathfrak{ue}(\mathfrak{F})$, i.e., for any $\mathsf{u}, \mathsf{w} \in \mathbf{U}(\mathbb{W})$:

$$\mathsf{u} R^{\mathbb{W}}_\alpha \mathsf{w} \text{ iff } \langle R_\alpha \rangle (X) \in \mathsf{u} \text{ for every } X \in \mathsf{w}.$$

The frame $(\mathfrak{G}^+)_+ = \left\langle \mathbf{U}(\mathbb{W}), \{R^{\mathbb{W}}_\alpha\}_{\alpha \in \tau} \right\rangle$ is called the *ultrafilter frame of the τ-algebra* $\mathfrak{G}^+$.

Finally, we put $\mathbb{W}^{\mathfrak{ue}} := \{\mathfrak{u}_{\mathbb{W}}(X) \mid X \in \mathbb{W}\}$ where $\mathfrak{u}_{\mathbb{W}}(X) = \{\mathsf{u} \in \mathbf{U}(\mathbb{W}) \mid X \in \mathsf{u}\}$. It is routine to check that $\left\langle R^{\mathbb{W}}_\alpha \right\rangle (\mathfrak{u}_{\mathbb{W}}(X)) = \mathfrak{u}_{\mathbb{W}}(\langle R_\alpha \rangle (X))$ and hence $\mathbb{W}^{\mathfrak{ue}}$ is a modal τ-algebra.

DEFINITION 106. Given a general τ-frame $\mathfrak{G} = \langle W, \{R_\alpha\}_{\alpha \in \tau}, \mathbb{W} \rangle$, *the ultrafilter extension of* $\mathfrak{G}$ is the general τ-frame $\mathfrak{ue}(\mathfrak{G}) := \left\langle \mathbf{U}(\mathbb{W}), \{R^{\mathbb{W}}_\alpha\}_{\alpha \in \tau}, \mathbb{W}^{\mathfrak{ue}} \right\rangle$, also known as the *general ultrafilter frame* of *the τ-algebra* $\mathfrak{G}^+$.

From the basic properties of ultrafilters, and the closure of $\mathbb{W}^{\mathfrak{ue}}$ under $\left\langle R^{\mathbb{W}}_\alpha \right\rangle$, it follows that $\mathfrak{G}^+ \cong \mathfrak{ue}(\mathfrak{G})^+$ for any general τ-frame $\mathfrak{G}$. Note, however, that $\mathfrak{ue}(\mathfrak{G}) \cong \mathfrak{G}$ does not hold in general, and in section 7.3 we will characterise the general frames for which this is the case. Still, since validity of modal formulae in $\mathfrak{G}$ and in $\mathfrak{G}^+$ coincide, we obtain the following.

THEOREM 107. *For any general τ-frame $\mathfrak{G}$, $\mathfrak{ue}(\mathfrak{G}) \equiv_{\mathrm{ML}} \mathfrak{G}$.*

DEFINITION 108. Let $\{\mathfrak{G}^i = \langle \mathfrak{F}^i, \mathbb{W}^i \rangle\}_{i \in I}$ be a family of general τ-frames indexed by a set I. For any ultrafilter $\mathbf{U}$ on I, the *ultraproduct of* $\{\mathfrak{G}^i\}_{i \in I}$ *over* $\mathbf{U}$ is the general τ-frame $\prod^{\mathbf{U}}_{i \in I} \mathfrak{G}^i := \langle \prod^{\mathbf{U}}_{i \in I} \mathfrak{F}^i, \mathbb{W}^{\mathbf{U}} \rangle$, where $\mathbb{W}^{\mathbf{U}} = \{\prod^{\mathbf{U}}_{i \in I} X^i \mid X^i \in \mathbb{W}^i \text{ for each } i \in I\}$.

Note that the ultraproduct of a family of Kripke frames regarded as full general frames is *not* a full general frame itself, so it differs from the ultraproduct of frames, as defined

earlier. To distinguish these, we call the former *general ultraproduct* of frames. Unlike the latter, every valuation in it is an ultraproduct of respective valuations in the components, whence the following preservation result (see [43, 44, 47]).

PROPOSITION 109. *For every family of general τ-frames $\left\{\mathfrak{G}^i = \left\langle \mathfrak{F}^i, \mathbb{W}^i \right\rangle\right\}_{i\in I}$, ultrafilter $\mathbf{U}$ on I, element $\mathbf{w_U} \in \prod_{i\in I}^{\mathbf{U}} \mathfrak{F}^i$, and formula φ of ML(τ) :*

(i) $\prod_{i\in I}^{\mathbf{U}} \mathfrak{G}^i, \mathbf{w_U} \models \varphi$ *iff* $\{j \in I \mid \mathfrak{G}^j, \mathbf{w}(j) \models \varphi\} \in \mathbf{U}$.

(ii) $\prod_{i\in I}^{\mathbf{U}} \mathfrak{G}^i \models \varphi$ *iff* $\{j \in I \mid \mathfrak{G}^j \models \varphi\} \in \mathbf{U}$.

7.3 Special types of general frames and persistence of modal formulae

Let $\mathcal{G}$ be the class of all general τ-frames of a fixed modal type τ, and let $\mathcal{C}$ be any subclass of $\mathcal{G}$.

DEFINITION 110. A formula $\varphi \in \mathrm{ML}(\tau)$ is *locally $\mathcal{C}$-persistent*, if for every general τ-frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle \in \mathcal{C}$, and $w \in \mathrm{dom}(\mathfrak{F})$, $\mathfrak{G}, w \models \varphi$ implies $\mathfrak{F}, w \models \varphi$; φ is *$\mathcal{C}$-persistent*, if for every general τ-frame $\mathfrak{G}= \langle \mathfrak{F}, \mathbb{W} \rangle \in \mathcal{C}$, $\mathfrak{G} \models \varphi$ implies $\mathfrak{F} \models \varphi$.

Clearly, local persistence implies persistence, but the converse does not always hold. While often the practically important notion is the latter, the former is more natural.

A general frame can be thought of as a frame in which a restriction on the valuations is imposed by allowing only those valuations which assign admissible sets to the propositional variables (and hence, to all formulae). Thus, the idea of persistence is that it enables one to conclude (local) validity, i.e., truth under *every* valuation, of a modal formula in a frame, based on its truth under *some* special valuations, viz. the admissible ones. In other words, a formula is $\mathcal{C}$-persistent if, whenever it is falsified in a Kripke frame $\mathfrak{F}$, it is falsified by *some* admissible valuation in *each* general frame from $\mathcal{C}$ over $\mathfrak{F}$. Thus, persistence gives a measure of the 'semantic complexity' of a formula, in terms of its falsifying valuations. Note that a modal formula is locally $\mathcal{G}$-persistent iff it is semantically equivalent to a constant formula (i.e., a formula without propositional variables). Indeed, every constant formula is $\mathcal{G}$-persistent. Conversely, if φ is $\mathcal{G}$-persistent, then for every pointed frame $(\mathfrak{F}, w)$, $\mathfrak{F}, w \models \varphi$ iff $\langle \mathfrak{F}, V_\perp \rangle, w \models \varphi$, where $V_\perp$ assigns $\emptyset$ to every atomic proposition, iff $\mathfrak{F}, w \models \varphi_\perp$ where $\varphi_\perp$ is obtained from φ by replacing all atomic propositions by $\perp$.

We will introduce some important classes of general frames, persistence with respect to which provides sufficient conditions for good expressive or axiomatic behaviour of the formulae.

DEFINITION 111. Let $\mathfrak{G}= \langle W, \{R_\alpha\}_{\alpha\in\tau}, \mathbb{W} \rangle$ be a general τ-frame and $\alpha \in \tau$. The relation R_α is *tight* in $\mathfrak{G}$ if for every $u, w \in W$: $uR_\alpha w$ iff for all $X \in \mathbb{W}$, $w \in X$ implies $u \in \langle R_\alpha \rangle(X)$; equivalently, iff $u \in \bigcap\{\langle R_\alpha \rangle(X) \mid X \in \mathbb{W} \text{ and } w \in X\}$.

Recall, for the compactness property below, that a family of sets $\mathcal{F}$ has the *finite intersection property* (FIP) if the intersection of every finite sub-family of $\mathcal{F}$ is non-empty.

DEFINITION 112. A general τ-frame $\langle W, \{R_\alpha\}_{\alpha\in\tau}, \mathbb{W} \rangle$ is:

- *differentiated*, if for every $u, u' \in W$, if $u \neq u'$ then there is $X \in \mathbb{W}$ such that $u \in X$ and $u' \notin X$;
- *tight*, if R_α is tight for every $\alpha \in \tau$;

– *discrete*, if $\{u\} \in \mathbb{W}$ for every $u \in W$;
– *elementary*, if every subset of W that is $\mathrm{FO}(\tau)$-definable with parameters (in the sense of Definition 39) is admissible;
– *compact*, if every family of admissible sets in $\mathfrak{G}$ with FIP has a non-empty intersection;[12]
– *refined*, if it is differentiated and tight;
– *descriptive*, if it is refined and compact.

Amongst all discrete general frames over a Kripke frame $\mathfrak{F}$, there is a *least* one, viz. $\mathfrak{D}(\mathfrak{F})$, generated from all singletons by closing under the Boolean and modal operators. It contains all finite and co-finite sets in $\mathfrak{F}$. Likewise, amongst all elementary general frames over a Kripke frame $\mathfrak{F}$, there is a *least* one, viz. $\mathfrak{E}(\mathfrak{F})$, in which the admissible sets are precisely the subsets of the domain of $\mathfrak{F}$ that are parametrically first-order definable in $\mathrm{FO}(\tau)$.

Assuming the type τ is fixed, the class of all differentiated (resp. tight, discrete, elementary, refined, descriptive) general τ-frames will be denoted by $\mathcal{DF}$ (resp. $\mathcal{T}, \mathcal{DI}, \mathcal{E}, \mathcal{R}, \mathcal{D}$).

Here are some relationships between these classes.

- Every full general frame is discrete, and therefore, refined (see below). Every finite, but no infinite, discrete general frame is descriptive, for otherwise the intersection of all sets $W \setminus \{w\}$ would have to be non-empty; on the other hand, every finite differentiated frame is full.

- Every discrete frame is refined. Indeed, for tightness note that in every discrete frame $xR_\alpha w$ holds iff $x \in \langle R_\alpha \rangle(\{w\})$. The converse need not hold, e.g., canonical general frames (see Chapter 7 of this handbook) are refined, even descriptive, but not discrete, being infinite.

- Every elementary frame is discrete, while the converse does not hold, as we will see further.

To summarise: $\mathcal{E} \subsetneqq \mathcal{DI} \subsetneqq \mathcal{R} = \mathcal{DF} \cap \mathcal{T}$; $\mathcal{D} \subsetneqq \mathcal{R}$; $\mathcal{D} \nsubseteq \mathcal{DI} \nsubseteq \mathcal{D}$.

Below, we list some remarks on the various notions of persistence and relationships between them. Analogous remarks apply to local persistence.

- First, note that if $\mathcal{C}_1 \subseteq \mathcal{C}_2$, then $\mathcal{C}_2$-persistence implies $\mathcal{C}_1$-persistence.

- A formula is $\mathcal{DI}$-persistent iff it is valid in a frame $\mathfrak{F}$ whenever it is valid in $\mathfrak{D}(\mathfrak{F})$. Likewise, a formula is $\mathcal{E}$-persistent iff it is valid in a frame $\mathfrak{F}$ whenever it is valid in $\mathfrak{E}(\mathfrak{F})$.

- While every (locally) $\mathcal{R}$-persistent formula is $\mathcal{DI}$-persistent, the converse does not hold, a simple witness being e.g., the 'density' formula $\Diamond p \to \Diamond\Diamond p$ (see [5, p.319]).

- Also, not every (even locally) $\mathcal{D}$-persistent formula is $\mathcal{DI}$-persistent (and hence, even less $\mathcal{R}$-persistent), a witness being *Geach's formula* $\Diamond\Box p \to \Box\Diamond p$, defining the Church–Rosser confluence property of the accessibility relation (see [5, p.305]).

[12] This is equivalent to the requirement that every ultrafilter over $\mathfrak{G}^+$ consists of all admissible sets containing a fixed state in $\mathfrak{G}$.

Moreover, not every $\mathcal{D}$-persistent formula is $\mathcal{E}$-persistent, as we will see in section 8.2.

- Not every (even locally) $\mathcal{E}$-persistent is $\mathcal{DI}$ -persistent, again witnessed by Geach's formula.

- Finally, not every (even locally) $\mathcal{DI}$-persistent formula is $\mathcal{D}$-persistent. The formula $\mathbf{vB} = \Box\Diamond\top \to \Box(\Box(\Box p \to p) \to p)$, proposed by van Benthem in [127], is an example. First, note that for every discrete general frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W}\rangle$ and $w \in \mathrm{dom}(\mathfrak{F})$, $\mathfrak{G}, w \models \mathbf{vB}$ implies $\mathfrak{G}, w \models \Box\Diamond\top \to \Box\bot$; hence $\mathfrak{G}_{\#}, w \models \Box\Diamond\top \to \Box\bot$. Indeed, assuming $\mathfrak{G}, w \models \Box\Diamond\top \wedge \neg\Box\bot$, for any successor u of w the valuation $W\backslash\{u\}$ for p falsifies $\mathbf{vB}$ at w. Furthermore, for every frame $\mathfrak{F}$ and $w \in \mathrm{dom}(\mathfrak{F})$, $\mathfrak{F}, w \models \Box\Diamond\top \to \Box\bot$ implies $\mathfrak{F}, w \models \mathbf{vB}$. Hence $\mathbf{vB}$ is locally $\mathcal{DI}$-persistent. On the other hand, $\mathbf{vB}$ is not $\mathcal{D}$-persistent. Indeed, as shown in [127] (see also [5, p.216]) $\mathbf{vB}$ is valid in a certain general frame $\mathfrak{J}$, the modal logic $\mathbf{KvB}$ of which is incomplete. That is because $\Box\Diamond\top \to \Box\bot$, not being valid in $\mathfrak{J}$, is not a theorem of $\mathbf{KvB}$ while, as seen above, it is valid in every frame for $\mathbf{KvB}$. Thus, while $\mathbf{vB}$ is valid in the (descriptive) canonical frame of $\mathbf{KvB}$, it fails in the underlying Kripke frame which falsifies $\Box\Diamond\top \to \Box\bot$.

  Consequently, not every locally $\mathcal{E}$-persistent formula is $\mathcal{D}$-persistent.

To summarise again, if we denote by $\mathcal{C}^p$ the set of all $\mathcal{C}$-persistent formulae, we have the following: $\mathcal{DF}^p \cap \mathcal{T}^p = \mathcal{R}^p \subsetneq \mathcal{DI}^p \subsetneq \mathcal{E}^p$; $\mathcal{R}^p \subsetneq \mathcal{D}^p$; $\mathcal{DI}^p \nsubseteq \mathcal{D}^p \nsubseteq \mathcal{E}^p$.

The same relationships hold for local persistence.

Now, we discuss some important results about refined and descriptive frames and the related persistence properties, while elementary frames and elementary persistence will be discussed in section 8.2.

First, note ([124]) that every general frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W}\rangle$ can be 'refined' by constructing a refined quotient of it over the set $W^{\sim}$ of all equivalence classes modulo the equivalence relation $\sim$, defined as $v \sim w$ iff $\forall X \in \mathbb{W}(v \in X \iff w \in X)$, and taking as admissible all sets of the type $X^{\sim} = \{w^{\sim} \mid w \in X\}$ for $X \in \mathbb{W}$. It now remains to 'tighten' all accessibility relations by closing under the definition of tightness: for every $u^{\sim}, w^{\sim} \in W^{\sim}$, $u^{\sim} R_{\alpha}^{\sim} w^{\sim}$ holds iff for all $X^{\sim} \in \mathbb{W}^{\sim}$ and $u' \sim u, w' \sim w$, if $w' \in X$ then $u' \in \langle R_{\alpha}\rangle(X)$. Note, however, that (see [10, p.263]) while for finite frames this construction produces a bounded morphic image, this is not necessarily the case when applied to infinite general frames.

Descriptive frames typically appear as the *canonical general frames* (see Chapter 7 of this handbook) of every normal modal logic without any special inference rules. Thus, all $\mathcal{D}$-persistent formulae are valid in the underlying canonical Kripke frames, and hence they axiomatise Kripke complete logics. For that reason the $\mathcal{D}$-persistent formulae are also called *canonical*.[13] However, in hybrid logics with nominals (see Chapter 14 of this handbook) or in logics with special additional rules of inference, e.g., the non-ξ rules in [137], $\mathcal{D}$-persistent formulae *need not* be canonical, because the canonical general frames

[13] Note that across the literature on modal logic the term 'canonicity' is used in somewhat different, and not entirely equivalent, senses (see [126, 127]). For instance, Fine defines in [28] canonicity of a set of formulae as validity of every formula of that set in any canonical frame built for a modal language with any cardinality of propositional variables. Since all canonical models generate descriptive frames, the notion of canonicity adopted here following [126] is at least as strong as Fine's.

for such logics are only discrete (for hybrid logics) or refined (in logics with additional 'context' rules, see [52]). In such cases, $\mathcal{DI}$-persistence or $\mathcal{R}$-persistence is the right notion of canonicity. $\mathcal{DI}$-persistent formulae have the important property to remain canonical when added as axioms to hybrid logics with nominals, while $\mathcal{R}$-persistent formulae remain canonical not only in the presence of other axioms, but even if additional rules of inference of the type mentioned above are added to the axiomatic system.

Descriptive frames feature prominently in the duality theory between general frames and modal algebras, as they turn out to be precisely the fixed points of ultrafilter extensions of general frames, which are essentially the Stone representations of modal algebras (see Chapter 6 of this handbook).

PROPOSITION 113. *A general τ-frame $\mathfrak{G}$ is descriptive iff $\mathfrak{G} \cong \mathfrak{ue}(\mathfrak{G})$.*

Indeed, the proof that every ultrafilter extension is descriptive is just a variation of the proof that every canonical general frame is descriptive (see Chapter 7 of this handbook). For the converse, the crucial observation is that, given a descriptive general frame $\mathfrak{G} = \langle \mathfrak{F}, \mathbb{W} \rangle$, for every $w \in \mathbf{F}$, the set $\mathsf{u}_{\mathbb{W}}[w] = \{X \in \mathbb{W} \mid w \in X\}$ is an ultrafilter in $\mathbb{W}$, and every ultrafilter in $\mathbb{W}$, due to the compactness of $\mathfrak{G}$, is of this type. Thus, the mapping $\lambda w.\mathsf{u}_{\mathbb{W}}[w]$ is a bijection (since $\mathfrak{G}$ is differentiated) between $\mathfrak{G}$ and $\mathfrak{ue}(\mathfrak{G})$. This bijection is in fact an isomorphism, due to the tightness of $\mathfrak{G}$.

Consequently, by Theorem 107, every general frame is modally equivalent to a descriptive frame. Therefore, every $\mathcal{D}$-persistent formula φ preserves its validity from a frame $\mathfrak{F}$ to the ultrafilter extension of the full general frame $\mathfrak{F}_{\max}$, which is based on $\mathfrak{ue}(\mathfrak{F})$. Since $\mathfrak{ue}(\mathfrak{F}_{\max})$ is descriptive, by $\mathcal{D}$-persistence, φ preserves validity from $\mathfrak{F}$ to $\mathfrak{ue}(\mathfrak{F})$. Conversely, if φ preserves validity in ultrafilter extensions of frames, then it is $\mathcal{D}$-persistent by Theorem 115. Thus, we obtain:

PROPOSITION 114. *A modal formula is (locally) $\mathcal{D}$-persistent iff its validity is (locally) preserved in ultrafilter extensions of frames.*

Every general τ-frame $\mathfrak{G} = \langle W, \{R_\alpha\}_{\alpha\in\tau}, \mathbb{W} \rangle$ determines a *topological space* $T(\mathfrak{G})$ with a base of clopen sets $\mathbb{W}$, and a set of closed sets denoted by $\mathbf{C}(\mathbb{W})$. For a detailed study of this topology, its properties and applications in modal logic see [114]. Hereafter, a *closed* set in the general τ-frame $\mathfrak{G}$ will mean a subset of the domain closed with respect to the topology $T(\mathfrak{G})$, i.e., an intersection of a family of admissible sets.

A number of important properties of general frames can be phrased in terms of their topology. For instance, in every discrete frame $\mathfrak{G}$ the topology $T(\mathfrak{G})$ is discrete. Indeed, every non-empty set is a union of its singleton subsets, which are open in $T(\mathfrak{G})$; hence every subset of $\mathfrak{G}$ is open. Also, differentiatedness of a general frame is equivalent to T_2-separability (Hausdorffness) of its topology, while compactness, as defined above, is equivalent to the standard topological notion of compactness. Thus, for any compact and differentiated τ-frame $\mathfrak{G}$, $T(\mathfrak{G})$ is a compact Hausdorff space.

Finally, it is instructive to explore which constructions on general frames preserve each of the classes discussed above. For instance, differentiatedness, tightness, and discreteness are preserved in generated subframes and disjoint unions, while compactness is not. Conversely, bounded morphisms preserve compactness, but not discreteness, differentiatedness and tightness. Besides, discreteness, differentiatedness, and tightness (and hence, refinedness), being properties definable in a suitable first-order language for states and admissible sets, and membership between them, are preserved in ultraproducts, while

descriptiveness is preserved in finite disjoint unions, but never in infinite ones, nor necessarily in ultraproducts [44, 47].

How does persistence determine the expressiveness of a formula? We will discuss this issue in section 8.2 in connection with first-order definability of modal formulae.

Before closing this section, let us highlight again the role of general frames in the modal theory of modal logic:

- general frames provide a natural link between the first-order semantics on Kripke structures and the second-order semantics on frames, and are thus analogous to Henkin's general models for second-order logic.
- general frames are essentially equivalent to modal algebras, via the duality theory outlined in Chapter 6 of this handbook, and thus provide algebraic semantics for modal logic.
- the notion of persistence of (the truth/validity of) modal formulae with respect to natural classes of general frames is instrumental in characterising their model-theoretic behaviour.

8 MODAL LOGIC ON FRAMES

So far we have mainly studied modal logic as a fragment of first-order logic over Kripke structures. In this section we discuss modal logic as a logic of *frames*, and thus as a fragment of universal monadic second-order logic MSO.

This fragment, while generally not very expressive and missing many simple first-order properties, nevertheless penetrates deeply into MSO. Perhaps its most interesting features are the recursive axiomatisability of validity and its finite model property, together implying decidability – a rare phenomenon in second-order logic when considered over arbitrary structures rather than special ones.

In this section we present some classical results characterising modally definable classes of frames, and discuss how persistence of modal formulae with respect to various classes of general frames can be used to determine their model-theoretic properties.

8.1 Modal definability of frame properties

Here we address the question which classes of frames are definable by modal formulae. A classical result from [51] answers this question in a traditional model-theoretic fashion, albeit using a somewhat ad-hoc construction, called *SA-construction* ('state-of-affairs construction'). Algebraically, it corresponds to taking a subalgebra of a homomorphic image, thus allowing a 'translation' of Birkhoff's theorem in terms of frame constructions, and so characterising equational classes of algebras as those closed under subalgebras, homomorphic images and direct products (see Chapter 6 of this handbook). Theorem 117 gives a more natural characterisation of the modally definable *elementary* classes. Here is another definability-by-preservation result, due to van Benthem (see [126, Theorem 3.5], [127, Theorem 16.5], [129]).

THEOREM 115. *A class of frames $\mathcal{K}$ is modally definable by a set of $\mathcal{D}$-persistent formulae iff it is closed under generated subframes, bounded morphisms, disjoint unions and ultrafilter extensions, and reflects ultrafilter extensions.*

Proof. We already know from sections 2 and 6, and Proposition 114 that every $\mathcal{D}$-persistent formula satisfies all preservation conditions of the theorem, whence the easier direction. Conversely, let $\mathcal{K}$ satisfy the preservation conditions. We show that $\mathcal{K} = \mathrm{FR}(\mathrm{Th}_{\mathrm{ML}}(\mathcal{K}))$. Let $\mathfrak{F} \models \mathrm{Th}_{\mathrm{ML}}(\mathcal{K})$. Recall that $\mathfrak{F}_{\max}$ denotes the full general frame over the frame $\mathfrak{F}$. Using the duality theory between general frames and modal algebras, and Birkhoff's theorem, one can show that $\mathfrak{ue}(\mathfrak{F}_{\max})$ is isomorphic to a generated general subframe of a bounded morphic image of $\mathfrak{ue}(\mathfrak{G}_{\max})$ where $\mathfrak{G}$ is a disjoint union of frames from $\mathcal{K}$. Now, $\mathfrak{G} \in \mathcal{K}$; hence $\mathfrak{ue}(\mathfrak{G}) \in \mathcal{K}$. So, tracing the underlying frames and using the closure conditions, we eventually find that $\mathfrak{ue}(\mathfrak{F}) \in \mathcal{K}$, whence $\mathfrak{F} \in \mathcal{K}$. ❑

We note that checking the conditions of the theorem above, even in the case when the class of frames is first-order definable, may be a practically very difficult task. A testimony for that is the fact that preservation of first-order formulae under ultrafilter extensions is Π^1_1-hard [122, Thm 2.3.17].

In the rest of this section we compare the expressiveness of modal logic over frames with first-order logic and some of its extensions within monadic second-order logic.

8.2 Modal logic versus first-order logic on frames

We have already seen that modal languages are generally incomparable with first-order languages in terms of definability of frame properties. Indeed, while simple elementary properties, such as irreflexivity, escape the basic modal language, it can capture non-elementary properties such as the one defining the class of all transitive frames in which there are no infinite chains of successors. By a simple compactness argument, this class is not elementary, while it is well-known to be defined by the *Gödel–Löb formula* GL (see e.g. [75]). This example also shows that the compactness theorem with respect to frame validity fails in modal logic. The downward Löwenheim–Skolem–Tarski theorem fails here, too. E.g., McKinsey's formula $\Box\Diamond p \to \Diamond\Box p$ (see [127], or [5, p.133]) is valid in a certain uncountable frame, but not in any countable elementary subframe of it. Another important example of a non-elementary modal formula (in the extended setting with the star operation for transitive closures) is Segerberg's induction axiom [117] IND : $[\alpha^*](p \to [\alpha]p) \to (p \to [\alpha^*]p)$.

The model-theoretic interplay

We compare modal formulae (respectively, modally definable properties of frames) and first-order formulae (respectively, properties definable in $\mathrm{FO}(\tau)$) from two perspectives:

- Which modally definable frame properties are first-order definable?
- Which first-order properties of frames are modally definable?

As already mentioned, there are two natural notions of first-order definability: by means of single sentences and by means of theories (possibly infinite sets of sentences). Regarding modally definable classes, however, these turn out to be equivalent. Indeed, if the class of frames $\mathrm{FR}(\varphi)$ is the class of models of an infinite set of $\mathrm{FO}(\tau)$-formulae Γ, then $\Gamma \models \varphi$ with respect to frame validity, which is a Π^1_1-property. The compactness theorem of first-order logic applies here, and $\Gamma_0 \models \varphi$ for some finite $\Gamma_0 \subseteq \Gamma$. Hence $\mathrm{FR}(\varphi)$ is defined by the conjunction over Γ_0. We can therefore refer to modally definable

classes which are first-order definable, and to modal formulae defining such classes, as *elementary* without risk of confusion.

On the other hand, it seems to be still unknown whether there is any FO-sentence equivalent to an infinite set of basic modal formulae but not to a single formula.[14]

The validity preservation results from sections 2 and 6 imply that every modally definable class of frames $\mathrm{FR}(\varphi)$ is closed under generated subframes, bounded morphic images (in particular, isomorphic copies), and disjoint unions, while it reflects ultrafilter extensions and ultraproducts. If, moreover, the formula φ is elementary, then $\mathrm{FR}(\varphi)$ is closed under ultraproducts, too. Conversely, if $\mathrm{FR}(\varphi)$ is closed under ultraproducts then, by the Keisler–Shelah theorem, $\mathrm{FR}(\varphi)$ is elementary. Moreover, by Proposition 85, closure of $\mathrm{FR}(\varphi)$ under ultrapowers suffices, and therefore, closure under elementary equivalence in $\mathrm{FO}(\tau)$ suffices, too. The latter, in turn, characterises $\Sigma\Delta$-elementary classes, i.e., unions of elementary classes. Thus, we have the following model-theoretic characterisation of the elementary modal formulae (see [44, 47, 127]).

THEOREM 116. *For any modal formula φ the following are equivalent:*

(i) *φ is elementary.*

(ii) $\mathrm{FR}(\varphi)$ *is closed under ultraproducts.*

(iii) $\mathrm{FR}(\varphi)$ *is closed under ultrapowers.*

(iv) $\mathrm{FR}(\varphi)$ *is closed under elementary equivalence, i.e., $\Sigma\Delta$-elementary.*

The result above correspondingly characterises elementary classes of frames that are known to be modally definable. This raises the natural question how to characterise, in model theoretic terms, modal definability of an elementary class of frames. Again, a classical result from [51] answers that question. Here is a somewhat strengthened version (see [5, Theorem 5.54]).

THEOREM 117 (Goldblatt–Thomason). *If a class of frames $\mathcal{K}$ is closed under ultrapowers (in particular, if $\mathcal{K}$ is elementary), then $\mathcal{K}$ is modally definable iff it is closed under generated subframes, bounded morphisms, and disjoint unions, and reflects ultrafilter extensions.*

Proof. One direction is a direct application of the preservation results from sections 2 and 6. For the other direction note that, by Theorem 90 reduced to underlying frames, $\mathcal{K}$ is closed under ultrafilter extensions, too. Thus, Theorem 115 applies, so $\mathcal{K}$ is modally definable, moreover by a set of $\mathcal{D}$-persistent formulae. ❑

We end with an important related result, originally due to Fine [28], later strengthened and proved by van Benthem [127, Theorem 16.7] as a corollary to Theorem 115.[15]

We call a modal formula φ *complete* if the modal logic axiomatised by φ is complete for the class of frames defined by φ.

THEOREM 118 (Fine–van Benthem).
Every complete and elementary modal formula φ is $\mathcal{D}$-persistent.

Proof. $\mathrm{FR}(\varphi)$ satisfies all closure conditions of Theorem 115, so $\mathrm{FR}(\varphi) = \mathrm{FR}(\Gamma)$ for some set of $\mathcal{D}$-persistent formulae Γ. The modal logic $\mathbf{K}_\tau + \Gamma$, axiomatised with the set

[14]There are known cases, however, where a first-order definable property is infinitely, but not finitely, axiomatisable in some extended modal languages. See, e.g., [54].

[15]For a stronger algebraic version of this theorem see [45], [5, Theorem 5.56], or Chapter 6 of this handbook.

of axioms Γ, is canonical and therefore complete. Hence $\mathbf{K}_\tau + \Gamma \vdash \varphi$. By compactness of modal derivations, $\mathbf{K}_\tau + \Gamma_0 \vdash \varphi$ for some finite subset Γ_0 of Γ. By completeness of φ, all formulae from Γ_0 are theorems of $\mathbf{K}_\tau + \varphi$. Hence φ is axiomatically equivalent, and therefore frame-equivalent, too, to the conjunction of Γ_0, which is itself a $\mathcal{D}$-persistent formula. ❑

It is known ([28], see also section 8.2) that the converse to the above theorem does not hold, viz. not every $\mathcal{D}$-persistent formula is elementary. An example is $\Diamond\Box(p \vee q) \to \Diamond(\Box p \vee \Box q)$ (see [28]). Nor is every elementary modal formula $\mathcal{D}$-persistent, as there are incomplete elementary modal formulae (e.g., van Benthem's formula **vB** discussed in section 7.3, see [128, p.72], also in [5, p.216]).

It had been a longstanding open problem, posed by Fine, whether every modal logic axiomatised by $\mathcal{D}$-persistent formulae is complete with respect to *some* elementary class. This question has recently been answered negatively in [50].

Persistence and first-order definability

Some persistence properties of modal formulae imply that they are elementary. Perhaps the first interesting result in that vein is due to Lachlan [89] who proved that every $\mathcal{R}$-persistent formula is elementary. A strengthening of Lachlan's result, using the argument in Goldblatt's proof of it in [44], is that every (locally) $\mathcal{DI}$-persistent formula is (locally) elementary. First, note that local non-validity of a modal formula, being a Σ^1_1-property, is preserved by ultraproducts [12, Corollary 4.1.14]. By the Keisler–Shelah theorem it suffices to show that local validity of locally $\mathcal{DI}$-persistent formulae is preserved under ultraproducts. This follows from the fact that local validity of modal formulae is locally preserved in ultraproducts of general frames (Proposition 109), and that any ultraproduct of full general frames is a discrete general frame.

Let us now turn to $\mathcal{E}$-persistent formulae. They were first studied by van Benthem in [127] in connection with the *substitution method* which can be used to establish the first-order definability of Sahlqvist formulae (see section 8.2). The idea of the substitution method is to identify finitely many 'characteristic' first-order definable valuations of the variables occurring in a given formula, such that the formula is (locally) valid in every frame in which it is (locally) valid for those characteristic valuations. For all Sahlqvist formulae, just one such valuation, the *minimal* one amongst all those satisfying the antecedent of the formula, suffices. Van Benthem provided an alternative characterisation of locally and globally $\mathcal{E}$-persistent formulae, which implies that they are locally elementary.

Given a $\mathrm{FO}(\tau_\Phi)$-formula $\beta(\mathbf{x})$ with unary predicates $P_1, \ldots, P_n$, assuming that the variables $\mathbf{x}$ do not occur bound in β and the variables $z_1, \ldots, z_k, y$ do not occur in β at all, we define a *universally parameterised* $\mathrm{FO}(\tau)$-*substitution instance* of β to be any $\mathrm{FO}(\tau)$-formula $\forall z_1 \ldots \forall z_k \beta[\sigma_1/P_1, \ldots, \sigma_n/P_n]$ obtained from β by selecting $\mathrm{FO}(\tau)$-formulae $\sigma_i = \sigma_i(\mathbf{x}, z_1, \ldots, z_k, y)$ for $i = 1, \ldots, n$, uniformly substituting $\sigma_i[x/y]$ for every occurrence of $P_i x$, and then universally quantifying over $z_1, \ldots, z_k$. Let $\Theta(\beta)$ be the set of all universally parameterised $\mathrm{FO}(\tau)$-substitution instances of β.

DEFINITION 119. A modal formula $\varphi = \varphi(p_1, \ldots, p_n)$ is a *van Benthem formula* if $\Theta(\mathrm{ST}(\varphi; x_0)) \models \forall P_1 \ldots \forall P_n \mathrm{ST}(\varphi; x_0)$. We let VB denote the class of van Benthem formulae (defined slightly differently in [127] as the class M^1_{sub}).

THEOREM 120. *A modal formula is locally $\mathcal{E}$-persistent iff it is a van Benthem formula.*

Proof. Recall that $\mathfrak{E}(\mathfrak{F})$ is the minimal elementary general frame over the Kripke frame $\mathfrak{F}$. Let $\varphi(p_1, \ldots, p_n) \in \mathrm{VB}$ and suppose $\mathfrak{E}(\mathfrak{F}), w \models \varphi$ for some frame $\mathfrak{F}$. Take any universally parametrised $\mathrm{FO}(\tau)$-substitution instance $\forall z_1 \ldots \forall z_k \mathrm{ST}(\varphi)[\sigma_1/P_1, \ldots, \sigma_n/P_n]$. Let $w_1, \ldots, w_k \in \mathrm{dom}(\mathfrak{F})$ and $X_i := \{u \in \mathrm{dom}(\mathfrak{F}) \mid \mathfrak{F} \models \sigma_i(w, w_1, \ldots, w_k, u)\}$ for $i = 1, \ldots, n$. Since $X_1, \ldots, X_n$ are admissible in $\mathfrak{E}(\mathbf{F})$, $(\mathfrak{F}; X_1, \ldots, X_n; w) \models \mathrm{ST}(\varphi)(P_1, \ldots, P_n; x_0)$. Therefore, $\mathfrak{F}, w \models \forall z_1 \ldots \forall z_k \mathrm{ST}(\varphi)[\sigma_1/P_1, \ldots, \sigma_n/P_n]$. Since $\varphi \in \mathrm{VB}$, that implies $\mathfrak{F}, w \models \varphi$.

Conversely, let φ be locally $\mathcal{E}$-persistent and suppose $\mathfrak{F}, w \models \Theta(\mathrm{ST}(\varphi; x_0))$. Then, reversing the argument above, we find that $\mathfrak{E}(\mathfrak{F}), w \models \varphi$, and therefore $\mathfrak{F}, w \models \varphi$ by local $\mathcal{E}$-persistence of φ. ❑

We can now strengthen the earlier persistence-implies-elementary results.

THEOREM 121. *Every (locally) $\mathcal{E}$-persistent formula is (locally) elementary.*

Proof. Clearly, for every modal formula φ, $\forall P_1 \ldots \forall P_n \mathrm{ST}(\varphi; x_0) \models \Theta(\mathrm{ST}(\varphi; x_0))$. By compactness, every van Benthem formula is a logical consequence of a finite subset of $\Theta(\mathrm{ST}(\varphi; x_0))$, and hence is equivalent to the conjunction over that set. ❑

Consequently, not every $\mathcal{D}$-persistent formula is $\mathcal{E}$-persistent. Neither is every (locally) elementary modal formula (locally) $\mathcal{E}$-persistent. An example (see [127]) is the formula $\mathrm{Mk4} = (\Box p \to \Box\Box p) \wedge (\Box\Diamond p \to \Diamond\Box p)$, which is elementary and valid in the general frame $\langle \mathbb{N}, <, \mathbb{W}\rangle$ where $\mathbb{W}$ is the set of all finite and co-finite subsets of $\mathbb{N}$, while if fails in $\langle \mathbb{N}, <\rangle$. Since $\mathbb{W}$ contains precisely all parametrically first-order definable sets in $\langle \mathbb{N}, <\rangle$, it is $\mathfrak{E}(\langle \mathbb{N}, <\rangle)$, so Mk4 is not $\mathcal{E}$-persistent. Similarly, $\mathrm{Mk4}' = (\Box p \to \Box\Box p) \wedge \Box(\Box p \to \Box\Box p) \wedge (\Box\Diamond p \to \Diamond\Box p)$ is locally elementary,[16] but not locally $\mathcal{E}$-persistent.

Sahlqvist formulae and inductive formulae

The model-theoretic results discussed above, however elegant, are usually not easy to apply, and are of no use to find the actual first-order formula corresponding to the modal formula. It is therefore natural to look for simpler and *effective* sufficient conditions for first-order definability of modal formulae. There can be no completely satisfactory outcome of that search, because that property is not decidable [11], and (at least) in a modal language with more than one modality, not even analytical [122, Thm 2.6.5]. Still, several increasingly general results to that aim were obtained during the 1970's, culminating with the celebrated *Sahlqvist theorem*, which not only identifies a large syntactic class of elementary modal formulae (see a simple definition of that class below), but also proves their canonicity. A variety of expositions of Sahlqvist's theorem can be found in several sources, e.g. [113, 115, 5, 84, 10], Chapters 6 and 7 of this handbook. Here we outline a generalisation of the class of Sahlqvist formulae in monadic poly-modal languages, sharing the same virtues as the original class, viz. the *inductive formulae* introduced and studied for arbitrary polyadic languages in [55].

We fix a modal language $\mathrm{ML}(\tau)$.

DEFINITION 122. Let # be a symbol not belonging to $\mathrm{ML}(\tau)$. Then a *box-form of #* in $\mathrm{ML}(\tau)$ is defined recursively as follows:

[16] The fact that Mk4 and Mk4′ are elementary is far from trivial, as the proof requires a form of the Axiom of Choice and cannot be formalised in ZF.

(i) $\#$ is a box-form of $\#$;

(ii) If $\mathbf{B}(\#)$ is a box-form of $\#$ and $\Box$ is a box-modality in $\mathrm{ML}(\tau)$, then $\Box\mathbf{B}(\#)$ is a box-form of $\#$;

(iii) If $\mathbf{B}(\#)$ is a box-form of $\#$ and A is a positive τ-formula, then $A \to \mathbf{B}(\#)$ is a box-form of $\#$.

Thus, box-forms of $\#$ are, up to semantic equivalence, of the type $\Box_1(A_1 \to \Box_2(A_2 \to \dots \Box_n(A_n \to \#)\dots)$, where $\Box_1, \dots, \Box_n$ are box-modalities and $A_1, \dots, A_n$ are positive formulae in $\mathrm{ML}(\tau)$.

DEFINITION 123. Given a propositional variable p, a *box-formula of* p is the result $\mathbf{B}(p)$ of substitution of p for $\#$ in any box-form $\mathbf{B}(\#)$. The last occurrence of the variable p is the *head* of $\mathbf{B}(p)$ and every other occurrence of a variable in $\mathbf{B}(p)$ is *inessential* there.

DEFINITION 124. A *(monadic) regular formula* is any modal formula built from positive formulae and negations of box-formulae by applying conjunctions, disjunctions, and boxes.

DEFINITION 125. The *dependency digraph* of a set $\mathcal{B} = \{\mathbf{B}_1(p_1), \dots, \mathbf{B}_n(p_n)\}$ of box-formulae is the digraph $G = \langle V, E\rangle$ where $V = \{p_1, \dots, p_n\}$ is the set of heads in A, and $p_i E p_j$ iff p_i occurs as an inessential variable in a box-formula from $\mathcal{B}$ with a head p_j. A digraph is called *acyclic* if it does not contain oriented cycles.

DEFINITION 126. An *inductive formula* is a regular formula with an acyclic dependency digraph of the set of all box-formulae occurring as subformulae in it.

We note that Sahlqvist formulae, up to semantic equivalence, are precisely those regular formulae in which the box-formulae are just *boxed atoms*, i.e., propositional variables prefixed by possibly empty strings of boxes. Thus, all Sahlqvist formulae fall into a simple particular case of inductive formulae, where the dependency digraph has no arcs at all.

The following extension of Sahlqvist's theorem was established in [55].

THEOREM 127. *Each inductive formula is locally elementary and locally $\mathcal{D}$-persistent. Moreover, its local first-order equivalent can be computed effectively.*

The inductive formulae are van Benthem formulae which, just like Sahlqvist formulae, have first-order definable minimal valuations, but they can only be computed inductively, in steps following the arcs of the dependency digraph, from sources to sinks.

Sahlqvist formulae satisfy a certain persistence property which can be extracted from the syntactic shape of the first-order formulae defining their minimal valuations. In the basic modal language these valuations are either the empty set, or the whole domain, or are finite unions of sets of the type $R^n(y)$ (recall that R^n is the n-fold composition of R with itself). Following [55], let us call a general frame *ample* if it contains all such sets as admissible, and the modal formulae locally persistent with respect to all ample general frames, *locally $\mathcal{A}$-persistent.* Thus, all Sahlqvist formulae in $\mathrm{ML}(\Diamond)$ are locally $\mathcal{A}$-persistent, and this property enables us to show that a given formula is not (even semantically equivalent to) a Sahlqvist formula.

EXAMPLE 128. As proved in [55], the formula $D = p \wedge \Box(\Diamond p \to \Box q) \to \Diamond\Box\Box q$ is not $\mathcal{A}$-persistent, and hence not equivalent to any Sahlqvist formula in $\mathrm{ML}(\Diamond)$. However, it is an inductive formula, whose dependency digraph over the set of heads $\{p, q\}$ has only one edge, from p to q. It has a local first-order correspondent $\mathrm{FO}(D) = \exists y(Rxy \wedge \forall z(R^2yz \to$

$\exists u(Rxu \wedge Rux \wedge Ruz)))$, which is not equivalent to a Kracht formula (i.e., a first-order equivalent to a Sahlqvist formula, see [84]).

The class of inductive formulae does not exhaust the potential of the method of substitutions, (in particular, minimal valuations), since, being syntactically defined (like Sahlqvist formulae), it is not closed even under tautological equivalence.

A more general and robust *algorithmic* approach to identifying elementary and $\mathcal{D}$-persistent modal formulae (covering all inductive formulae) is outlined in [14]. The algorithm presented there is based on a modal version of Ackermann's lemma (which essentially formalises the idea of minimal valuations) and, when successful, computes effectively a first-order equivalent of the input modal formula and at the same time establishes its $\mathcal{D}$-persistence.

Shallow formulae and $\mathcal{R}$-persistence

The property of $\mathcal{R}$-persistence is much stronger than $\mathcal{D}$-persistence. Perhaps the largest syntactic class of $\mathcal{R}$-persistent formulae identified so far is the class of *shallow formulae* [122, Thm 2.4.7]: those in which every occurrence of a propositional variable is in the scope of at most one modal operator. Note that syntactically shallow formulae are not subsumed by the class of Sahlqvist formulae, nor even by the class of inductive formulae.

8.3 Modal logic and first-order logic with least fixed points

With every first-order language FO(τ) we associate its extension LFP(τ) with *least fixed point operators*. For background on LFP see e.g. [25] or [2]. LFP is a rather expressive proper extension of FO which however still shares nice properties with with FO, e.g., the downward Löwenheim–Skolem theorem [30] and the 0-1 law (see [64]).

Which modal formulae are (locally) definable in LFP(τ)? Which LFP(τ)-formulae are modally definable on frames? No explicit model-theoretic criteria seem to be known as yet and these questions are most likely undecidable.

A number of well-known non-elementary modal formulae, such as the Gödel-Löb formula GL and Segerberg's induction axiom IND have local equivalents in LFP(τ) while, for instance, the McKinsey formula is outside that class. Indeed, take van Benthem's uncountable frame from [127] in which that formula is valid. Flum's argument from [30], proving the downward Löwenheim–Skolem–Tarski theorem for LFP, produces a countable elementary subframe of it which must satisfy that formula, too, which is not possible, as shown in [127].

Still, a large, effectively defined class of LFP(τ)-expressible modal formulae can be identified by noting that the idea of using minimal valuations to eliminate the universal second-order quantifiers in the standard translation of frame validity of modal formulae goes beyond first-order logic. Indeed, the same idea works perfectly for all (polyadic) regular formulae, defined for monadic languages in section 8.2. In cases where the dependency graph has loops and cycles, the minimal valuations are recursively defined and eventually expressed in LFP(τ). In particular, this applies to Gödel–Löb and Segerberg formulae, being regular formulae. The following was shown in [55].

THEOREM 129. *Every regular formula has a local correspondent in* LFP(τ)*, which can be obtained effectively.*

We illustrate the idea of computing LFP(τ)-equivalents of regular formulae with GL.

$$\mathrm{ST}(\mathrm{GL}) = \forall x_1(x_0Rx_1 \to (\forall x_0(x_1Rx_0 \to Px_0) \to Px_1)) \to \forall x_1(x_0Rx_1 \to Px_1),$$

which can be rewritten as $\forall x_1(x_0Rx_1 \to (R[x_1] \subseteq P) \to Px_1)) \to R[x_0] \subseteq P$ (where $R[x] := \{y \mid xRy\}$). The antecedent can be expressed as

$$\Phi(P) \subseteq P, \quad \text{where} \quad \Phi(P) = \{x_1 \mid x_0Rx_1 \wedge R[x_1] \subseteq P\}\,.$$

Note that, since $\Phi(P)$ is positive in P, and hence monotone, there is a $\subseteq$-minimal valuation for P satisfying $\Phi(P) \subseteq P$, viz. $V_m(p) = \mu X.\Phi(X)$. Then, the local equivalent of GL in LFP(τ) is obtained by substituting that minimal valuation in the consequent: $\mathrm{LFP}(\tau)(GL; x_0) = \forall x_1(x_0Rx_1 \to \mu X.\Phi(X)(x_1))$. By unfolding, based on the Knaster–Tarski theorem, that equivalent is:

$\forall x_1(x_0Rx_1 \to$

$\exists n \geq 0\ \forall y_1 \ldots \forall y_n(x_1Ry_1 \to x_0Ry_1 \wedge (\ldots(y_{n-1}Ry_n \to x_0Ry_n \wedge R[y_n] = \emptyset)\ldots)),$

i.e., 'local' transitivity and non-existence of infinite R-chains starting at x_0.

While Theorem 129 may be regarded as an extension of the definability part of the Sahlqvist theorem, it cannot match the canonicity part of it. Not only are there regular formulae which are not $\mathcal{D}$-persistent (e.g., GL and IND) but there are even ones which are not complete, such as $\Box(\Box p \leftrightarrow p) \to \Box p$ from [6], which can be easily pre-processed into a semantically equivalent regular formula. It is weaker than GL but has the same class of frames, and is therefore incomplete. On the other hand, it is a plausible conjecture that every modal formula with a minimal valuation expressible in LFP(τ) is semantically equivalent to a regular formula.

In order to apply the method of minimal valuations, one has to identify, en route, those FO(τ)-formulae γ for which there is a minimal interpretation for each occurring unary predicate P. In recent work van Benthem [132] has obtained syntactic and model theoretic characterisations of these formulae, involving predicates of arbitrary arity (see Chapter 1 of this handbook).

Finally, we note that an algorithm for computing LFP(τ)-equivalents of classical modal formulae, based on Ackermann's method for second-order quantifier elimination, and in particular covering the example above, has been developed in [103].

8.4 Modal logic and second-order logic

The standard translation embeds ML(τ), with respect to frame validity, into the monadic Π^1_1-extension of the first-order language FO(τ_Φ). We already know that the embedding is proper. Still, a natural question arises whether the preservation conditions of Theorem 117 are sufficient to guarantee modal definability of monadic Π^1_1-formulae, as well. As van Benthem has noted in [127, p.53], this is not the case in the basic modal language, witnessed by the property 'non-existence of infinite R-chains' (i.e., well-foundedness of R^{-1}), which satisfies all those preservation conditions and moreover is bisimulation invariant. Still, that property of frames is defined in the extension of the basic modal language with the universal modality $[U]$, by the formula $[U](\Box p \to p) \to p$ (see [54]). (Contrast this with Observation 42, that as a property of Kripke structures, it is not definable even in ML_∞.) Thus, one may ask if the natural preservation conditions characterising modal definability of elementary properties (closure under generated subframes, bounded morphisms, and disjoint unions, and reflection of ultrafilter extensions) do not apply also to a

wider class (if not the whole of Π^1_1), but for a suitably extended modal language? Surely, some of the results characterising modal definability of properties of Kripke structures would still be useful and relevant here: if the first-order matrix of a Π^1_1-formula, where all second order quantifiers are in a prefix, meets the conditions for having a modal correspondent on Kripke structures, then the whole formula is frame-definable by the same modal correspondent. It is not currently known if this observation can be turned into a general criterion for modal definability of monadic second-order formulae.

Modal logic penetrates quite deep into monadic second-order logic $\mathrm{MSO}(R)$ (with full quantification over unary predicate variables, over the vocabulary with the single binary relation R). As proved by Thomason [124], logical consequence in terms of frame validity of the latter can be reduced to the former in the following sense. There exists an effective translation t of $\mathrm{MSO}(R)$ into ML, and a special modal formula δ such that for every set Σ of $\mathrm{MSO}(R)$-sentences and any $\mathrm{MSO}(R)$-sentence φ: $\Sigma \models_2 \varphi$ iff $\{\delta\} \cup t[\Sigma] \models_{\mathrm{FR}} t(\varphi)$. Here $\models_2$ denotes second-order semantic consequence which, as a consequence from Tarski's non-definability theorem, is not arithmetically definable, and $\Gamma \vDash_{\mathrm{FR}} \psi$ means that the modal formula ψ is valid in every frame where all modal formulae from Γ are valid. Consequently, $\vDash_{\mathrm{FR}}$ is not recursively axiomatisable, unlike validity in modal logic.

Furthermore, as noted in [127, p.23], full second-order logic, and even the theory of finite types, can be reduced to $\mathrm{MSO}(R)$, too.

For more on the relations between modal logic and second-order logic, see [127], [24], and Chapter 10 of this handbook. Also, [122, 121, Chapter 12] considers the extension of modal logic with propositional quantifiers, which goes much farther into second-order logic.

9 FINITE MODEL THEORY OF MODAL LOGICS

9.1 Finite versus classical model theory

When only finite structures are admitted, the model theoretic basis changes dramatically. For instance, unless the logic under consideration has the finite model property, satisfiability does not imply finite satisfiability, and hence a semantic consequence $\varphi \models \psi$ may be true in the sense of finite models without being classically valid. Crucial tools of classical model theory, most notably the completeness and compactness theorems for FO, fail in restriction to just finite models. From a modelling point of view, on the other hand, the restriction to just finite models is often natural. In applications, in which the intended models ought to be finite, reasoning on the basis also of infinite models may be inadequate and give misleading results. Applications in computer science like specification and verification, or also database theory, for instance, often call for the restriction to finite models, and have had a significant impact on the development of finite model theory.

The methodological shift encountered is highlighted by the failure of classical theorems and tools, most notably of the compactness theorem but also most other key theorems from classical model theory in its wake, see [25]. Certainly results from classical model theory cannot be expected to go through automatically; often they fail, and some still obtain, albeit with new proofs. Modal model theory, in particular, has a number of examples of the latter kind, and sometimes the new proofs shed new light also on the classical version. For some concrete examples, close to (classical) modal model theory, which

illustrate the interesting relationship with finite model theory, consider the following.

Interpolation for ML goes through via the finite model property (FMP), treated in section 3.3. If $\models \varphi \to \psi$ is valid in finite structures, it must also be valid generally, as a counterexample $\mathfrak{M}, w \models \varphi \wedge \neg\psi$ would also yield a counterexample in the sense of finite model theory, by FMP. Clearly a classical interpolant χ with $\models (\varphi \to \chi) \wedge (\chi \to \psi)$, is an interpolant also in the sense of finite model theory.

The modal characterisation theorem. Note how both sides of the equivalence expressed in Theorem 55 change their meaning when interpreted in the sense of finite model theory: both bisimulation invariance and logical equivalence only refer to finite structures. In particular, bisimulation invariance in finite structures does not imply bisimulation invariance over all structures. Trivial examples are provided by formulae without finite models that happen not to be bisimulation invariant for infinite models. Also, while Ehrenfeucht–Fraïssé techniques remain valid, compactness does not and the classical proof with its necessary detour through infinite models is no longer available. As discussed in section 4.2, however, the theorem itself persists in the form of Theorem 61 as a theorem of finite model theory due to Rosen [112]. Interestingly the new proofs in [112, 105] are valid classically as well as in finite model theory and have lead to additional insights into the classical result. In contrast, the failure of the corresponding characterisation theorem for FO^2 in finite model theory shows that the finite model property does not guarantee a smooth passage to finite model theory. While an FO sentence that is (classically) invariant under 2-pebble game equivalence is logically equivalent to a sentence in FO^2, this characterisation breaks down for finite model theory. The FO sentence saying that a binary relation is a linear ordering, which is 2-pebble invariant only in restriction to finite structures, is not expressible in FO^2 even over finite structures.

Similarly, Rosen [112] has a proof of the finite model theory version of the modal existential preservation theorem: $\varphi \in \mathrm{ML}$ is preserved under extensions (holds inside the whole Kripke structure if it holds in a substructure) iff it is equivalent to an existential modal formula (built from positive and negated atoms by means of only $\wedge$, $\vee$ and $\Diamond$ – disallowing $\Box$ or nesting of $\neg$ and $\Diamond$). The corresponding preservation theorem for first-order logic is known to become invalid in restriction to just finite structures.

Modal logic stands out in comparison with first-order logic or the FO^k in having a comparatively smooth finite model theory that preserves a number of classical theorems, as is the case for the above examples.

The variations of basic modal logic mentioned in section 5.1 have partly also been investigated with respect to their finite model theory, with several results that suggest a similarly smooth behaviour. Their characterisations as fragments of FO, in terms of invariance under correspondingly refined notions of bisimulation, have been studied in finite model theory in [106] with further ramifications w.r.t. other restricted classes of finite frames in [17]. Just as is the case with van Benthem–Rosen characterisation, Theorems 55 and 61 surprisingly many of these characterisations go through in restriction to finite Kripke structures just as classically, albeit with rather specific new proofs. The following may serve as a typical representative for several related results from [106, 17]. Also compare Proposition 68; this should be contrasted with the failure of, for instance, the corresponding characterisation of FO^2 in finite model theory.

THEOREM 130. *For any $\varphi(x) \in \mathrm{FO}$, the following are equivalent:*

(i) *φ is invariant under global bisimulation over finite Kripke structures.*

(ii) *φ is equivalent to a formula of* ML[∀] *over finite Kripke structures.*

Similarly are equivalent:

(i) *φ is bisimulation invariant over finite, rooted Kripke structures.*

(ii) *φ is equivalent to a formula of* ML[∀] *over finite, rooted Kripke structures.*

Related open problems concern the status in finite model theory of Theorem 65, for the guarded fragment GF in arbitrary relational similarity types, and particularly strikingly of Theorem 76, for the modal μ-calculus.

But finite model theory also deals with new questions, which only arise in the context of finite structures. We devote the rest of this section to two sketches dealing with two very specific issues of this kind: one from descriptive complexity (section 9.2), the other one 0-1 laws (section 9.3). Descriptive complexity deals with the relationship between the algorithmic complexity and the logical definability of properties of finite structures; here finite structures feature as input to algorithmic problems and logic becomes a measure of complexity. In 0-1 laws, and more generally asymptotic probability, one deals with the statistics of logically defined properties over the collection of all size n structures in the limit as n goes to infinity; here finite structures form the sample space for probabilistic analysis. Compare [25, 93] for general background on these topics in finite model theory.

9.2 Capturing bisimulation invariant Ptime

Descriptive complexity aims for the description and analysis of computational complexity by means of logics. A key example is the long open problem of a *logic for Ptime*. One seeks a logic (with effective syntax) whose formulae define precisely those classes of finite relational structures, for which membership can be decided in polynomial time.[17] By a well-known result of Immerman [76] and Vardi [134], the least fixed point extension of first-order logic, LFP, is the solution for classes of finite, linearly ordered relational structures. The problem remains open to date for not necessarily ordered structures. Interestingly, the corresponding problem for bisimulation closed classes of finite Kripke structures does admit a natural solution [104] (cf. [94] for another, related capturing result).

Consider the framework of basic modal logic with a single modality associated with the binary relation R and with finitely many atomic propositions p_i. Let $\mathcal{Q}$ be a class of finite pointed Kripke structures (i.e., a property of finite pointed Kripke structures) of that type. $\mathcal{Q}$ corresponds to a *bisimulation invariant* property if it is closed under bisimulation in the sense that for any two $(\mathfrak{M}, u) \rightleftarrows (\mathfrak{M}', u')$: $(\mathfrak{M}, u) \in \mathcal{Q}$ iff $(\mathfrak{M}', u') \in \mathcal{Q}$. Recall the bisimulation quotients $\mathfrak{M}[u]/\rho^{\mathfrak{M}}$ of pointed Kripke structures $(\mathfrak{M}, u)$ as discussed in section 3.6. Bisimulation closure of $\mathcal{Q}$ implies that

$$\mathcal{Q} = \big\{(\mathfrak{M}, u) \mid (\mathfrak{M}[u]/\rho^{\mathfrak{M}}, [u]_{\rho^{\mathfrak{M}}}) \in \mathcal{Q}\big\}.$$

Membership in $\mathcal{Q}$ can therefore be determined via passage to canonical quotient representations, and in terms of the intersection of $\mathcal{Q}$ with the class $\mathcal{C}$ of all canonical quotient representations. Note that $\mathcal{C}$ consists of all finite rooted Kripke structures of the appropriate type in which each bisimulation type is realised exactly once (in other words, with

[17] One also has to require an effective link from syntax to Ptime algorithms for its evaluation, in order to avoid pathological solutions.

identity as the largest bisimulation). As largest bisimulations and bisimulation quotients are polynomial time computable, it follows that $\mathcal{Q}$ is in Ptime if, and only if, $\mathcal{Q} \cap \mathcal{C}$ is. The following special property of $\mathcal{C}$ opens up a reduction to the case of linearly ordered structures, which then leads to the desired capturing result. By a canonical linear ordering of a structure we mean an ordering that is determined by the isomorphism type of that structure.

LEMMA 131. *There is a polynomial time algorithm which for every* $(\mathfrak{M}, u) \in \mathcal{C}$ *computes a canonical linear ordering of the domain.*

In fact, a linear ordering w.r.t. bisimulation type can be generated in an inductive refinement procedure which, in its n-th stage, produces a linear ordering of the $\rightleftarrows_n$-classes within any given finite Kripke structure. This is based on a lexicographic lift of the ordering on $\rightleftarrows_n$-classes to an ordering of the $\rightleftarrows_{n+1}$-classes, similar to the colour refinement technique in graph theory. Over any finite Kripke structure the common refinement of this process is a linear ordering of $\rightleftarrows$-classes; for structures in $\mathcal{C}$ one obtains an actual linear ordering, as each $\rightleftarrows$-class is inhabited by a single state.

Moreover, a representation of this linearly ordered version of the quotient structure $\mathfrak{M}[u]/\rho^{\mathfrak{M}}$ is uniformly LFP-definable over the given structures $(\mathfrak{M}, u)$ themselves. This means that in LFP over the $(\mathfrak{M}, u)$ one can also uniformly define any LFP definable property of their linearly ordered quotients $\mathfrak{M}[u]/\rho^{\mathfrak{M}}$. By the Immerman–Vardi result this includes all Ptime properties of these quotient structures, since they are linearly ordered. Together these observations yield an abstract capturing result: an effective syntactic normal form for the definition of precisely those bisimulation invariant properties that are in Ptime. As shown in [104] one can further isolate a natural extension of the modal μ-calculus, a multi-dimensional μ-calculus $\mathrm{L}^{\omega}_{\mu}$, with the property that a class $\mathcal{Q}$ of finite pointed Kripke structures is bisimulation closed and in Ptime if, and only if, $\mathcal{Q}$ is the class of finite models of a formula $\varphi \in \mathrm{L}^{\omega}_{\mu}$. The logic $\mathrm{L}^{\omega}_{\mu}$ is the natural bisimulation-safe least fixed-point extension of basic modal logic over the n-th cartesian power of a Kripke structure (intuitively: n-dimensional ML), for arbitrary $n \in \mathbb{N}$.

PROPOSITION 132. *Let* $\mathcal{Q}$ *be a class of finite pointed Kripke structures of fixed finite type. Then the following are equivalent:*

(i) $\mathcal{Q}$ *is bisimulation closed and in Ptime.*

(ii) $\mathcal{Q}$ *is definable by a formula of the multi-dimensional* μ*-calculus* $\mathrm{L}^{\omega}_{\mu}$.

9.3 0-1 laws in modal logic

Another of the major specific topics in finite model theory is the asymptotic behaviour of the probability for a given property $\mathcal{P}$ to be true in a randomly chosen structure of size n (taken up to isomorphism), in a suitably defined probabilistic space. If that probability has a limit as n increases without bound, that limit is called the *(unlabelled) asymptotic probability of* $\mathcal{P}$.

A fundamental result in this area is the *0-1 law* for first-order logic, stating that the asymptotic probability for every first-order definable property of relational structures exists and equals either 0 or 1, i.e., every such property is either *almost surely true* or *almost surely false*. This result was first proved in [40] (using 'almost sure' quantifier elimination), later established independently by Fagin [27] who moreover obtained a purely logical characterisation of the set of first-order sentences that are almost surely

true, as the first-order theory of the so-called *countable random structure*. Prior to Fagin's discovery, Gaifman had studied in [37] infinite random structures as probabilistic models for arbitrary relational first-order languages and had proved that the first-order theory of such structures is axiomatised by an infinite set of *extension axioms*: sentences that require every n-tuple to be extendible to an $(n+1)$-tuple in every possible (i.e., consistent) way. Furthermore, he showed that the first-order theory of all extension axioms is complete and ω-categorical.[18] Thus, Fagin established the following *transfer theorem*, which immediately implies the 0-1 law: a first-order property of relational structures is almost surely true iff it is true in the (unique, up to isomorphism) countable random structure. Grandjean [63] proved that the complexity of checking if a given first-order formula is almost surely true is decidable in Pspace, in sharp contrast to Trachtenbrot's theorem that validity of first-order formulae on *all* finite structures is not even recursively axiomatisable.

The transfer theorem was subsequently extended and the 0-1 law proved for several extensions of first-order logic: for first-order logic with fixed point operators by Blass, Gurevich and Kozen, later subsumed by the 0-1 law for infinitary logic with finitely many variables $L^{\omega}_{\infty\omega}$, proved by Kolaitis and Vardi; for some prefix-defined fragments of monadic second-order logic, again by Kolaitis and Vardi, who also established curious parallel between decidability and 0-1 laws for such fragments. On the other hand, the 0-1 law fails in monadic second-order logic, even in its Σ^1_1-fragment. For references and further details on these results, see, e.g., [64, 25, 93, 53].

In the framework of modal logic, there are two natural notions of (asymptotic) probability 'in the finite': with respect to Kripke structures and with respect to frames. The 0-1 law with respect to Kripke structures follows directly from Fagin's theorem. Moreover, Halpern and Kapron [66] showed that the modal formulae almost surely valid in finite Kripke structures are precisely the theorems of the non-normal *Carnap's logic* [8]. As for almost sure frame validity, a complete axiomatisation of the modal logic ML^r of the countable random frame has been obtained in [53], where it has also been proved that ML^r has the finite model property and is decidable. It is also shown there that not all modal formulae that are almost surely frame-valid are in ML^r, thus refuting the transfer theorem for frame validity in modal logic. Perhaps the simplest such formula, which fails in the countable random frame, is $\neg\Box\Box(p \leftrightarrow \neg\Diamond p)$, proven later in [90] to be almost surely true. Note that no such formula is frame-definable in fixed point logic LFP, or even in $L^{\omega}_{\infty\omega}$, because the transfer theorem does hold for these.

The failure of the transfer theorem for frame validity in modal logic cast a serious doubt on the truth of the 0-1 law there (claimed in [66]) which was soon justified by le Bars [90] who proved that the formula $\neg p \land q \land \Box\Box((p \lor q) \to \neg\Diamond(p \lor q)) \to \Diamond\Box\neg p$ has no asymptotic probability, by using involved combinatorial-probabilistic methods. Thus, basic modal logic provides the smallest currently known natural fragment of monadic Π^1_1 (resp. Σ^1_1), in a vocabulary with just a single binary relation, where the 0-1 law fails.

As noted in [53] the modal formulae which are almost surely frame-valid form a normal modal logic ML^{as}, which contains ML^r. It is a currently open problem whether ML^{as} is decidable, and its complete axiomatisation has not been established yet. However, a conjecture raised in [53] claims that all axioms that have to be added to ML^r

[18] The probabilistic aspect of this result is rather curious: it means that, assuming uniform distribution, any randomly constructed countable relational structure is isomorphic with probability 1 to the countable random structure! In the case of graphs, that structure was previously known as the *Radó graph.*

in order to axiomatise ML^{as} are of a uniform, semantic nature, namely: there is an infinite collection $\mathcal{F}$ of special finite frames, and each $\mathfrak{F} \in \mathcal{F}$ determines an axiom $\varphi_{\mathfrak{F}}$ valid in 'almost every' finite frame[19] iff that frame cannot be mapped by a bounded morphism onto $\mathfrak{F}$. For instance, the formula $\neg\Box\Box(p \leftrightarrow \neg\Diamond p)$ corresponds to the frame $\langle\{a,b\},\{\langle a,b\rangle,\langle b,a\rangle,\langle b,b\rangle\}\rangle$.

CONCLUDING REMARKS

In summary, the semantics of modal logic has (at least) two emblematic features which have a crucial impact on its model theory and which we have attempted to reflect in the composition of this chapter.

Modal logic is local. Truth of a formula is evaluated at a current state (possible world); this localisation is preserved (and carried) along the edges of the accessibility relations by the restricted, relativised quantification corresponding to the modal operators. This feature is reflected by the notion of *bisimulation* between states and between Kripke structures, respectively. The notion of bisimulation invariance plays a key role in characterising what is modally definable, as captured in the van Benthem–Rosen theorem (Theorems 55 and 61 here). Moreover, bisimulation (and its game characterisation) plays a role in modal model theory analogous to that of partial isomorphism (and its Ehrenfeucht–Fraïssé characterisation) in classical model theory. From yet another perspective, the characteristic power of preservation under bisimulations in modal logic can be compared to the characteristic power of preservation under ultraproducts in first-order logic. Quite naturally, therefore, bisimulation emerges as the central and unifying truth-preserving model-theoretic construction in modal logic, and all other basic constructions on which the classical model theory of modal logic builds (generated substructures, bounded morphisms, disjoint unions) are definable in terms of it or at least closely related to it. By systematically developing the bisimulation-based approach to modal model theory in this chapter, we hope to have given a modern treatment on this classical theme. Furthermore, the central role of bisimulations and bisimulation invariance properties is so robustly preserved, *mutatis mutandis*, in the rich and diverse variety of extensions of basic modal logic, that it can be adopted as a benchmark of what constitutes a modal language.

Modal logic is multi-layered. On Kripke structures the modal language is a bounded variable, guarded fragment of first-order logic, while on Kripke frames, due to universal quantification over valuations, it becomes a fragment of universal monadic second-order logic. Each of these semantic layers leads to its own model-theoretic agenda and development, but the two interact closely through various model-theoretic constructions and preservation results presented here, and blend together in the notion of general frames, dually re-incarnated as modal algebras. General frames emerge as a third, intermediate semantic layer of modal logic, casting a bridge between the other two. In particular, by means of a hierarchy of persistency properties, general frames provide a yardstick to measure the 'expressive complexity' of modal formulae, and determine their model-theoretic

[19] More precisely, in every finite frame in which each state is reachable from any other state by a path of length ≤ 2.

behaviour. This chapter presents the basics of the modal model theory in each of these three layers and illustrates the use of the main tools and results arising in each one of them.

While trying to give a comprehensive account of the main issues and results of both classical and modern model theory of modal logic, we have not covered a number of important and relevant topics and research developments, either for lack of space or because they are adequately treated in other chapters of this handbook. A certainly incomplete list of the more conspicuous omissions (in no particular order) includes:

- model theory of extended modal languages: see [18] and [122] for a recent treatise;
- model theory of combined modal logics: see Chapter 15 of this handbook and [35];
- Lindström-type theorems for modal logic: see [19, 133];
- reductions of polyadic to monadic modal languages and their model theoretic implications, including transfer of properties: see [85, 41], and Chapter 8 of this handbook;
- Kracht's internal definability theory [84];
- Zakharyaschev's canonical formulae, providing a uniform characterisation of normal modal logics extending K4: see [10, 9], and Chapter 7 of this handbook;
- model-building techniques such as mosaics and networks used for more advanced completeness and decidability proofs: see, e.g., [99] and [5, Ch. 6.4 and 7.4].
- model completions in modal logic [39];
- bisimulation quantifiers and their use for proving uniform interpolation of various modal logics by Visser [139], Ghilardi and Zawadowski [39] (where bisimulation quantifiers are related to model completions), and of the modal mu-calculus by D'Agostino and Hollenberg [16].

It is natural to conclude a handbook chapter by attempting to identify main general trends of the current and future development of the topic under consideration.

To begin with, let us recall and revisit van Benthem's three 'pillars of wisdom' supporting the classical edifice of modal logic: the *Definability (Correspondence), Completeness, and Duality theories* [128]. Each of these has played a crucial role in the development of modal model theory, and will continue to play such a role, with an accordingly modernised and updated agenda.

In particular, analysing the expressive power of modal languages with respect to each of its semantic layers remains one of the main directions of research in modal logic, of growing importance and complexity, due to the active expansion and diversification of modal logic. Accordingly, the classical correspondence theory between modal and first-order logic, much of which has been reflected in the chapter, is gradually ramifying into a hierarchy of correspondence theories, aiming at mapping the variety of modal logics into the hierarchy of classical logical languages centered around first-order logic. An example is the currently emerging correspondence theory between modal logic and LFP.

Establishing completeness results of modal deductive systems designed to capture an intended semantics also remains one of the core areas of modal logic (as of logic in general) which requires increasingly sophisticated and powerful techniques to match the more and more complex modal languages and their semantics. The involved completeness proofs for the modal mu-calculus (see Chapter 12 of this handbook) and CTL* (see [111]), and the still open completeness problem for Parikh's (full) Game Logic (see Chapter 20 of this handbook) are cases in point.

Likewise for decidability and complexity, where model-theoretic tools and techniques, such as the model-building techniques mentioned above as well as game-theoretic methods, are gaining increasing recognition and variety of applications.

New directions and problem areas in modal model theory itself, or using model-theoretic methods, are emerging, too. Many of them, such as finite model theory and descriptive complexity, finite and infinite state model checking, arise from actual or potential applications of modal logic to computer science and related fields and follow recent trends in classical model theory. Let us note, however, that while the present day model theory of modal logic is still using mainly results and techniques from the classical era of first-order model theory, the enormous development and sophistication of that field over the past decades is yet to make its full impact on modal model theory.

In closing, being aware that we cannot possibly offer a definitive treatment of such a rich and dynamic subject as the model theory of modal logic, we hope to have whetted readers' appetites and their desire to explore it further and to add to it new discoveries of their own.

ACKNOWLEDGEMENTS

We are indebted to Maarten de Rijke for his careful reading, critical remarks, corrections and numerous helpful suggestions for improvement. We also thank Achim Blumensath, Willem Conradie, Ian Hodkinson, Mark Reynolds, Balder ten Cate and Johan van Benthem for valuable comments or corrections. Most of the work of Valentin Goranko on this chapter was done while he worked at the Rand Afrikaans University (now, the University of Johannesburg), and he would like to acknowledge the financial support provided by that university and by the National Research Foundation of South Africa. Martin Otto was partially supported by a British EPSRC grant, originally held at the University of Wales Swansea, during a major period of his work on this chapter.

1 INTRODUCTION

Modal logic is not an isolated field. When studied from a mathematical perspective, it has evident connections with many other areas in logic, mathematics and theoretical computer science. Other chapters of this handbook point out some of the links between modal logic and areas like (finite) model theory or automata theory. Here we will outline the *algebraic* and *coalgebraic* environments of the theory of modal logic.

First we approach modal logic with the methodology of *algebraic logic*, a discipline which aims at studying all kinds of logics using tools and techniques from universal algebra — in fact, much of the theory of universal algebra was developed in tandem with that of algebraic logic. The idea is to associate, with any logic L, a class $\mathsf{Alg}(L)$ of algebras, in such a way that (natural) logical properties of L correspond to (natural) algebraic properties of $\mathsf{Alg}(L)$. Carrying out this program for modal logic, we find that normal modal logics have algebraic counterparts in varieties of *Boolean algebras with operators* (BAOs). In the simplest case of monomodal logics, the algebras that we are dealing with are simply *modal algebras*, that is, expansions of Boolean algebras with a single, unary operation that preserves finite joins (disjunctions). One advantage of the algebraic semantics over the relational one is that it allows a general *completeness* result, but the algebraic approach may also serve to prove many significant results concerning properties of modal logics such as completeness, canonicity, and interpolation. As we will see, a crucial observation in the algebraic theory of modal logic is that standard algebraic constructions correspond to well-known operations on Kripke frames. These correspondences can be made precise in the form of categorical *dualities*, which may serve to explain much of the interaction between modal logic and universal algebra. Our discussion of the algebraic approach towards modal logics takes up the sections 3 to 8.

The *coalgebraic* perspective on modal logic is much more recent (see section 9 for references). Coalgebras are simple but fundamental mathematical structures that capture the essence of dynamic or evolving systems. The theory of universal coalgebra seeks to provide a general framework for the study of notions related to (possibly infinite) behavior such as invariance, and observational indistinguishability. When it comes to modal logic, an important difference with the algebraic perspective is that coalgebras *generalize* rather than *dualize* the model theory of modal logic. Many familiar notions and constructions, such as bisimulations and bounded morphisms, have analogues in other fields, and find their natural place at the level of coalgebra. Perhaps even more important is the realization that one may generalize the concept of modal logic from Kripke frames to arbitrary coalgebras. In fact, the link between (these generalizations of) modal logic and coalgebra is so tight, that one may even claim that modal logic is the natural logic for coalgebras — just like equational logic is that for algebra. The second and last part of this chapter, starting from section 9, is devoted to coalgebra.

What is the point of taking such an abstract perspective on modal logic, be it algebraic or coalgebraic? Obviously, making the above kind of mathematical generalizations, one should not aim at solving all concrete problems for specific modal logics. Rather, the approach may serve to isolate those aspects of a problem that are easy in the sense of being solvable by general means; it thus enables us to focus on the remaining aspects that are specific to the problem at hand. To give an example, it is certainly not the case that all modal formulas are canonical, but Sahlqvist's theorem considerably simplifies completeness proofs by taking care of the canonical part of the axiomatization. A second

benefit of embedding modal logic in its mathematical context is that it may lead to a better understanding of notions from modal logic. Taking an example from coalgebra, the notion of a bounded morphism between Kripke models (or frames), becomes much more natural once we understand that it coincides with the natural coalgebraic notion of a homomorphism.

Our main aim with this chapter is to give the reader an impression of both the algebraic and the coalgebraic perspective on modal logic. Our focus will be on concepts and ideas, but we will also mention important techniques and landmark results; proofs, or rather proof sketches, are given as much as possible. Despite its over-average length, a text of this size cannot come close to being comprehensive; our main selection criterion has been to focus on *generality* of methods and results. Unfortunately, even some important topics have fallen prey to this, most particularly, the *algebras of relations*, even though they played and continue to play a crucial role in the history of algebraic logic. Fortunately, these kinds of BAOs are well documented elsewhere, see for instance HENKIN, MONK & TARSKI [57] for cylindric algebras, or HIRSCH & HODKINSON [58] for relation algebras. A second topic receiving only fragmented attention is *historical context*. While we do attribute results as much as possible, readers with an interest in the (fascinating!) history of modal logic, will not find much to suit their taste here. Rather, they should consult GOLDBLATT [44], or perhaps the historical notes of BLACKBURN, DE RIJKE & VENEMA [13]. Finally, a warning: in this chapter we assume familiarity with basic notions from category theory (such as functors, duality), universal algebra (such as congruences, free algebras), and more specifically, Boolean algebras. Readers encountering unfamiliar concepts in this chapter are advised to consult some text book in universal algebra or category theory. For convenience, in an appendix we have summed up all the material that we consider to be background knowledge.

2 BASICS OF MODAL LOGIC

In this section we briefly review the basic definitions of modal logic. Starting with syntax, we take a fairly general approach towards modal languages and allow modal connectives of arbitrary finite rank. A *modal similarity type* is a set τ of modal connectives, together with an arity function $ar : \tau \to \omega$ assigning to each symbol $\nabla \in \tau$ a *rank* or *arity* $ar(\nabla)$. Given a modal similarity type τ and a set X of variables we inductively define the set $Fma_\tau(X)$ of *modal τ-formulas in X* by the following rule:

$$\varphi ::= x \in X \mid \top \mid \bot \mid \neg\varphi \mid \varphi \wedge \psi \mid \varphi \vee \psi \mid \nabla(\varphi_1, \ldots, \varphi_n)$$

with $\nabla \in \tau$ and $n = ar(\nabla)$. We will use standard abbreviations such as $\to$ and $\leftrightarrow$; we also define the *dual* operator Δ of $\nabla \in \tau$ as $\Delta(\varphi_1, \ldots, \varphi_n) := \neg\nabla(\neg\varphi_1, \ldots, \neg\varphi_n)$. Unary modalities are usually called *diamonds*, and their duals, *boxes*; to denote these modalities we reserve (possibly indexed) symbols of the shape $\Diamond$ and $\Box$, respectively.

Throughout this chapter we will work with an arbitrary but fixed modal similarity type τ. Often, we will provide proofs only for the *basic modal similarity type* which consists of a single diamond that will always simply be denoted as $\Diamond$ (its dual as $\Box$). Unless explicitly stated otherwise, we are always dealing with a fixed, countably infinite set X of variables; in order not to clutter up notation we will suppress explicit references to X as much as possible.

It will be convenient to have names and notation for some special formulas that behave just like ordinary diamond formulas of the form $\Diamond v$. Fix a special dummy variable v. In the basic modal language, we may define a *compound diamond* as any disjunction of formulas of the form $\Diamond^n v$ (here $\Diamond^0\varphi := \varphi$ and $\Diamond^{n+1}\varphi := \Diamond\Diamond^n\varphi$). In a language with diamonds only, the compound diamonds may be defined as follows:

$$\blacklozenge ::= v \mid \Diamond_i\blacklozenge \mid \blacklozenge_1 \vee \blacklozenge_2.$$

An example is $\Diamond_1\Diamond_0(\Diamond_1 v \vee v) \vee \Diamond_1\Diamond_1 v$. We will write $\blacklozenge\varphi$ for the formula in which every occurrence of v is substituted by φ (note that v is the *unique* variable occurring in a compound diamond). Induced and compound *boxes* are defined in the obvious, dual, way.

The general case, which readers may safely choose to skip, is a bit more involved. For any modality ∇ of arity $n > 1$, and any $1 \leq i \leq n$, the formula $\Diamond_{(\nabla,i)}v := \nabla(\top,\ldots,\top,v,\top,\ldots,\top)$ (i.e., all arguments are $\top$ except for the i-th one which is v) is called the i-th *induced diamond* of ∇. The collection $CD(\tau)$ of *compound diamonds* of τ is defined via:

$$\blacklozenge ::= v \mid \Diamond_i\blacklozenge \mid \Diamond_{(\nabla,i)}\blacklozenge \mid \blacklozenge_1 \vee \blacklozenge_2.$$

Modal logic can be approached from a semantic or from a purely syntactic/axiomatic angle. In this chapter we follow both approaches, starting with the semantic one.

DEFINITION 1. A *τ-frame* is a structure $\mathbb{S} = \langle S, R\rangle$ where S is a non-empty set of objects called *states*, *points*, or *worlds*, and R is an interpretation assigning an $n+1$-ary relation R_∇ on S to every n-ary modal connective ∇. A *valuation* on $\mathbb{S}$ is a map $V : X \to \mathcal{P}(S)$ assigning a subset of S to each variable x. A *τ-model* is a structure $\mathbb{M} = \langle S, R, V\rangle$ such that $\langle S, R\rangle$ is a τ-frame, on which V is a valuation; the frame $\langle S, R\rangle$ is called the *underlying frame* of $\mathbb{M}$.

The notion of *truth* is defined by formula induction. The set of points where φ is true will always be denoted as $[\![\varphi]\!]$.

DEFINITION 2. Given a τ-model $\mathbb{M}$, we define by induction when a formula φ is *true* at a state s of $\mathbb{M}$, notation: $\mathbb{M}, s \Vdash \varphi$:

$$\begin{array}{rll}
\mathbb{M}, s \Vdash x & \text{if} & s \in V(x), \\
\mathbb{M}, s \Vdash \top & & \text{always}, \\
\mathbb{M}, s \Vdash \bot & & \text{never}, \\
\mathbb{M}, s \Vdash \neg\varphi & \text{if} & \mathbb{M}, s \not\Vdash \varphi, \\
\mathbb{M}, s \Vdash \varphi \wedge \psi & \text{if} & \mathbb{M}, s \Vdash \varphi \text{ and } \mathbb{M}, s \Vdash \psi, \\
\mathbb{M}, s \Vdash \varphi \vee \psi & \text{if} & \mathbb{M}, s \Vdash \varphi \text{ or } \mathbb{M}, s \Vdash \psi, \\
\mathbb{M}, s \Vdash \nabla(\varphi_1,\ldots,\varphi_n) & \text{if} & R_\nabla s s_1 \ldots s_n \text{ for some } s_1,\ldots,s_n \text{ such that } \mathbb{M}, s_i \Vdash \varphi_i \text{ for} \\
& & \text{all } i \leq n.
\end{array}$$

We write $\mathbb{M} \Vdash \varphi$ if φ is true *throughout* $\mathbb{M}$, that is, true at every state of $\mathbb{M}$.

DEFINITION 3. Given a τ-frame $\mathbb{S}$, we say that a modal formula φ is *valid* in $\mathbb{S}$, notation: $\mathbb{S} \Vdash \varphi$ if φ is true throughout any model based on $\mathbb{S}$. Similarly standard definitions apply to sets of formulas and classes of frames.

Using the notation $Q[s] := \{t \mid Qst\}$ for any binary relation Q, we define the relation $R_{\mathbb{S}}$ such that $R_{\mathbb{S}}[s]$ consists of those points that can be reached from s in one step using any of the accessibility relations, and R^{ω} as the reflexive and transitive closure of $R_{\mathbb{S}}$.

We may extend the interpretation R of a τ-frame $\mathbb{S} = \langle S, R\rangle$ to the compound diamonds by putting

$$\begin{array}{rcl} R_{v} & := & Id\ (= \{(s,s) \mid s \in S\}) \\ R_{\diamond_{(\nabla,i)}\blacklozenge} & := & \{(s, s_i) \mid R_{\nabla} s s_1 \cdots s_n \text{ for some } s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_n \in S\} \circ R_{\blacklozenge}, \\ R_{\diamond\blacklozenge} & := & R_{\diamond} \circ R_{\blacklozenge}, \\ R_{\blacklozenge_1 \vee \blacklozenge_2} & := & R_{\blacklozenge_1} \cup R_{\blacklozenge_2}. \end{array}$$

It is then straightforward to verify, in any frame $\mathbb{S}$, that $R^{\omega} = \bigcup_{\blacklozenge \in CD(\tau)} R_{\blacklozenge}$, and that for any valuation V it holds that

$$\mathbb{S}, V, s \Vdash \blacklozenge\varphi \text{ iff } \mathbb{S}, V, t \Vdash \varphi \text{ for some } t \text{ with } R_{\blacklozenge}st.$$

That is, compound diamonds indeed behave like diamonds.

Frames and models do not exist in isolation. Given two τ-frames $\mathbb{S}$ and $\mathbb{S}'$, a map $\theta : S \to S'$ is called a *bounded morphism* from $\mathbb{S}$ to $\mathbb{S}'$, notation: $\theta : \mathbb{S} \to \mathbb{S}'$, if θ satisfies the following conditions for all $\nabla \in \tau$:

(forth) $R_{\nabla} s s_1 \ldots s_n$ only if $R'_{\nabla}\theta(s)\theta(s_1)\ldots\theta(s_n)$, and

(back) $R'_{\nabla}\theta(s)s'_1 \ldots s'_n$ only if there are $s_1, \ldots, s_n$ such that $R_{\nabla} s s_1 \ldots s_n$ and $\theta(s_i) = s'_i$ for each i.

We let Fr_{τ} denote the category with τ-frames as objects and bounded morphisms as arrows.

If such a bounded morphism θ is surjective, we call $\mathbb{S}'$ a *bounded morphic image* of $\mathbb{S}$, notation: $\mathbb{S} \twoheadrightarrow \mathbb{S}'$; if θ is injective we write $\mathbb{S} \rightarrowtail \mathbb{S}'$ and call the subframe of $\mathbb{S}'$ based on the image $\theta[S]$ a *generated subframe* of $\mathbb{S}'$. We leave it for the reader to verify that the structure $\langle T, R{\restriction}T\rangle$ (where $R{\restriction}T$ maps each $\nabla \in \tau$ to the *restriction* of R_{∇} to T) is a generated subframe of $\mathbb{S}$ if and only if T is a *hereditary* subset of S, that is, if $t \in T$ then $R_{\nabla} t t_1 \ldots t_n$ implies that all the t_i belong to T. Given a point r in $\mathbb{S}$, we denote with $\mathbb{S}_r$ the least generated subframe containing r; the domain of this subframe is thus the set $R^{\omega}[r]$. If $\mathbb{S} = \mathbb{S}_r$ we call r a *root* of $\mathbb{S}$, and say that $\mathbb{S}$ is *rooted*. Finally, given a *family* $\{\mathbb{S}_i \mid i \in I\}$ of τ-frames, we define its *disjoint union* $\sum_{i\in I} \mathbb{S}_i$ as the structure $\langle \sum_{i\in I} S_i, \{R_{\nabla} \mid \nabla \in \tau\}\rangle$, where the domain $\sum_{i\in I} S_i = \bigcup_{i\in I}\{i\} \times S_i$ is the disjoint union of the domains S_i, and the relation R_{∇} is given by $R_{\nabla}(i,s)(i_1,s_1)\ldots(i_n,s_n) \;:\Longleftrightarrow\; i = i_1 = \ldots = i_n$ and $(R_i)_{\nabla} s s_1 \ldots s_n$.

REMARK 4. More general than Kripke frames are the neighborhood frames, which we now review very briefly, and for the basic modal similarity type only. The reader can find more details on these structures in Chapter 1 of this volume. A *neighborhood frame* is a structure $\mathbb{S} = \langle S, \sigma\rangle$ with $\sigma : S \to \mathcal{PP}(S)$; such a structure is called *monotone* if $\sigma(s)$ is upwards closed for all $s \in S$, that is, $X \in \sigma(s)$ and $X \subseteq Y$ imply $Y \in \sigma(s)$. Elements of $\sigma(s)$ are called *neighborhoods* of s, and the semantics of the modality ∇ (we will not use $\diamond$ and $\Box$ in this context) in a *neighborhood model* $\mathbb{M} = \langle S, \sigma, V\rangle$ with $V : X \to \mathcal{P}(S)$ a valuation is given by

$$\mathbb{M}, s \Vdash \nabla\varphi \text{ if } [\![\varphi]\!] \in \sigma(s), \tag{1}$$

that is, $\nabla\varphi$ holds at s iff s has a neighborhood of φ-points. Both the box and the diamond interpretation in Kripke models follow the pattern of (1): take $\sigma_\Diamond(s) = \{A \subseteq S \mid A \cap R[s] \neq \varnothing\}$, and $\sigma_\Box(s) = \{A \subseteq S \mid R[s] \subseteq A\}$, respectively.

A map $f : S \to S'$ is a *neighborhood morphism* between two neighborhood frames $\langle S, \sigma\rangle$ and $\langle S', \sigma'\rangle$ if for all $s \in S$ and all $X' \subseteq S'$ it holds that $X' \in \sigma'(fs)$ iff $f^{-1}[X'] \in \sigma(s)$.

Now we turn to the more syntactic approach towards modal logic. We identify logics with sets of theorems — the more general approach based on *consequence relations* will be discussed in Chapter 8 of this book. A *modal τ-logic* is then a set $L \subseteq Fma_\tau$ which (i) contains all classical propositional tautologies, and (ii) is closed under the derivation rules (MP) of *Modus Ponens* (if both φ and $\varphi \to \psi$ belong to L then so does ψ), and (US) of *uniform substitution* (if φ belongs to L then so do all of its substitution instances). If a formula φ belongs to a modal logic L then we say that φ is a *theorem* of L, notation: $\vdash_L \varphi$.

A modal logic is called *classical* if it is closed under the following rule: $\vdash_L \varphi_i \leftrightarrow \psi_i \Rightarrow \vdash_L \nabla(\varphi_1, \ldots, \varphi_n) \leftrightarrow \nabla(\psi_1, \ldots, \psi_n)$; *monotone* if it is closed under $\vdash_L \varphi_i \to \psi_i \Rightarrow \vdash_L \nabla(\varphi_1, \ldots, \varphi_n) \to \nabla(\psi_1, \ldots, \psi_n)$; and *normal* if it contains in addition, for each $\nabla \in \tau$, the axioms $\neg\nabla^i\bot$ and $\nabla(\overline{p}, q \vee q', \overline{r}) \to \nabla(\overline{p}, q, \overline{r}) \vee \nabla(\overline{p}, q', \overline{r})$ where $\overline{p}$ and $\overline{r}$ denote arbitrary sequences of propositional variables of combined length $ar(\nabla) - 1$. We leave it as an exercise for the reader to verify that this definition coincides with the standard one in the case of basic modal logic.

The *minimal* classical, monotone and normal modal logics for a similarity type τ are denoted as $\mathbf{C}_\tau$, $\mathbf{M}_\tau$ and $\mathbf{K}_\tau$, respectively. Here we use the convention that $\mathbf{C}$, $\mathbf{M}$ and $\mathbf{K}$ denote the minimal logics for the basic modal similarity type. It is easy to see that the collection of normal modal logics is closed under taking arbitrary intersections and therefore forms a complete lattice under the inclusion ordering. Hence, with any set Γ of τ-formulas we may associate the *least* normal modal τ-logic extending $\mathbf{K}$ and containing all formulas in Γ; this logic is denoted as $\mathbf{K}_\tau.\Gamma$. We say that this logic is *axiomatized* by Γ, since any theorem in $\mathbf{K}_\tau.\Gamma$ can be obtained as the result of a *derivation* from the axioms of the logic (including formulas in Γ) using its derivation rules. Similar definitions and notation apply to extensions of $\mathbf{C}_\tau$ and $\mathbf{M}_\tau$.

The validity relation $\Vdash$ between frames and formulas induces a Galois connection consisting of two maps, *Log* and Fr, defined as follows. Given a class C of frames, $Log(\mathsf{C})$, the *logic of* C, is the set of modal formulas that are valid in C. Conversely, given a set Γ of formulas, let $\mathsf{Fr}(\Gamma)$ denote the class of frames on which Γ is valid. (We call this a Galois connection because we always have $\mathsf{C} \subseteq \mathsf{Fr}(\Gamma)$ iff $\Gamma \subseteq Log(\mathsf{C})$.) The *stable* sets of formulas of this connection, that is, the sets Γ such that $\Gamma = Log(\mathsf{Fr}(\Gamma))$ are called *(Kripke) complete logics* — we leave it for the reader to verify that such sets are indeed normal modal logics. On the other side, the *stable* frame classes, that is, the ones that are closed under the composition $\mathsf{Fr} \circ Log$, are called *(modally) definable*. Not all modal logics are Kripke complete (see Chapter 7 of this volume) and not all frame classes are modally definable (see Chapter 1 of this volume).

3 MODAL LOGIC IN ALGEBRAIC FORM

As indicated in the introduction, it is the aim of algebraic logic to study logic by algebraic means. Nowadays, most people will associate modal logic primarily with relational structures, but, as with other branches of logic, the 19th century infancy of modern symbolic modal logic was completely algebraic, see MacColl [82]). Somehow during the 20th century however, the traditions of algebraic logic and of modal logic got separated, and for decades proceeded without any interaction whatsoever. In particular, while Jónsson & Tarski [70] introduced not only Boolean algebras with operators and their representation over relational structures, but also the rudiments of canonicity and correspondence theory, this seminal work did not mention modal logic, and it was completely overlooked by modal logicians for many years. This is not to say that algebras were to remain absent from the modal logic tradition — they were introduced by Lemmon [80]. But only in the 1970s, probably with the discovery of the fundamental incompleteness of the relational semantics by Thomason [102], did universal algebraic (and topological) methods regain importance — as examples we mention Blok [14], Esakia [23], Goldblatt [37, 38], and Rautenberg [91]. And it would even have to wait until the 1990s before the algebraic and modal traditions would be completely rejoined, with collaborations between modal and algebraic logicians (leading to, for instance, the introduction of the guarded fragment in Andréka, van Benthem & Németi [7]), with modal logicians investigating algebras of relations from a modal perspective (Marx & Venema [84]), or with algebraic logicians responding to the modal tradition (Jónsson [69]). It is from this perspective that the algebraic part of this chapter has been written.

Before we explain how to *algebraize* modal logic using the key structures of Boolean algebras with operators (BAOs), let us first briefly introduce the algebraic perspective on (propositional) logic itself. Think of proposition letters as atomic objects referring to entities called propositions, and of connectives as function symbols to be interpreted as operations on propositions. Then notice the complete analogy between the definitions of formulas and terms, respectively, and already we have worked our way towards one of the key ideas underlying the algebraic approach towards (propositional) logic: *propositional formulas can be seen as algebraic terms denoting propositions.*

DEFINITION 5. Given a modal similarity type τ, we define its corresponding algebraic similarity type $Bool_\tau$ simply as the union of τ with the Boolean similarity type $Bool = \{\top, \bot, \neg, \wedge, \vee\}$.

We will use $\approx$ as the equality symbol of this algebraic language; as abbreviations we use $\not\approx$ and $\preceq$ in their standard meaning. Since the standard Boolean symbols are function symbols in this algebraic language, we will not use them to denote Boolean combination of equations. For that purpose we let the symbols & and $\Rightarrow$ denote conjunction and implication, respectively.

The set $Fma_\tau(X)$ of formulas over a set of variables X can then be identified with the set $Ter_{Bool_\tau}(X)$ of algebraic $Bool_\tau$-terms over X. More importantly, we may impose *algebraic structure* on formulas.

DEFINITION 6. The τ-*formula algebra* is the structure $\mathbb{F}\mathsf{ma}_\tau := \langle Fma_\tau, \{\heartsuit^{\mathbb{F}\mathsf{ma}_\tau} \mid \heartsuit \in Bool_\tau\}\rangle$, where for each (Boolean or modal) connective $\heartsuit$, its interpretation

$$\heartsuit^{\mathbb{F}\mathsf{ma}_\tau} : \ (\varphi_1, \ldots, \varphi_n) \mapsto \heartsuit(\varphi_1, \ldots, \varphi_n)$$

defines a map of arity $n = ar(\heartsuit)$ on Fma_τ.

As a first advantage of this algebraic point of view, recall that substitutions are completely determined by their values on the variables. Putting this algebraically, for any function σ assigning formulas to variables, the substitution induced by σ is the unique extension $\widetilde{\sigma}$ of σ to an *endomorphism* on the formula algebra. More generally, it is easy to see that given an arbitrary algebra $\mathbb{A}$ of type $Bool_\tau$, any assignment mapping variables to elements of the carrier of $\mathbb{A}$ has a unique extension $\widetilde{\alpha}$ which is a *homomorphism* from $\mathbb{F}\mathsf{ma}_\tau$ to $\mathbb{A}$. That is, we have the following result.

PROPOSITION 7. $\mathbb{F}\mathsf{ma}_\tau$ *is the* ω*-generated absolutely free algebra of the similarity type* $Bool_\tau$.

Logical languages may now be interpreted in many different kinds of algebras; but of course, we are only interested in structures that can plausibly be viewed as algebras of propositions.

EXAMPLE 8. Consider the *truth value* algebra $\mathbb{2}$ of the Boolean similarity type. Its carrier is given as the set $2 = \{0, 1\}$ where 0 ('false') and 1 ('true') are the classical truth values, while its interpretation of the Boolean connectives/function symbols is given by the standard *truth tables*. Given a *valuation* $V : X \to 2$ of truth values to propositional variables, we can simply *compute* the truth value $\widetilde{V}(\varphi)$ of any propositional formula φ, using the unique homomorphism $\widetilde{V} : \mathbb{F}\mathsf{ma}_\tau \to \mathbb{2}$ extending the assignment V. That is, we see another manifestation of the absolute freeness of the formula algebra.

The algebras arising from the relational semantics of modal languages are the so-called complex algebras. (This terminology dates back to the times when subsets of groups were referred to as *complexes* of the group.)

DEFINITION 9. Given an $n+1$-ary relation R on a set S, define the n-ary map $\langle R\rangle$ on the power set of S by

$$\langle R\rangle(a_1, \ldots, a_n) := \{s \in S \mid Rss_1 \ldots s_n \text{ for some } s_1, \ldots, s_n \text{ with } s_i \in a_i \text{ for all } i\}.$$

The *complex algebra* $\mathbb{S}^+$ of a τ-frame $\mathbb{S}$ is obtained by expanding the power set algebra $\mathbb{P}(S)$ with operations $\langle R_\nabla\rangle$ for each modal connective ∇; that is,

$$\mathbb{S}^+ := \langle \mathcal{P}(S), S, \varnothing, \sim_S, \cap, \cup, \{\langle R_\nabla\rangle \mid \nabla \in \tau\}\rangle. \tag{2}$$

Given a frame class C, we let $\mathsf{Cm}(\mathsf{C})$ denote the class of complex algebras of frames in C; conversely, for a class K of algebras, $\mathsf{Str}(\mathsf{K})$ denotes the class of frames whose complex algebras belong to K.

REMARK 10. More generally, given a neighborhood frame $\mathbb{S} = \langle S, \sigma\rangle$, define the map $\sigma^+ : \mathcal{P}(S) \to \mathcal{P}(S)$ by $\sigma^+(A) := \{s \in S \mid A \in \sigma(s)\}$, and define $\mathbb{S}^+$ as the expansion of $\mathbb{P}(S)$ with the operation σ^+.

From the perspective of complex algebras, a *valuation* is nothing but an *assignment* of variables to elements of the complex algebra of $\mathbb{S}^+$. Furthermore, and much more importantly, given a valuation V on a frame $\mathbb{S}$, a straightforward induction proves that

$$\mathbb{S}, V, s \Vdash \varphi \text{ iff } s \in \widetilde{V}(\varphi), \tag{3}$$

where $\widetilde{V} : \mathbb{F}\mathsf{ma}_\tau \to \mathbb{S}^+$ is the unique homomorphism extending V. With the *meaning function* $[\![\cdot]\!]^{\mathbb{S},V}$ defined as the function that maps a formula φ to its *extension* $[\![\varphi]\!] := \{s \in S \mid \mathbb{S}, V, s \Vdash \varphi\}$, what (3) reveals is that, in a slogan, *meaning is a homomorphism*:

PROPOSITION 11. *Let V be some valuation on a τ-frame $\mathbb{S}$. Then the meaning function $[\![\cdot]\!]^{\mathbb{S},V}$ is the unique homomorphism $\widetilde{V} : \mathbb{F}\mathsf{ma}_\tau \to \mathbb{S}^+$ that extends V.*

As a corollary of this, let $\varphi^\approx$ denote the equation $\varphi \approx \top$, then we find that for any τ-frame $\mathbb{S}$, and any τ-formulas φ, ψ:

$$\mathbb{S} \Vdash \varphi \text{ iff } \mathbb{S}^+ \models \varphi^\approx \quad \text{and} \quad \mathbb{S} \Vdash \varphi \leftrightarrow \psi \text{ iff } \mathbb{S}^+ \models \varphi \approx \psi, \tag{4}$$

that is, the validity of a *formula* in the frame $\mathbb{S}$ corresponds to that of an *equation*[1] in the complex algebra of $\mathbb{S}$, and vice versa. We have arrived at one of the most fundamental notion of algebraic logic, namely, that of a class of algebras *algebraizing* a logic.

DEFINITION 12. Let L be a modal τ-logic, and K a class of $Bool_\tau$-algebras. We say that K *algebraizes* L, if we have

$$\vdash_L \varphi \quad \text{iff} \quad \mathsf{K} \models \varphi^\approx, \tag{5}$$

$$\mathsf{K} \models \varphi \approx \psi \quad \text{iff} \quad \vdash_L \varphi \leftrightarrow \psi, \tag{6}$$

for all formulas/terms φ and ψ.

The point of this definition is to alert the reader that algebraizations constitute stronger links between logics and classes of algebras than the mere existence of a completeness result, as would be expressed by (5) on its own. If the class K algebraizes the modal logic L, then it is not just the case that K contains all the information of L through the translation $(\cdot)^\approx$, but also, L encodes the full equational theory of K through the translation mapping an equation $\varphi \approx \psi$ to the formula $\varphi \leftrightarrow \psi$. Furthermore, the second translation is an *inverse* to the first one in the sense that if we translate the formula φ back and forth, the result $\varphi \leftrightarrow \top$ is L-equivalent to φ. Given the Boolean backbone of modal logics, this property holds vacuously, so there is no need to formulate this as an additional clause of the definition.

Also, observe that it immediately follows from the definition that if K algebraizes L, then so does the variety generated by K.

REMARK 13. The above definition is a specific instantiation of a much wider notion, which is due to Blok & Pigozzi [16]. The basic idea of a class of algebras *algebraizing* a logic always involves uniform translations from formulas to equations, and from equations to formulas, that are, modulo equivalence, inverse to each other. But the general case is of course not limited to modal logics, or to logics extending classical propositional logic; also, the translations may be from formulas to sets of equations, and from equations to sets of formulas.

The most important point is however that the natural habitat of the concept is that of *consequence relations* rather than of logics (in our sense of the word, that is, of logics as sets of sentences). In this more general setting, the requirement that the translations are each other's inverse, is expressed on the logical side by means of the consequence relation, and can equivalently be described on the algebraic side using (infinitary versions of) quasi-equations. For more details on modal consequence relations and the way to algebraize them, the reader is referred to Chapter 8 of this volume. For the general theory of algebraizing logics, see Czelakowski [21] or Font & Jansana [26].

[1] In the sequel, we will be sloppy about the distinction between a formula and its equational translation, writing for instance $\mathbb{A} \models \varphi$ if we mean $\mathbb{A} \models \varphi^\approx$.

In any case, it will be clear that we can already state our first algebraization result, the proof of which is immediate from (4):

THEOREM 14. *Let* C *be a class of* τ*-frames. Then* $\mathsf{Cm}(\mathsf{C})$ *algebraizes* $Log(\mathsf{C})$.

Turning to the algebraization of arbitrary modal logics, we now introduce the key players: *Boolean algebras with operators*, together with some related concepts.

DEFINITION 15. Given two Boolean algebras $\mathbb{B}$ and $\mathbb{B}'$, it is often convenient to call a function $f : B \to B'$ a *map from* $\mathbb{B}$ *to* $\mathbb{B}'$. Such a map is called *monotone* if $a \leq b$ in $\mathbb{B}$ implies $f(a) \leq' f(b)$ in $\mathbb{B}'$, *normal* if $f(\bot) = \bot'$, and *additive* if[2] $f(a \vee b) = f(a) \vee' f(b)$, and *multiplicative* if $f(a \wedge b) = f(a) \wedge' f(b)$. We will call an operation $f : B^n \to B$ an *operator* if it is normal and additive in each of its coordinates.

BAE_τ denotes the class of τ*-expanded Boolean algebra*, (shortly, τ-BAEs), that is, of algebras

$$\mathbb{A} = \langle A, \top, \bot, -, \wedge, \vee, \{\nabla^{\mathbb{A}} \mid \nabla \in \tau\} \rangle$$

with a Boolean *reduct* $\langle A, \top, \bot, -, \wedge, \vee \rangle$ that is indeed a Boolean algebra. $\mathbb{A}$ is called a *monotone* τ-expanded Boolean algebra, or a τ-BAM, if each $\nabla^{\mathbb{A}}$ is a monotone operation, and a *Boolean algebra with* τ*-operators*, or τ-BAO, if each $\nabla^{\mathbb{A}}$ is an operator. The classes of these algebras are denoted as, respectively, BAM_τ and BAO_τ. In the case of the basic modal similarity type, we speak of *modal* algebras rather than of τ-BAOs; MA denotes the class of these algebras. Given a set Γ of modal τ-formulas, and a class K of τ-expanded Boolean algebras, we define $\mathsf{K}(\Gamma)$ as the class of algebras in K that validate the set of equations $\Gamma^{\approx} := \{\gamma \approx \top \mid \gamma \in \Gamma\}$.

Given two τ-BAEs $\mathbb{A}$ and $\mathbb{A}'$, we call a map $\eta : A \to A'$ a *Boolean homomorphism* if it is a homomorphism from the Boolean reduct of $\mathbb{A}$ to that of $\mathbb{A}'$, and a *modal homomorphism* it if is a homomorphism with respect to the modal operations. Thus a homomorphism between two τ-BAEs is a map that is both a Boolean and a modal homomorphism. We let BAE_τ, BAM_τ, etc. also denote the category with the τ-BAEs, ..., as objects and the homomorphisms as arrows.

EXAMPLE 16. Algebras of the form $\mathbb{S}^+$, with $\mathbb{S}$ some τ-frame, are the prime specimens of Boolean algebras with operators. These algebras are sometimes referred to as *concrete* BAOs.

More generally, the complex algebra of a neighborhood frame (see Remark 10) is an example of a BAE for the basic modal similarity type; it is easy to see that such an $\mathbb{S}^+$ belongs to BAM iff $\mathbb{S}$ is a monotone neighborhood frame.

Our terminological convention will be that properties of and notions pertaining to Boolean algebras (such as atomicity, completeness, filters, ...) apply to an expanded Boolean algebra as they apply to its underlying Boolean algebras.

All of the properties defined in Definition 15 can be given in equational form, so all of the classes defined there are in fact *varieties*. In the next section we discuss the algebraic properties of these varieties; let us first see why they are so important from a logical perspective. This can be formulated very concisely.

THEOREM 17. *Let* Γ *be a set of modal* τ*-formulas. Then* $\mathsf{BAE}_\tau(\Gamma)$ *algebraizes* $\mathbf{C}_\tau.\Gamma$, $\mathsf{BAM}_\tau(\Gamma)$ *algebraizes* $\mathbf{M}_\tau.\Gamma$, *and* $\mathsf{BAO}_\tau(\Gamma)$ *algebraizes* $\mathbf{K}_\tau.\Gamma$. *In particular,* $\mathsf{MA}(\Gamma)$ *algebraizes* $\mathbf{K}.\Gamma$.

[2]Observe that we write $\vee$ and $\vee'$ rather than $\vee^{\mathbb{A}}$ and $\vee^{\mathbb{A}'}$, respectively; this convention will always apply to the interpretations of the Boolean symbols, and sometimes to the modal connectives as well.

Note that this theorem implies a general, algebraic, *completeness* result: for instance, concerning modal logics in the basic modal similarity type, it states that

$$\vdash_{\mathbf{K}.\Gamma} \varphi \text{ iff } \mathsf{MA}(\Gamma) \models \varphi^{\approx}. \tag{7}$$

That is to say, φ is a theorem of the logic *axiomatized* by Γ if and only if φ is valid in the class of algebras *defined* by Γ.

The key tool in the *proof* of Theorem 17 is played by the so-called *Lindenbaum-Tarski algebra* of a logic. The introduction of this fundamental tool is based on the observation that for all classical modal logics, the notion of logical equivalence is a congruence on the formula algebra.

DEFINITION 18. Let L be a modal τ-logic. The relation $\equiv_L$ between formulas is defined by putting $\varphi \equiv_L \psi$ if $\varphi \leftrightarrow \psi$ is an L-theorem.

PROPOSITION 19. *For any classical modal τ-logic L, the relation $\equiv_L$ is a congruence on the formula algebra $\mathbb{F}\mathsf{ma}_\tau$.*

DEFINITION 20. Given a modal τ-logic L, we denote the congruence class of the formula χ under the relation $\equiv_L$ by $[\chi]_L$; for a set of formulas Φ, we let $[\Phi]_L$ denote the set $\{[\varphi]_L \mid \varphi \in \Phi\}$. The quotient algebra $\mathbb{F}\mathsf{ma}_\tau/{\equiv_L}$ is called the *Lindenbaum-Tarski* algebra of L, notation: $\mathbb{F}_L$.

Note that the elements of the Lindenbaum-Tarski algebra $\mathbb{F}_L$ are the equivalence classes of the relation $\equiv_L$ of the set Fma_τ. The algebraic operations are defined as follows: $\top^{\mathbb{F}_L} = [\top]_L$, $\perp^{\mathbb{F}_L} = [\perp]_L$, $[\varphi]_L \wedge^{\mathbb{F}_L} [\psi]_L = [\varphi \wedge \psi]_L$, etc. We briefly remind the reader that all of these definitions could be parameterized by making the set X of variables explicit.

It is hard to overestimate the importance of Lindenbaum-Tarski algebras. For a start, the algebra $\mathbb{F}_L$ contains all the information of its logic L, in the following sense.

THEOREM 21. *Let L be a modal logic for some similarity type τ. Then for any two τ-formulas φ and ψ, we have*

$$\mathbb{F}_L \models \varphi \approx \psi \textit{ iff } \varphi \equiv_L \psi.$$

Proof. For the direction from left to right, consider the natural assignment $\nu : x \mapsto [x]_L$. It follows from the validity of $\varphi \approx \psi$ in $\mathbb{F}_L$ that $\widetilde{\nu}(\varphi) = \widetilde{\nu}(\psi)$. But an easy formula induction shows that $\widetilde{\nu}(\chi) = [\chi]_L$, for all formulas χ. Hence we obtain that $[\varphi]_L = [\psi]_L$, that is, $\varphi \equiv_L \psi$.

For the reverse direction, let α be some assignment on the Lindenbaum-Tarski algebra. Choose for each variable x a representative $\sigma(x)$ of the equivalence class $\alpha(x)$; that is, for each variable x we have that $\alpha(x) = [\sigma(x)]_L$. Note that this map σ is nothing but a substitution; recall that $\widetilde{\sigma}$ is the extension of σ to all formulas. It is not hard to prove that all formulas χ satisfy $\widetilde{\alpha}(\chi) = [\widetilde{\sigma}(\chi)]_L$. But it follows from $\varphi \equiv_L \psi$ that $\widetilde{\sigma}(\varphi) \equiv_L \widetilde{\sigma}(\psi)$, since L is closed under uniform substitution. Hence we find that $\widetilde{\alpha}(\varphi) = \widetilde{\alpha}(\psi)$. And since α was arbitrary, this shows that $\mathbb{F}_L \models \varphi \approx \psi$, as required. ❑

On the other hand, Lindenbaum-Tarski algebras play an important algebraic role as well, as is concisely formulated in the following Theorem.

THEOREM 22. *For any classical modal τ-logic L, $\mathbb{F}_L$ is the ω-generated free algebra for the variety $\mathsf{BAE}_\tau(L)$.*

Proof. Let $\mathbb{A}$ be an algebra in $\mathsf{BAE}_\tau(L)$, and consider an arbitrary map $\alpha : [X]_L \to A$ (recall that X denotes the set of variables, and that $[X]_L = \{[x]_L \mid x \in X\}$). We will prove that α can be extended to a homomorphism from $\mathbb{F}_L$ to $\mathbb{A}$.

To this aim, consider the composition $\alpha \circ \nu : X \to A$ of α with the natural map $\nu : x \mapsto [x]_L$. It follows from the universal mapping property of $\mathbb{F}\mathsf{ma}_\tau$ over X that this map can be extended to a homomorphism $\widetilde{\alpha \circ \nu} : \mathbb{F}\mathsf{ma}_\tau \to \mathbb{A}$.

We claim that $\ker(\widetilde{\nu}) \subseteq \ker(\widetilde{\alpha \circ \nu})$. To see this, consider formulas φ and ψ such that $(\varphi, \psi) \in \ker(\nu)$; then $[\varphi]_L = [\psi]_L$, and so $\varphi \equiv_L \psi$. It follows from $\mathbb{A}$ being in $\mathsf{BAE}_\tau(L)$ that $\mathbb{A} \models \varphi \approx \psi$, so $\varphi \approx \psi$ certainly holds in $\mathbb{A}$ under the assignment $\alpha \circ \nu$. But that is just another way of saying that $(\varphi, \psi) \in \ker(\widetilde{\alpha \circ \nu})$.

But then from this claim it follows that the map $\widetilde{\alpha} : Fma_\tau/{\equiv_L} \to A$, given by

$$\widetilde{\alpha}([\varphi]_L) := \widetilde{\alpha \circ \nu}(\varphi)$$

is well-defined. It is not hard to show that $\widetilde{\alpha}$ is in fact a homomorphism from $\mathbb{F}_L$ to $\mathbb{A}$, and since it clearly extends α, we have established the universal mapping property of $\mathbb{F}_L$ for $\mathsf{BAE}_\tau(L)$ over $[X]_L$. ❑

Finally, in order to prove the Algebraization Theorem 17 from these two theorems, we need one additional result concerning varieties of the form $\mathsf{BAE}_\tau(L)$ if L is a modal logic axiomatized by a set Γ of formulas. We leave the rather tedious but straightforward proof of this proposition as an exercise for the reader.

PROPOSITION 23. *Let* Γ *be a set of* τ*-formulas. Then* $\mathsf{BAE}_\tau(\mathbf{C}_\tau.\Gamma) = \mathsf{BAE}_\tau(\Gamma)$, $\mathsf{BAE}_\tau(\mathbf{M}_\tau.\Gamma) = \mathsf{BAM}_\tau(\Gamma)$, *and* $\mathsf{BAE}_\tau(\mathbf{K}_\tau.\Gamma) = \mathsf{BAO}_\tau(\Gamma)$.

This finishes our introduction to the algebraization of modal logics. In section 6 we will have a lot more to say about the link between normal modal logics and varieties of BAOs.

4 VARIETIES OF EXPANDED BOOLEAN ALGEBRAS

In this section we discuss what the theory of universal algebra has to say about Boolean algebras with operators and their siblings.

Lattices of congruences

A very important theme in universal algebra has been to relate the properties of a variety to the shape of the congruence lattices of its algebras. In the case of Boolean algebras and their expansions, this has turned out to be particularly fruitful.

DEFINITION 24. An algebra $\mathbb{A}$ has *permuting congruences* if $\Theta_1 \circ \Theta_2 = \Theta_2 \circ \Theta_1$ for all congruences Θ_1, Θ_2 over $\mathbb{A}$; $\mathbb{A}$ is *congruence distributive* if $\mathbb{C}\mathsf{g}(\mathbb{A})$, its lattice of congruences, is distributive.

These properties hold of a variety if they hold of each of its members; and a variety is called *arithmetical* if it is both congruence permutable and congruence distributive.

It is a rather strong property for an algebra to have permuting congruences, or to be congruence distributive, and both notions have important applications. Concerning the second notion, we will see an important property of congruence distributive varieties

in Theorem 35. In order to motivate the first concept here we just mention that it allows a considerable simplification in the computation of joins in congruence lattices: whereas in general the join $\Theta_1 \vee \Theta_2$ of two congruences Θ_1 and Θ_2 is given as $\Theta_1 \vee \Theta_2 = \Theta_1 \ \cup \ (\Theta_1 \circ \Theta_2) \ \cup \ (\Theta_1 \circ \Theta_2 \circ \Theta_1) \ \cup \ \cdots$, in the case of permuting congruence this rearranges itself as $\Theta_1 \vee \Theta_2 = \Theta_1 \circ \Theta_2$.

THEOREM 25. *Varieties of expanded Boolean algebras are arithmetical.*

Proof. This proof can be seen as a consequence of a result by A. Pixley, who proved that a variety is arithmetical if and only if it admits the definition of so-called *Mal'cev* and $\frac{2}{3}$*-majority terms.* For some detail, let V be a variety of expanded Boolean algebras. First consider the ternary (Boolean) term $p(x, y, z)$ given by

$$p(x, y, z) := (x \wedge z) \vee (x \wedge \neg y \wedge \neg z) \vee (\neg x \wedge \neg y \wedge z).$$

We leave it for the reader to verify that this is a *Mal'cev* term, that is,

$$\mathsf{V} \models p(x, x, z) \approx z \text{ and } \mathsf{V} \models p(x, z, z) \approx x. \tag{8}$$

From this it follows that V is congruence permutable: let $\mathbb{A}$ be some algebra in the variety and let $a, b \in A$ be elements such that $(a, b) \in \Theta_1 \circ \Theta_2$ for some congruences Θ_1 and Θ_2. Then there is some $c \in A$ with $(a, c) \in \Theta_1$ and $(c, b) \in \Theta_2$. From this it follows that $(a, b) \in \Theta_2 \circ \Theta_1$, because

$$a = p^{\mathbb{A}}(a, b, b)\Theta_2 p^{\mathbb{A}}(a, c, b)\Theta_1 p^{\mathbb{A}}(c, c, b) = b.$$

This proves that $\Theta_1 \circ \Theta_2 \subseteq \Theta_2 \circ \Theta_1$ which means that $\mathbb{A}$ has permuting congruences. Congruence distributivity can be proven in a similar way: consider the term M given by

$$M(x, y, z) := (x \vee y) \wedge (y \vee z) \wedge (z \vee x).$$

The reader will have little trouble in showing that

$$\mathsf{V} \models M(x, x, y) \approx M(x, y, x) \approx M(y, x, x) \approx x, \tag{9}$$

i.e., M is a $\frac{2}{3}$*-majority term.* In a similar way as above we can then use (9) to show V is congruence distributive. ❑

Congruences and filters

One of the nicest features of BAOs is that their congruences can be characterized by certain *subsets* of the algebra.

DEFINITION 26. Let $\mathbb{B}$ be a Boolean algebra. A subset $F \subseteq B$ is called a *(Boolean) filter* of $\mathbb{B}$ if it (i) contains the top element of $\mathbb{B}$, (ii) is closed under taking meets (that is, if $a, b \in F$ then $a \wedge b \in F$), and (iii) is an *up-set* (that is, $a \in F$ and $a \leq b$ imply $b \in F$). A filter F is *proper* if it does not contain the bottom element of $\mathbb{B}$, or equivalently, if $F \neq B$. We let $Fi(\mathbb{B})$ denote the collection of filters of $\mathbb{B}$.

EXAMPLE 27. It is not difficult to see that the set $Fi(\mathbb{B})$ is closed under taking intersections; hence, we may speak of the *smallest* filter F_D containing a given set $D \subset B$; this filter can also be defined as the following set

$$F_D = \{\top\} \cup \{b \in B \mid \text{ there are } d_1, \ldots, d_n \in D \text{ such that } d_1 \wedge \cdots \wedge d_n \leq b\},$$

which explains why we also refer to this set as the filter *generated by* D. In case that D is a singleton $\{a\}$, we write $a\!\uparrow$ for $F_{\{a\}}$; this set is called the *principal filter generated by* a. Clearly we have $a\!\uparrow := \{b \in \mathbb{B} \mid a \leq b\}$.

The filter F_D is proper iff D has the so-called *finite meet property* (that is, $\bigwedge D_0 > \bot$ for all finite subsets $D_0 \subseteq D$).

DEFINITION 28. Let $\mathbb{A}$ be a BAO; a subset $F \subseteq A$ is a *modal* or *open filter* of $\mathbb{A}$ if F is a filter of (the underlying BA of) $\mathbb{A}$ which is closed under the application of boxes; that is, $a \in F$ implies $\Box_i a \in F$ for all boxes $\Box_i$. (If the language has modalities of arity higher > 1, we need to strengthen this to requiring that F is closed under the application of induced boxes.) The collection of modal filters of $\mathbb{A}$ is denoted as $MFi(\mathbb{A})$.

In any BAO $\mathbb{A}$, the sets $\{\top^{\mathbb{A}}\}$ and A are modal filters; the singleton $\{\top^{\mathbb{A}}\}$ is called the *trivial* (modal) filter of $\mathbb{A}$, and any filter different from A is called *proper*.

The following theorem will prove to be extremely useful.

THEOREM 29. *Let $\mathbb{A}$ be a Boolean algebra with operators. Then*

1. *the collection $MFi(\mathbb{A})$ is closed under taking arbitrary intersections and hence forms a complete lattice with respect to the subset ordering;*

2. *this lattice is isomorphic to the congruence lattice of $\mathbb{A}$ through the isomorphism $\Pi : MFi(\mathbb{A}) \to Cg(\mathbb{A})$ given by*

$$\Pi_M := \{(a, b) \in A \times A \mid a \leftrightarrow b \in M\},$$

and its inverse $N : Cg(\mathbb{A}) \to MFi(\mathbb{A})$ by

$$N_\Theta := \{a \in A \mid (a, \top) \in \Theta\}.$$

It follows from the completeness of the lattice of modal filters of a BAO $\mathbb{A}$, that with each set $D \subseteq A$ we may associate the *smallest* modal filter M_D including D. The following proposition explains why we also refer to M_D as the modal filter *generated by* D:

PROPOSITION 30. *Let $\mathbb{A}$ be a Boolean algebra with τ-operators, and D a subset of A. Then*

$$M_D = \{a \in A \mid \blacksquare_1 d_1 \wedge \ldots \wedge \blacksquare_n d_n \leq a \textit{ for some } \blacksquare_1, \ldots, \blacksquare_n \in CD(\tau),\ d_1, \ldots, d_n \in D\}.$$

In particular, when D is a singleton, say, $D = \{d\}$, we find

$$M_d = \{a \in A \mid \blacksquare d \leq a \textit{ for some } \blacksquare \in CD(\tau),\ d \in D\}.$$

Subdirect irreducibility

We now turn to the algebraic notion of subdirect irreducibility, which plays an important role in the analysis of varieties. The motivation for introducing this concept is the search for the universal algebraic analogon of the prime numbers, as it were. That is, we want to isolate a class of algebraic building blocks that are basic in the sense that (i) every algebra may be decomposed into basic ones, while (ii) the basic ones themselves only

allow trivial decompositions. Now there are various interpretations of the words 'basic' and 'decomposition'.

DEFINITION 31. An algebra $\mathbb{A}$ is *simple* if its only homomorphic images are $\mathbb{A}$ itself and the trivial algebra of its similarity type, and *directly indecomposable* if in any decomposition $\mathbb{A} \cong \prod \mathbb{A}_i$, $\mathbb{A}$ is isomorphic to one of the $\mathbb{A}_i$.

Both of these notions are important and interesting, but neither one is exactly what we want. The notion of simplicity is too restrictive since not every variety is generated by its simple members. And, whereas every finite algebra is isomorphic to a direct product of directly indecomposable algebras, this does not hold for all infinite algebras. For instance, it is not hard to see that the algebra $\mathbb{2}$ of Example 8 is the only nontrivial directly indecomposable Boolean algebra, while a straightforward cardinality argument shows that no countably infinite algebra can be isomorphic to a direct power of $\mathbb{2}$.

Hence, in order to meet our criteria, we arrive at a notion which at first sight may seem somewhat involved. In words, an algebra is subdirectly irreducible iff it does not allow a proper *subdirect* decomposition.

DEFINITION 32. Let $\mathbb{A}$ be an algebra, and $\{\mathbb{A}_i \mid i \in I\}$ a family of algebras of the same type. An embedding η of $\mathbb{A}$ into $\prod_{i\in I} \mathbb{A}_i$ is called *subdirect* if $\pi_i \circ \eta$ is surjective for each projection function π_i. If $\mathbb{A}$ is a subalgebra of $\prod_{i\in I} \mathbb{A}_i$, then we say that $\mathbb{A}$ is a *subdirect product of* the family $\{\mathbb{A}_i \mid i \in I\}$, or that the family forms a *subdirect decomposition of* $\mathbb{A}$, if the inclusion map is a subdirect embedding.

$\mathbb{A}$ is called *subdirectly irreducible*, or, briefly, *s.i.*, if for every subdirect embedding $\eta : \mathbb{A} \to \prod_{i\in I} \mathbb{A}_i$ there is an $i \in I$ such that $\pi_i \circ \eta : \mathbb{A} \to \mathbb{A}_i$ is an isomorphism.

In practice, one always uses a nice characterization of subdirect irreducibility in terms of the congruence lattice of the algebra, and similarly for simple and directly indecomposable algebras. For the proof of this proposition we refer to any standard textbook on universal algebra. For a proper understanding of its formulation, recall that any algebra $\mathbb{A}$ always has at least two congruences: the *diagonal* relation $\Delta_A = \{(a, a) \mid a \in A\}$, and the *global* relation $\Upsilon_A = A \times A$.

PROPOSITION 33. *Let $\mathbb{A}$ be an algebra. Then*

1. *$\mathbb{A}$ is simple iff $Cg(\mathbb{A}) = \{\Delta, \Upsilon\}$;*
2. *$\mathbb{A}$ is directly indecomposable iff there are no two congruences Θ_1 and Θ_2 such that $\Theta_1 \wedge \Theta_2 = \Delta$ and $\Theta_1 \circ \Theta_2 = \Upsilon$;*
3. *$\mathbb{A}$ is subdirectly irreducible iff it has a monolith, that is, a smallest non-diagonal congruence.*

The following theorem can be read as stating that, indeed, subdirect irreducibility is the proper concept when it comes to finding the basic building blocks of varieties.

THEOREM 34 (Birkhoff). *Every algebra can be subdirectly decomposed into subdirectly irreducible algebras. As a corollary, every variety is generated by its subdirectly irreducible members.*

As a corollary of this theorem, we see that the study of the lattice of subvarieties of a given variety can be conducted by way of inspecting the s.i. members of the variety. In the case of expanded Boolean algebras, the logical meaning of this is that it gives us a

tool for the study of extensions of a given modal logic. For, as we will see in section 6 that the subvarieties of the variety determined by a modal logic, correspond to the extensions of that logic. Also, because expanded Boolean algebras are congruence distributive, we may apply *Jónsson's Lemma*. This result involves the class operations H, S and Pu, which are defined in the appendix.

THEOREM 35 (Jónsson). *Let K be a class of algebras such that $\mathsf{Var}(\mathsf{K})$ is congruence distributive. Then all subdirectly irreducible members of $\mathsf{Var}(\mathsf{K})$ belong to $\mathsf{HSPu}(\mathsf{K})$.*

The use of this theorem lies in the fact that if K generates a congruence distributive variety V, then the s.i. members of V still resemble the algebras in K in many ways. For instance, if K is a *finite* set of *finite* members, then $\mathsf{Pu}(\mathsf{K}) = \mathsf{K}$; hence we obtain the following result for finitely generated varieties of expanded Boolean algebras.

COROLLARY 36. *Let K be a finite set of finite τ-expanded Boolean algebras. Then $\mathsf{Var}(\mathsf{K})$ only has finitely many subvarieties, each of which is determined by a subset of $\mathsf{HS}(\mathsf{K})$.*

Finally, restricting our attention to Boolean algebras with operators, we encounter yet another nice property, namely that we can characterize subdirect irreducibility of an algebra by the existence of one *single* element — one with rather special properties, that is.

DEFINITION 37. An element e of a BAO $\mathbb{A}$ is called *essential* or an *opremum* if $e < \top$, while for all $b < \top$ there is a compound modality $\blacklozenge$ such that $\blacksquare b \leq e$. Dually, we say that an element ρ is *radical in* $\mathbb{A}$, or a *radix of* $\mathbb{A}$, if $\rho > \bot$, while for all $a > \bot$ there is a compound modality $\blacklozenge$ such that $\rho \leq \blacklozenge a$.

Clearly, an element e of a BAO is essential iff its complement $-e$ is radical. In the sequel this fact will be used implicitly, context deciding which formulation is the most convenient.

EXAMPLE 38. Let $\mathbb{S}$ be a *rooted* frame with root r. It is easy to see that the singleton $\{r\}$ is radical in $\mathbb{S}^+$: let $a \subseteq S$ be a nonempty element of $\mathbb{S}^+$. Take an element s from a; since r is a root of $\mathbb{S}$, there must be some compound modality $\blacklozenge$ such that $R_\blacklozenge rs$; from this it is immediate that $\{r\} \subseteq \langle R_\blacklozenge \rangle a$.

The following theorem (or at least, the more important statement concerning subdirect irreducibility) is due to Rautenberg, see for instance [91].

THEOREM 39. *Let $\mathbb{A}$ be a nontrivial Boolean algebra with τ-operators. Then $\mathbb{A}$ is simple iff every non-top element of A is essential, and subdirectly irreducible iff it has an essential element.*

Proof. It follows immediately from Theorem 29 that $\mathbb{A}$ is s.i. iff it has a smallest non-trivial modal filter, and it is not hard to see that any such filter is of the form M_e for some element e of $\mathbb{A}$. The proof of the statement on subdirect irreducibility is thus complete if we can show that for an arbitrary element $e \in A$:

$$M_e \text{ is a smallest nontrivial modal filter iff } e \text{ is essential.} \tag{10}$$

First suppose that M_e is a smallest nontrivial modal filter. Since M_e is nontrivial, it follows immediately that $e \neq \top$. In order to show that e is essential, consider an arbitrary element $a < \top \in A$, and consider the filter M_a generated by a. It follows from

our assumption on M_e that $M_e \subseteq M_a$, so that $e \in M_a$. Hence we may deduce from Proposition 30 that there is some compound modality $\blacklozenge$ such that $\blacksquare a \leq e$. This suffices to prove that e is essential.

For the converse direction, suppose that e is essential, and let M be an arbitrary nontrivial modal filter on $\mathbb{A}$. That is, $M \neq \{\top\}$, so M contains an element $a \neq \top$. but then it follows from the essentiality of e that there is some compound modality $\blacklozenge$ such that $\blacksquare a \leq e$; this shows that $e \in M$, whence $M_e \subseteq M$. In other words, M_e is the smallest modal filter on $\mathbb{A}$.

The proof concerning simplicity is completely similar and therefore left as an exercise. ❑

5 FRAMES AND ALGEBRAS

5.1 *Introduction*

The algebraic study of modal logic was started in section 3. Its main result, Theorem 17, links normal modal logics to varieties of Boolean algebras with operators by stating a general algebraization result. But no matter how well-behaved these algebras are, most modal logicians will still prefer the relational semantics, either because they find it more intuitive, or because frames simply happen to be the structures in which they take an (application driven) interest. Hence there is an obvious need to understand the precise relation between the worlds of frames and algebras, respectively. As we will discuss in this section, much of this relation can be understood within the framework of two dualities, both of which relate algebras to (topological) frames, and one forgetful functor. In order to explain why *two* dualities are needed, it is best to consider *finite* structures first. For the sake of a smooth presentation we confine ourselves to the basic modal language.

Let $\mathsf{FinFram}$ and FinMA denote the respective categories of finite frames with bounded morphisms, and of finite modal algebras with homomorphisms. Recall that in Definition 9 we coded up a frame $\mathbb{S} = (S, R)$ by means of its *complex algebra* $\mathbb{S}^+$. Conversely, if $\mathbb{A} = \langle A, \perp, \top, -, \wedge, \vee, \diamond \rangle$ is a finite modal algebra, then we can base a frame on the set $At(\mathbb{A})$ of *atoms* (see Definition 40) of $\mathbb{A}$ by putting

$$R_\diamond pq \ :\Longleftrightarrow \ \ p \leq \diamond q.$$

It is then easy to see that

$$\mathbb{S} \cong (\mathbb{S}^+)_+ \text{ and } \mathbb{A} \cong (\mathbb{A}_+)^+$$

for an arbitrary finite frame $\mathbb{S}$ and an arbitrary finite modal algebra $\mathbb{A}$. And, with the appropriate extension of the constructions $(\cdot)^+$ and $(\cdot)_+$ to functors, we can in fact establish that

$$(\cdot)^+ \text{ and } (\cdot)_+ \text{ form a dual equivalence between } \mathsf{FinFram} \text{ and } \mathsf{FinMA}. \tag{11}$$

Unfortunately, there is no way to remove the restriction to finite structures in (11) and obtain a dual equivalence between the categories Fr and MA. In fact, since the category MA has an initial object (the free modal algebra over zero generators), while Fr does not have a final object (cf. section 10 for details), *no* duality whatsoever can be established between these two categories. However, there *is* a natural way to associate a frame with an arbitrary modal algebra $\mathbb{A}$, if we let *ultrafilters* generalize the notion of an atom. That

is, we can simply base the *ultrafilter frame* $\mathbb{A}_\bullet$ of $\mathbb{A}$ on the collection of ultrafilters of (the Boolean reduct of) $\mathbb{A}$ by putting

$$R_\Diamond uv \;:\Longleftrightarrow\; \Diamond a \in u \text{ for all } a \in v.$$

Again, this construction can be extended to a functor $(\cdot)_\bullet$ from MA to Fr.

We will see that there is interesting interaction between the functors $(\cdot)^+$ and $(\cdot)_\bullet$. The most important result is the Jónsson-Tarski representation theorem stating that every modal algebra $\mathbb{A}$ can be embedded in its 'double dual' $\mathbb{A}^\sigma := (\mathbb{A}_\bullet)^+$. As we will see in the next section, this result lies at the root of the application of algebra in modal completeness results.

While there is no duality between the categories Fr and MA, with some modifications, both functors $(\cdot)^+$ and $(\cdot)_\bullet$ do provide interesting dualities. Here there are two basic observations. First, the complex duality functor $(\cdot)^+$ is injective on objects; that is, any frame may be recovered (modulo isomorphism) from its complex algebra. Second, although the functor $(\cdot)_\bullet$ does not have this property (sse Example 53), there is a simple remedy for this problem, namely, to *add* the missing information, topologically encoded, to the frame $\mathbb{A}_\bullet$ of an algebra $\mathbb{A}$. Thus we see that two fairly nice dualities can be found if we remove the finiteness constraint on *either* side of the duality (11):

- a 'complex' or 'discrete' duality obtains (see Theorem 47) if we consider the entire category on the frame side, and a *subcategory* of *perfect* algebras with *complete* homomorphisms on the other side;
- a 'topological' duality obtains (see Theorem 67) if, conversely, we keep the category on the algebra side intact, but *add topological structure* on the frame side.

Both dualities restrict to (11) in the finite case, and the topological and the complex duality are linked by the functor that *forgets* the topological structure on the frame side. Furthermore, similar results can be proved connecting (monotone) neighborhood frames and (monotone) expanded Boolean algebras. In fact, the picture sketched above applies to far wider contexts [68].

For a brief overview of this section, below we first introduce the above mentioned functors and dualities, in some detail. We then see how the algebraic notions of subdirect irreducibility and simplicity turn up on the other side of this duality. We finish the section with a brief discussion of the interaction of the functors $(\cdot)^+$ and $(\cdot)_\bullet$ with more 'intrinsic' constructions on algebras and frames such as products and disjoint unions.

5.2 Complex duality

We have already seen how to transform frames into algebras; we now consider these complex algebras from a more abstract perspective. In order to characterize them among the class of all Boolean algebras with operators, we need some terminology.

DEFINITION 40. A Boolean algebra $\mathbb{B}$ is called *complete* if it is complete as a lattice, that is, if every subset X of B has both a meet (or greatest lower bound) $\bigwedge X$ and a join (or least upper bound) $\bigvee X$. $\mathbb{B}$ is called *atomic* if below every non-bottom element of $\mathbb{B}$ there is an *atom*, (i.e., an element p satisfying $\bot < p$ while there is no a such that $\bot < a < p$).

Now let $\mathbb{B}$ and $\mathbb{B}'$ be two Boolean algebras; a map $f : B \to B'$ is called *completely additive* if it preserves all non-empty joins, that is, if for all non-empty subsets X of B for which $\bigvee X$ exists, it holds that

$$f(\bigvee X) = \bigvee' f[X].$$

An n-ary operation f on a Boolean algebra $\mathbb{B}$ is called a *complete operator* if it preserves all joins in each coordinate (or, equivalently, if it is normal and completely additive in each of its coordinates). Finally, a Boolean algebra with operators is called *perfect* if it is complete and atomic, and all its operators are complete.

The reader can easily verify that all complex algebras are perfect. It is equally easy to see that every finite BAO is perfect, since such an algebra has no infinite joins, and a straightforward induction proves that operators preserve finite joins in each of their arguments. For an example of an operator that is not complete, let S be an infinite set, and define $f : \mathcal{P}(S) \to \mathcal{P}(S)$ by putting $f(X) = X$ if X is finite while $f(X) = S$ otherwise.

In the very same way as we defined above for finite structures, given a perfect BAO we can define a frame based on the set of atoms of $\mathbb{A}$. In fact, for the definition to make sense, we only need the BAO to be atomic.

DEFINITION 41. Let $\mathbb{B}$ be an atomic Boolean algebra, and f an n-ary operator on $\mathbb{B}$. Define the $n+1$-ary relation Q_f on $At(\mathbb{B})$ by

$$Q_f p_0 p_1 \dots p_n \;:\Longleftrightarrow\; p_0 \leq f(p_1, \dots, p_n).$$

Given an atomic τ-BAO $\mathbb{A}$, define its *atom structure* $\mathbb{A}_+$ as the τ-frame $\mathbb{A}_+ = \langle At\mathbb{A}, \{Q_{\nabla^{\mathbb{A}}} \mid \nabla \in \tau\}\rangle$.

Now that we have ways to turn frames into atomic algebras and vice versa, the natural question is how these constructions interact. The following proposition seems to be folklore.

PROPOSITION 42. *Let, for a modal similarity type τ, $\mathbb{S}$ be a τ-frame, and $\mathbb{A}$ an atomic τ-BAO. Then*

1. $\mathbb{S} \cong (\mathbb{S}^+)_+$;
2. $\mathbb{A} \cong (\mathbb{A}_+)^+$ *iff* $\mathbb{A}$ *is perfect.*

Proof. Concerning the first part, it is straightforward to verify that the map $\iota : x \mapsto \{x\}$ is the required isomorphism. For the second item, let the map $\epsilon : A \to \mathcal{P}(At(\mathbb{A}))$ be given by $\epsilon(a) := \{p \in At\mathbb{A} \mid p \leq a\}$. The crucial observation in the proof is that

$$\epsilon \text{ embeds } \mathbb{A} \text{ into } (\mathbb{A}_+)^+ \text{ iff all operations of } \mathbb{A} \text{ are complete.} \qquad (12)$$

This map is then an isomorphism iff $\mathbb{A}$ is perfect. ❑

As we will see now, the link between frames and algebras is not restricted to objects. With the natural definition for morphisms between perfect BAOs, we will see how to turn bounded morphisms between frames into these *complete* BAO homomorphisms, and vice versa.

DEFINITION 43. Let $\mathbb{A}$ and $\mathbb{A}'$ be two perfect τ-BAOs. A *complete homomorphism* from $\mathbb{A}$ to $\mathbb{A}'$ is a homomorphism $\eta : \mathbb{A} \to \mathbb{A}'$ which preserves *all* meets and joins. That is, for every subset $X \subseteq A$ we have that $\eta(\bigvee X) = \bigvee' \eta[X]$ and $\eta(\bigwedge X) = \bigwedge' \eta[X]$. We let BAO_τ^+ denote the category of perfect Boolean algebras with τ-operators as objects, and complete homomorphisms as arrows.

DEFINITION 44. Let $\mathbb{S}$ and $\mathbb{S}'$ two τ-frames. Given a bounded morphism $\theta : \mathbb{S} \to \mathbb{S}'$, define the map $\theta^+ : \mathcal{P}(S') \to \mathcal{P}(S)$ by

$$\theta^+(X') := \{s \in S \mid \theta(s) \in X'\}.$$

Conversely, given perfect τ-BAOs $\mathbb{A}$ and $\mathbb{A}'$ and a complete homomorphism $\eta : \mathbb{A} \to \mathbb{A}'$, define the map $\eta_+ : At(\mathbb{A}') \to A$, which can be shown to map atoms to atoms, by

$$\eta_+(p') := \bigwedge\{a \in A \mid p' \leq \eta(a)\}.$$

It is our aim to prove that $(\cdot)^+$ and $(\cdot)_+$ form a duality between the categories Fr_τ and BAO_τ^+. We first show functoriality:

PROPOSITION 45. *$(\cdot)^+$ is a contravariant functor from Fr_τ to BAO_τ^+.*

Proof. The important issue here is that for any bounded morphism $\theta : \mathbb{S} \to \mathbb{S}'$, the map θ^+ is a complete homomorphism from $\mathbb{S}'^+$ to $\mathbb{S}^+$. It is easy to see that θ^+ is a complete Boolean homomorphism between the respective power set algebras; in order to prove that it is also a modal homomorphism, it suffices to show that for an $n+1$-ary relation R we have

$$\langle R\rangle(\theta^+(X_1), \ldots, \theta^+(X_n)) = \theta^+\left(\langle R'\rangle(X_1, \ldots, X_n)\right) \tag{13}$$

in case θ is a bounded morphism with respect to R and R'. Here it is interesting to note that in fact the inclusion $\subseteq$ is equivalent to the *forth property*, and the converse inclusion $\supseteq$, to the *back property* of θ. In a way, (13) can be seen as a piece of evidence that bounded morphisms provide in fact the right kind of morphism between frames. ❑

PROPOSITION 46. *$(\cdot)_+$ is a contravariant functor from BAO_τ^+ to Fr_τ.*

Proof. Here the first point is to prove that if $\eta : \mathbb{A} \to \mathbb{A}'$ is a complete Boolean homomorphism between the perfect τ-BAOs $\mathbb{A}$ and $\mathbb{A}'$, then η_+ maps atoms of $\mathbb{A}'$ to atoms of $\mathbb{A}$. To see this, let p' be an atom of $\mathbb{A}'$; it suffices to show that $\eta_+(p')$ is *join prime* in $\mathbb{A}$. That is, we assume that $\eta_+(p') \leq \bigvee X$ for some $X \subseteq A$, and have to show that $\eta_+(p') \leq x$ for some $x \in X$. From the assumption we may derive that

$$p' \leq' \eta\eta_+(p') \leq' \eta(\bigvee X) = \bigvee{}' \eta[X].$$

Here the first inequality directly follows from the definition of $\eta_+(p')$. But since p' is an atom of $\mathbb{A}'$, the fact that $p' \leq' \bigvee' \eta[X]$ implies that $p' \leq' \eta(x)$ for some $x \in X$. The definition of $\eta_+(p')$ then immediately gives that $\eta_+(p') \leq' x$.

Unfortunately, we do not have the space here to prove that if η is in addition a modal homomorphism, then η_+ is a bounded morphism, or that the operation $(\cdot)_+$ commutes with function composition, i.e., that $(\theta \circ \eta)_+ = \eta_+ \circ \theta_+$ if $\eta : \mathbb{A} \to \mathbb{A}'$ and $\theta : \mathbb{A}' \to \mathbb{A}''$ are complete homomorphisms. ❑

The following result, that we will refer to as the *complex duality* for BAOs, is due to Thomason [103] (for the basic modal logic case).

THEOREM 47. *The functors* $(\cdot)^+$ *and* $(\cdot)_+$ *constitute a dual equivalence between the categories* Fr_τ *and* BAO^+_τ.

Proof. Given the results already established, it suffices to prove that the isomorphisms $\iota_\mathbb{S} : \mathbb{S} \to (\mathbb{S}^+)_+$ and $\epsilon_\mathbb{A} : \mathbb{A} \to (\mathbb{A}_+)^+$, defined in the proof of Proposition 42, are *natural*. For instance, concerning ϵ, we have to prove that $\epsilon_{\mathbb{A}'} \circ \eta = (\eta_+)^+ \circ \epsilon_\mathbb{A}$ for an arbitrary complete homomorphism $\eta : \mathbb{A} \to \mathbb{A}'$. The reader can easily verify this by a direct calculation. ❑

5.3 *Ultrafilter frames*

Now let us see how to remove the restriction to finite structures on the algebra side of (11); our first goal is to represent arbitrary (that is, not necessarily finite or even atomic) algebras by frames. But, given a BAO $\mathbb{A}$, what to take as the points of a frame representing $\mathbb{A}$? This problem of course already appears on the Boolean level, and its solution is provided by Stone's representation theorem. This celebrated piece of mathematics states that every Boolean algebra can be embedded in the set algebra over its *ultrafilters*; let us briefly review the basic facts concerning ultrafilters.

DEFINITION 48. Let $\mathbb{B}$ be a Boolean algebra. An *ultrafilter* of $\mathbb{B}$ is a proper filter u such that either a or $-a$ belongs to u, for all $a \in B$. The collection of ultrafilters of $\mathbb{B}$ is denoted as $Uf(\mathbb{B})$. Given a set S, we sometimes refer to ultrafilters of the power set algebra of S as *ultrafilters over* S.

EXAMPLE 49. Given a set S, and an element $s \in S$, define the *principal* ultrafilter π_s as the set $\{X \subseteq S \mid s \in X\}$. It is straightforward to verify that this set is indeed an ultrafilter over S. More generally, if p is an atom of the BA $\mathbb{B}$, then the principal filter $p{\uparrow} = \{a \in B \mid p \leq a\}$ is in fact an ultrafilter; it is in this sense that ultrafilters form a generalization of atoms.

For an example of a non-principal ultrafilter, consider the Boolean algebra of finite and cofinite sets of some infinite set T; the collection of cofinite subsets of T forms an ultrafilter of this algebra.

As a last example, ultrafilters can be seen to generalize the notion of a *maximal consistent set*. Consider the Lindenbaum-Tarski algebra $\mathbb{F}_L$ of a modal logic L; it is easy to verify that Φ is a maximal L-consistent set of formulas if and only if the set $\{[\varphi]_L \mid \varphi \in \Phi\}$ is an ultrafilter of $\mathbb{F}_L$.

Ultrafilters can be characterized as the proper filters that are maximal with respect to the inclusion ordering; this identification provides the key tool for establishing the existence of ultrafilters, as the proof sketch of the following Theorem reveals.

THEOREM 50 (Ultrafilter Theorem). *Any proper filter of a Boolean algebra* $\mathbb{B}$ *can be extended to an ultrafilter of* $\mathbb{B}$.

Proof. Given a proper filter F, apply Zorn's Lemma to the collection C of proper filters that extend F, and obtain a proper filter u that is maximal in C. It is not hard to prove that u is in fact a maximal proper filter, and from this it is easily follows that u is an ultrafilter. ❑

Stone's representation theorem suggests to take the collection $Uf(\mathbb{A})$ of a BAO $\mathbb{A}$ as the *domain* of a frame that will represent $\mathbb{A}$; for the *accessibility relation* on this ultrafilter frame we will (in the case of the basic modal similarity type) make the ultrafilter v visible from u if there is no explicit information preventing this; that is, if there is no $a \in v$ with $\Diamond a \notin u$. For an arbitrary similarity type we have the following definition.

DEFINITION 51. Given an n-ary operator f on the Boolean algebra $\mathbb{B}$, define its *dual relation* R_f as the $n+1$-ary relation on $Uf(\mathbb{B})$ given by:

$$R_f uu_1 \cdots u_n \;:\Longleftrightarrow\; f(a_1, \ldots, a_n) \in u \text{ for all } a_1 \in u_1, \ldots, a_n \in u_n.$$

Now let $\mathbb{A}$ be a Boolean algebra with τ-operators; then we define the *ultrafilter frame* or *canonical structure* of $\mathbb{A}$ as the structure

$$\mathbb{A}_\bullet := \langle Uf(\mathbb{A}), \{R_{\nabla^\mathbb{A}} \mid \nabla \in \tau\}\rangle.$$

Given a class K of algebras, we let $\mathsf{Cst}(\mathsf{K})$ denote the class of ultrafilter frames of algebras in K.

EXAMPLE 52. Recall from Chapter 2 of this volume that the *canonical frame* of a normal modal logic L is the structure $\mathbb{C}_L = \langle C, R\rangle$ where C is the set of maximally L-consistent set of formulas, and (we confine ourselves to the basic modal similarity type) R is the canonical accessibility relation given by $Ruv \;:\Longleftrightarrow\; \Diamond\varphi \in u$ for all φ in v. Using the identification that we made in Example 49 of maximal L-consistent sets with ultrafilters of the Lindenbaum-Tarski algebra $\mathbb{F}_L$, it is fairly obvious that the canonical frame for L is isomorphic to the ultrafilter frame of $\mathbb{F}_L$.

As a second example of the ultrafilter frame construction we mention that the *ultrafilter extension* $\mathbf{ue}\mathbb{S}$ of a frame $\mathbb{S}$ (as defined in Chapter 5 of this volume) is nothing but the 'double dual' $(\mathbb{S}^+)_\bullet$ of $\mathbb{S}$. Verifying this is simply a matter of unraveling the definitions.

Unlike the complex algebra functor, the ultrafilter frame construction is not injective.

EXAMPLE 53. Let A be the collection of finite and cofinite subsets of $\mathbb{N}$, and let B contain in addition those sets of natural numbers that differ in at most finitely many elements from either the set E of evens or the set O of odds. Both A and B are closed under the Boolean operations, and it is easy to see that A has exactly one non-principal ultrafilter, and B, exactly two: one containing the set E, and one the set O. Now suppose that we create algebras $\mathbb{A}$ and $\mathbb{B}$ by endowing A and B with some dummy operator, say, the identity map. Then we find that the respective ultrafilter frames $\mathbb{A}_\bullet$ and $\mathbb{B}_\bullet$ are isomorphic: both have countably many points, and in both cases, the accessibility relation is simply the diagonal. But the algebras $\mathbb{A}$ and $\mathbb{B}$ are clearly not isomorphic.

As we will see further on, the following theorem from Jónsson & Tarski [70] is not only vital when it comes to applications of the algebraic approach in modal completeness theory. It is also a manifestation of a fundamental mathematical concept, namely that of a *representation* theorem stating that every abstract structure in an axiomatically defined class is in fact isomorphic to a concrete, 'intended' structure of the kind that the axioms try to capture.

THEOREM 54 (Jónsson-Tarski Representation Theorem). *Let $\mathbb{A}$ be a Boolean algebra with τ-operators. Then the Stone representation map $\widehat{\cdot} : A \to \mathcal{P}Uf(\mathbb{A})$ given by*

$$\widehat{a} := \{u \in Uf(\mathbb{A}) \mid a \in u\} \tag{14}$$

is an embedding of $\mathbb{A}$ *into* $(\mathbb{A}_\bullet)^+$.

Proof. We omit details concerning the Boolean part of this theorem, which is of course nothing but Stone's representation theorem for Boolean algebras.

Concerning the additional operations, we restrict ourselves to the basic modal similarity type. So we consider a modal algebra $\mathbb{A} = \langle A, \top, \bot, -, \wedge, \vee, \diamond \rangle$ and show that

$$\widehat{\diamond a} = \langle R_\diamond \rangle \widehat{a}. \tag{15}$$

First we consider an ultrafilter $u \in \langle R_\diamond \rangle \widehat{a}$. It follows by the definition of $\langle R_\diamond \rangle$ (see 9) that there is an ultrafilter v such that $R_\diamond uv$ and $v \in \widehat{a}$, that is, $a \in v$. Then by definition of $R_\diamond$ it follows that $\diamond a \in u$, and, hence, that $u \in \widehat{\diamond a}$. This proves that $\widehat{\diamond a} \subseteq \langle R_\diamond \rangle \widehat{a}$.

For the converse direction, take an arbitrary ultrafilter $u \in \widehat{\diamond a}$; that is, $\diamond a \in u$. We have to come up with an ultrafilter v such that (i) $R_\diamond uv$ and (ii) $v \in \widehat{a}$, or, equivalently, $a \in v$. We first reformulate the first condition:

$$R_\diamond uv \text{ iff } a \in v \text{ for all } a \text{ with } -\diamond - a \in u. \tag{16}$$

Hence, by the Ultrafilter Theorem 50 it suffices to show that the set $\{x \in A \mid -\diamond -x \in u\} \cup \{a\}$ has the finite meet property, see Example 27. In order to prove this, first observe that the set $\{x \in A \mid -\diamond -x \in u\}$ is closed under taking meets — this easily follows from the additivity of $\diamond$ and the fact that u is a filter.

But then it is left to show that $x \wedge a > \bot$ for any $x \in A$ with $-\diamond -x \in u$. Suppose for contradiction that $x \wedge a = \bot$. We obtain $a \leq -x$ so $\diamond a \leq \diamond -x$ by monotonicity of $\diamond$, and so we find $\diamond -x$ in u because $\diamond a \in u$. This gives the desired contradiction since we already had $-\diamond -x$ in u. ❏

DEFINITION 55. Given a Boolean algebra with τ-operators $\mathbb{A}$, the 'double dual' algebra $(\mathbb{A}_\bullet)^+$ is known as the *canonical embedding algebra of* $\mathbb{A}$, the *canonical extension of* $\mathbb{A}$ and the *perfect extension of* $\mathbb{A}$; we will mainly use the second term, and usually denote the structure as $\mathbb{A}^\sigma$.

The Jónsson-Tarski theorem thus states that the constructions $(\cdot)^+$ and $(\cdot)_\bullet$ interact well if we start with algebras: $\mathbb{A} \rightarrowtail (\mathbb{A}_\bullet)^+$ for every BAO $\mathbb{A}$. Unfortunately, if we start with frames, then the return is less safe: for a τ-frame $\mathbb{S}$, the map $s \mapsto \pi_s$ (assigning to points of $\mathbb{S}$ their associated principal ultrafilters) is an embedding of $\mathbb{S}$ into $(\mathbb{S}^+)_\bullet$ only if $\mathbb{S}$ is *image finite*. (In fact, the condition of image-finiteness is also sufficient.) And if $\mathbb{S}$ contains a point from which paths of arbitrary finite length emanate, but no infinite path, then there is *no* bounded morphism from $\mathbb{S}$ to $(\mathbb{S}^+)_\bullet$ whatsoever. From this it follows that there is no way to extend the ultrafilter frame construction to a functor that is *adjoint* to that of taking complex algebras. This is a notable divergence of the case of Boolean algebras per se (that is, without operators) — the formation of the canonical extension $\mathbb{B}^\sigma$ of a Boolean algebra $\mathbb{B}$ is a *free* construction, see [68] for more information on these matters.

Nevertheless, the operation of taking ultrafilter frames can be extended to a functor, as follows.

DEFINITION 56. Let $\mathbb{A}$ and $\mathbb{A}'$ be two Boolean algebras with τ-operators. Given a homomorphism $\eta : \mathbb{A} \to \mathbb{A}'$, we define the map $\eta_\bullet : Uf\,\mathbb{A}' \to \mathcal{P}(A)$, which can be shown to map ultrafilters to ultrafilters, by putting

$$\eta_\bullet(u') := \{a \in A \mid \eta(a) \in u\}. \tag{17}$$

PROPOSITION 57. $(\cdot)_\bullet$ *is a contravariant functor from* BAO_τ *to* Fr_τ.

Proof. If $\eta : \mathbb{A} \to \mathbb{A}'$ is a Boolean homomorphism, then it follows almost immediately that $\eta_\bullet$ maps ultrafilters to ultrafilters, while it is not too hard either to prove that, for any modality ∇ of rank, say, n:

$$\begin{array}{rl} \eta_\bullet \text{ has the forth property for } R_\nabla & \text{if} \quad \nabla'(\eta a_1, \ldots, \eta a_n) \leq \eta(\nabla(a_1, \ldots, a_n)), \\ \eta_\bullet \text{ has the back property for } R_\nabla & \text{if} \quad \nabla'(\eta a_1, \ldots, \eta a_n) \geq \eta(\nabla(a_1, \ldots, a_n)). \end{array}$$

This shows that $\eta_\bullet$ is a bounded morphism from $\mathbb{A}'_\bullet$ to $\mathbb{A}_\bullet$ if $\eta : \mathbb{A} \to \mathbb{A}'$ is a homomorphism. It is then left to show that $(\cdot)_\bullet$ is functorial, and in particular, that $(\eta \circ \theta)_\bullet = \theta_\bullet \circ \eta_\bullet$ for homomorphisms $\theta : \mathbb{A} \to \mathbb{A}'$ and $\eta : \mathbb{A}' \to \mathbb{A}''$. This can be checked by a straightforward calculation which we leave for the reader. ❑

5.4 *Topological duality*

In the previous subsection we encountered a problem of the functor $(\cdot)_\bullet$: in general, algebras cannot be retrieved from their ultrafilter frames. A very simple remedy is then to *add* this information to the frame by melting algebra and frame into one structure. Since this issue already pertains at the level of Boolean algebras (without additional operations), that is where we start the discussion.

DEFINITION 58. A *field of sets* is a pair $\langle S, A\rangle$ with $A \subseteq \mathcal{P}(S)$ being closed under all Boolean set-theoretic operations, or equivalently, with A such that $\langle A, S, \varnothing, \sim_S, \cap, \cup\rangle$ is a subalgebra of $\mathbb{P}S$. The elements of A are called the *admissible* subsets of S.

Given a Boolean algebra $\mathbb{A} = \langle A, \top, \bot, -, \wedge, \vee\rangle$, put $\widehat{A} := \{\widehat{a} \subseteq Uf(\mathbb{A}) \mid a \in A\}$, with $\widehat{\cdot}$ as in (15), and define $\mathbb{A}_* := \langle Uf\mathbb{A}, \widehat{A}\rangle$ as the *associated field of sets* of $\mathbb{A}$. Conversely, the *associated Boolean algebra* of a field of sets $\mathbb{S} = \langle S, A\rangle$ is the structure $\mathbb{S}^* := \langle A, S, \varnothing, \sim_S, \cap, \cup\rangle$.

It will be clear that the Boolean algebras $\mathbb{A}$ and $(\mathbb{A}_*)^*$ will always be isomorphic; however, we will only have that $\mathbb{S} \cong (\mathbb{S}^*)_*$ if $\mathbb{S}$ has some special properties.

DEFINITION 59. A field of sets $\mathbb{S} = \langle S, A\rangle$ is *discrete* if A contains all singletons of S, *differentiated* if for any two distinct points $s \neq t$ of S there is a set $a \in A$ such that $s \in a$ and $t \notin a$, and *full* if $A = \mathcal{P}(S)$. $\mathbb{S}$ is *compact* if every subset of A with the finite intersection property has a non-empty intersection, and *descriptive* if it is both differentiated and compact.

In a descriptive field of sets, the points and the admissible sets are in *balance*: there are sufficiently many admissible sets to separate distinct points, while there are enough points to witness all the ultrafilters of the algebra. More precisely, one can prove that for any field of sets $\mathbb{S} = \langle S, A\rangle$, the map

$$s \mapsto \{a \in A \mid s \in a\} \tag{18}$$

provides an bijection between $\mathbb{S}$ and the collection of ultrafilters of $\mathbb{S}^*$ iff $\mathbb{S}$ is descriptive.

REMARK 60. Our terminology strongly suggests a topological connection. In order to make this explicit, note that the collection of admissible sets of a field of sets $\mathbb{S} = \langle S, A\rangle$ forms a basis for a topology σ_A; and that, conversely, we may take the set $Clp(\mathbb{X})$ of *clopen* (that is, closed and open) elements of a topology $\mathbb{X} = (X, \tau)$ as a collection of

admissible sets. In accordance with this, we define a subset $X \subseteq S$ to be *open* if it is a union of admissible sets, and *closed* if it is an intersection of admissible sets. Thus the study of fields of sets takes us into a rather specific branch of set-theoretic topology in which all spaces are *zero-dimensional*, that is, have a basis of clopens.

One may prove for any field of sets $\mathbb{S} = \langle S, A\rangle$ that $\mathbb{S}$ is descriptive iff $\langle S, \sigma_A\rangle$ is a *Stone space*, that is, σ_A is a compact, Hausdorff and zero-dimensional topology. Basically then, descriptive fields of sets and Stone spaces are two ways of formulating the same mathematical objects; the difference is no more than a matter of focus, be it on the topology itself, or rather on its sets of clopens.

The topological nature also comes out clearly when we discuss *morphisms.*

DEFINITION 61. Given two fields of sets $\mathbb{S} = \langle S, A\rangle$ and $\mathbb{S}' = \langle S', A'\rangle$, we call a map $\theta : S \to S'$ *continuous* if the set

$$\theta^*(a') := \{s \in S \mid \theta(s) \in a'\} \tag{19}$$

belongs to A for all $a' \in A'$.

We define the dual $\eta_* : \mathit{Uf}\,\mathbb{A}' \to \mathit{Uf}\,\mathbb{A}$ of a morphism $\eta : \mathbb{A} \to \mathbb{A}'$ between two Boolean algebras as the map $\eta_*(u') := \{a \in A \mid \eta(a) \in u'\}$.

Without further proof we mention (our reformulation of) the following seminal result from Stone [101] (see Johnstone [68] for an extensive discussion of its impact).

THEOREM 62 (Stone duality). *The functors $(\cdot)^*$ and $(\cdot)_*$ form a dual equivalence between the category of Boolean algebras with homomorphism, and that of descriptive fields of sets with continuous maps.*

The duality for BAOs can now be developed by incorporating the ultrafilter functor $(\cdot)_\bullet$ into the Stone duality: the dual object representing a Boolean algebra with operators will combine the BAO and its dual Kripke frame in one structure.

DEFINITION 63. A *general τ-frame* is a structure $\mathbb{G} = \langle G, R, A\rangle$, where $R = \{R_\nabla \mid \nabla \in \tau\}$ is a family of relations on G, such that (i) $\langle G, R\rangle$ is a τ-frame and (ii) $\langle G, A\rangle$ is a field of sets such that (iii) A is closed under the operation $\langle R_\nabla\rangle$ for each operation symbol $\nabla \in \tau$. The structure $\langle G, R\rangle$ is called the *underlying* Kripke frame of $\mathbb{G}$.

Given a general frame $\mathbb{G} = \langle G, R, A\rangle$, define $\mathbb{G}^*$ as the subalgebra of $\langle G, R\rangle^+$ with carrier A. Conversely, given a τ-BAO $\mathbb{A}$, define its dual general frame $\mathbb{A}_*$ as the structure $\langle \mathit{Uf}(\mathbb{A}), \{R_{\nabla^{\mathbb{A}}} \mid \nabla \in \tau\}, \widehat{A}\rangle$.

As in the case of the duals of Boolean algebras, general frames of the form $\mathbb{A}_*$ are rather special, also with respect to the interaction between their relational and the topological side. We let notions like differentiatedness apply to a general frame $\langle G, R, A\rangle$ as it applies to the underlying field of sets $\langle G, A\rangle$.

DEFINITION 64. A general frame $\mathbb{G} = \langle G, R, A\rangle$ is *tight* if every tuple $(s, s_1, \ldots, s_n)$ which is *not* in the relation R_∇ (with ∇ an arbitrary relation symbol of arity n) is witnessed by admissible sets $a_1, \ldots, a_n$ such that $s_i \in a_i$ for each i, while $s \notin \langle R_\nabla\rangle(a_1, \ldots, a_n)$. $\mathbb{G}$ is *refined* if it is both differentiated and tight, and *descriptive* if it is both refined and compact.

REMARK 65. An easy proof shows that we may reformulate the property of tightness equivalently by requiring that (restricting to the basic modal language here) $R[s] = \bigcap\{a \in A \mid s \in [R]a\}$ for each point s in $\mathbb{G} = \langle G, R, A\rangle$. In other words, the relation R

is *point-closed*, since each point of $\mathbb{G}$ has a *closed* successor set — closed in the induced topology σ_A, that is. Thus from a topological perspective, descriptive general frames can be identified with point-closed relational Stone spaces.

In order to turn the constructions $(\cdot)^*$ and $(\cdot)_*$ into functors we have to introduce morphisms between (descriptive) general frames as well. Again, we combine modal and topological aspects in the natural way.

DEFINITION 66. Given two general frames $\mathbb{G} = \langle G, R, A\rangle$ and $\mathbb{G}' = \langle G', R', A'\rangle$, a map $\theta : G \to G'$ is called a *continuous bounded morphism* if it is both a bounded morphism from $\langle G, R\rangle$ to $\langle G', R'\rangle$ and a continuous map from $\langle G, A\rangle$ to $\langle G', A'\rangle$. The category of descriptive general τ-frames with continuous bounded morphisms is denoted as DGF_τ.

Now let us see how $(\cdot)^*$ and $(\cdot)_*$ operate on morphisms. For the definition of θ^* for θ a continuous bounded morphism we refer to (19); conversely, given a homomorphism $\eta : \mathbb{A} \to \mathbb{A}'$ between two τ-BAOs, define η_* as in Definition 61, that is: $\eta_*(u') := \{a \in A \mid \eta(a) \in u\}$. We have now arrived at the main result of this subsection, Theorem 67 below, which is due to Goldblatt [37, 39]. Independently, Esakia [23] came up with such a duality for a more specific variety of algebras.

THEOREM 67. *The functors $(\cdot)^*$ and $(\cdot)_*$ constitute a dual equivalence between the categories BAO_τ and DGF_τ.*

Proof. It is rather straightforward to verify that $(\cdot)^*$ and $(\cdot)_*$ are functors which form a dual adjunction between the categories DGF_τ and BAO_τ. It is then left to show that $\mathbb{G} \cong (\mathbb{G}^*)_*$ for any descriptive general frame $\mathbb{G}$, and that $\mathbb{A} \cong (\mathbb{A}_*)^*$ for any Boolean algebra with τ-operators $\mathbb{A}$. But both of these claims are easy to establish: for the first isomorphism, take the map of (18); and for the second isomorphism, simply take the Stone embedding $\widehat{\cdot}$ of (14). The proof details are left to the reader. ❑

It is straightforward to derive from this duality that for any class C of general frames, the class of dual algebras algebraizes C (once we have properly defined all notions involved), but we leave the details for the reader.

5.5 Simplicity and Subdirect irreducibility

As an application of these dualities, let us look at the frame counterparts of the notions of simplicity and subdirect irreducibility. In the complex duality of section 5.2, this question has a satisfactory answer, at least for subdirect irreducibility:

THEOREM 68. *Let $\mathbb{S}$ be a τ-frame. Then*

1. *$\mathbb{S}^+$ is simple only if each point is a root of $\mathbb{S}$;*
2. *$\mathbb{S}^+$ is subdirectly irreducible iff $\mathbb{S}$ is rooted.*

Proof. Concerning subdirect irreducibility, the direction from right to left, first mentioned in Goldblatt [39], was already treated in Example 38. The proof of the converse implication appeared first in Sambin [99]. For its details, suppose that ρ is a radix of the algebra $\mathbb{S}^+$, and consider an arbitrary point $s \in S$. Then by definition of radicality we find that $\rho \subseteq \langle R_\blacklozenge\rangle\{s\}$ for some compound modality $\blacklozenge$. It is easy to see that this implies $R_\blacklozenge rs$ for each $r \in \rho$, so that each element of ρ is in fact a root of $\mathbb{S}$. Hence,

if $\mathbb{S}^+$ is simple, then every point is a root of $\mathbb{S}$, since every non-empty subset of S is a radix of $\mathbb{S}^+$ by Theorem 39. If $\mathbb{S}^+$ is s.i., then by the same theorem it has at least one radix; rootedness of $\mathbb{S}$ thus follows from the fact that radical elements are non-empty by definition. ❑

Perhaps contrary to the reader's expectation, the converse of Theorem 68(1) is not true.

EXAMPLE 69. Consider the frame $\mathbb{Z} = (Z, R)$ for the basic modal similarity type, with Z as the set of integers and Rxy iff $|x - y| = 1$. Then clearly every integer is a root of $\mathbb{Z}$, while on the other hand, $\mathbb{Z}^+$ is not simple. An easy way to see this is by proving that the only radical elements of $\mathbb{Z}^+$ are the finite subsets of $\mathbb{Z}$.

In the topological duality of section 5.4, the correspondence between subdirect irreducibility and rootedness is not so nice either. In general, subdirect irreducibility of $\mathbb{A}$ neither implies rootedness of $\mathbb{A}_*$, nor is it implied by it, as the following examples from Sambin [99] witness.

EXAMPLE 70. For an example of the first kind, take the subalgebra $\mathbb{A} \rightarrowtail \langle N, > \rangle^+$ based on the collection of finite and cofinite subsets of the set N of natural numbers. As we will see later on, $\mathbb{A}$ is not subdirectly irreducible. However, the frame $\mathbb{A}_\bullet$ is rooted, since it adds one reflexive point ω (corresponding to the ultrafilter of the cofinite sets) to $\langle N, > \rangle$, in such a way that ω sees all other points.

Conversely, consider the frame $\mathbb{Z}$ of the previous example, and take its subalgebra $\mathbb{B}$ based on the finite and cofinite sets. It is easy to see that $\mathbb{B}$ is s.i.: simply note that every singleton is radical. However, the one reflexive point ∞ that $\mathbb{B}_*$ adds to $\mathbb{Z}$ is not related to any other point in $\mathbb{B}_*$. Hence, $\mathbb{B}_*$ provides an example of an s.i. algebra of which the dual general frame has no roots at all.

These examples indicate that if we are looking for a characterization of the notion of subdirect irreducibility, it does not suffice to look at the dual Kripke frame alone: we have to take the topology into account. Our characterization will be in terms of so-called topological roots or, briefly, topo-roots. Recall that a *root* of a τ-frame $\mathbb{S} = \langle S, R \rangle$ is a point r of $\mathbb{S}$ such that $R^\omega[r] = S$, where the relation R^ω is given as the union of the accessibility relations of the compound diamonds. It is straightforward to verify that in a frame of the form $\mathbb{A}_*$ this boils down to

$$R^\omega uv \text{ iff there is a compound diamond } \blacklozenge \text{ with } \blacklozenge a \in u \text{ for all } a \in v. \tag{20}$$

Our definition of the *topo*-reachability relation is obtained by swapping the universal and the existential quantifier in (20).

DEFINITION 71. Given a Boolean algebra with operators $\mathbb{A}$, define the *topo-reachability* relation $R^\star \subseteq Uf\mathbb{A} \times Uf\mathbb{A}$ as follows:

$$R^\star uv \text{ iff for all } a \in v \text{ there is a compound diamond } \blacklozenge \text{ with } \blacklozenge a \in u. \tag{21}$$

We let $T_{\mathbb{A}}$ denote the set of *topo-roots* of $\mathbb{A}_*$; that is, the collection of those ultrafilters u such that $R^\star[u] = Uf\mathbb{A}$.

The topological terminology will be clarified by the following alternative characterization of $R^\star$.

PROPOSITION 72. *Let $\mathbb{A}$ be some Boolean algebra with τ-operators, and u some ultrafilter of $\mathbb{A}$. Then $R^\star[u] = \overline{R^\omega[u]}$; that is, $R^\star[u]$ is the topological closure of $R^\omega[u]$ in the Stone topology of $\mathbb{A}_*$.*

As the following theorem from Venema [108] witnesses, topo-roots provide the right tool for the characterization of the notions of simplicity and subdirect irreducibility.

THEOREM 73. *Let $\mathbb{A}$ be a Boolean algebra with τ-operators. Then*

1. *$\mathbb{A}$ is simple iff $T_{\mathbb{A}} = Uf\mathbb{A}$;*
2. *$\mathbb{A}$ is subdirectly irreducible iff $T_{\mathbb{A}}$ is open and non-empty.*

Unfortunately, we do not have the space for a proof or even a proof sketch. We confine ourselves to noting that the proof makes use of the correspondence between modal filters of $\mathbb{A}$ and closed, hereditary subsets of $\mathbb{A}_*$.

EXAMPLE 74. It is now obvious why the algebra $\mathbb{A}$ of Example 70 is not s.i.: its dual frame does have a (single) root ω but the set $\{\omega\}$ of roots is not open in the topology of $\mathbb{A}_*$. The algebra $\mathbb{B}$ of the same example on the other hand *is* s.i. Whereas its dual frame $\mathbb{B}_\bullet$ has no *roots* at all, almost every point of $\mathbb{B}_*$ is a topo-root.

As corollaries of the last theorem we obtain some (well-)known results showing that in many cases, nicer characterizations are indeed possible. We call a Boolean algebra with operators *ω-transitive* if it has a *master modality*, that is, a compound diamond $\Diamond$ such that $\blacklozenge a \leq \Diamond a$ for all compound diamonds $\blacklozenge$ and all a in $\mathbb{A}$. (With some authors, this property goes under the name of *weak* transitivity). The following result is due to Sambin [99] (whereas in the closely related field of intuitionistic logic, similar characterizations of s.i. Heyting algebras in terms of their dual structures had been known for some time, cf. Esakia [24]).

COROLLARY 75. *Let $\mathbb{A}$ be an ω-transitive Boolean algebra with operators. Then $\mathbb{A}$ is subdirectly irreducible iff the collection of roots of $\mathbb{A}_*$ is non-empty and open.*

Proof. This follows from Theorem 73 by the observation that if $\mathbb{A}$ is ω-transitive, then $R^\star = R^\omega = R_\Diamond$ (where $\Diamond$ is the master modality of $\mathbb{A}$), whence the notions of root and topo-root coincide. ❑

Results concerning the duals of *finite* BAOs are already covered by Theorem 68, since for finite BAOs the complex and the topological dualities coincide.

5.6 Class operations

While the functors $(\cdot)^+$ and $(\cdot)_\bullet$ do not form a duality, they do provide an interesting link between the categories Fr_τ and BAO_τ. We already discussed the role of the 'double duals', that is, the *canonical embedding algebra* $\mathbb{A}^\sigma = (\mathbb{A}_\bullet)^+$ of a BAO $\mathbb{A}$, and the *ultrafilter extension* $(\mathbb{S}^+)_\bullet$ of a frame $\mathbb{S}$. But there is also a wealth of results concerning the direct interaction of the mentioned functors with the more 'intrinsic' constructions on algebras and frames. We confine ourselves here to the algebraic operations of taking homomorphic images, subalgebras and products, and their frame counterparts of taking generated subframes, bounded morphic images, and disjoint unions. The results listed in

Theorem 76 are more or less direct consequences of the dualities established earlier on; therefore, we leave the proofs to the reader.

THEOREM 76. *Let $\mathbb{S}$, $\mathbb{S}'$ and all $\mathbb{S}_i$ with $i \in I$ be τ-frames, and let $\mathbb{A}$, $\mathbb{A}'$ and all $\mathbb{A}_j$ with $j \in J$ be Boolean algebras with τ-operators. Then*

1. $\theta : \mathbb{S} \rightarrowtail \mathbb{S}'$ *only if* $\theta^+ : \mathbb{S}'^+ \twoheadrightarrow \mathbb{S}^+$;
2. $\theta : \mathbb{S} \twoheadrightarrow \mathbb{S}'$ *only if* $\theta^+ : \mathbb{S}'^+ \rightarrowtail \mathbb{S}^+$;
3. $\eta : \mathbb{A} \rightarrowtail \mathbb{A}'$ *only if* $\eta_\bullet : \mathbb{A}'_\bullet \twoheadrightarrow \mathbb{A}_\bullet$;
4. $\eta : \mathbb{A} \twoheadrightarrow \mathbb{A}'$ *only if* $\eta_\bullet : \mathbb{A}'_\bullet \rightarrowtail \mathbb{A}_\bullet$;
5. $\left(\sum_{i\in I} \mathbb{S}_i\right)^+ \cong \prod_{i\in I} \mathbb{S}_i^+$;
6. $\left(\prod_{j\in J} \mathbb{A}_j\right)_\bullet \cong \sum_{j\in J} (\mathbb{A}_j)_\bullet$

In general it is not true that the ultrafilter frame $(\prod_{j\in J} \mathbb{A}_j)_\bullet$ is isomorphic to the disjoint union $\sum_{j\in J}(\mathbb{A}_j)_\bullet$: the problem is that for infinite J, not every ultrafilter of the product can be linked to an ultrafilter of one of the factors. Fortunately, we do have the following 'second best' connection, essentially due to Gehrke [27], which states that the ultrafilter frame of the product is isomorphic to the disjoint union of the ultrafilter frames of all *ultraproducts* of the original algebras over the index set.

THEOREM 77. *Let $\{\mathbb{A}_i \mid i \in I\}$ be a family of Boolean algebras with τ-operators. Then*

$$\left(\prod_{i\in I} \mathbb{A}_i\right)_\bullet \;\cong\; \sum_{D\in Uf(I)} \left(\prod\nolimits_D \mathbb{A}_i\right)_\bullet .$$

Proof. Given an element a of $\mathbb{A} := \prod_I \mathbb{A}_i$, let $d(a) := \{i \in I \mid a(i) \neq \bot\}$ be the *support set* of a. Then it is not hard to prove that $d[u] := \{d(a) \mid a \in u\}$ is an ultrafilter over I for every $u \in Uf(\mathbb{A})$.

Now given an ultrafilter D over I, the natural homomorphism $\nu^D : a \mapsto a/D$ is a surjective homomorphism from $\mathbb{A}$ onto $\mathbb{A}_D := \prod_D \mathbb{A}_i$. So by Theorem 76(4), its dual $\nu^D_\bullet : (\mathbb{A}_D)_\bullet \to \mathbb{A}_\bullet$ is a frame embedding. We now claim that

$$Range\left(\nu^D_\bullet\right) = \{u \in Uf\mathbb{A} \mid d[u] = D\}. \tag{22}$$

For the inclusion $\subseteq$, take an arbitrary ultrafilter z of $\mathbb{A}_D$. For any $a \in \nu^D_\bullet(z)$, it holds by definition that $\nu^D(a) = a/D$ belongs to z; but then a/D must be distinct from the bottom element of $\mathbb{A}_D$. Hence $d(a) \in D$ by definition of d. Since this applies to arbitrary $a \in \nu^D_\bullet(z)$ it follows that $d[\nu^D_\bullet(z)] \subseteq D$. But then we must have equality because both $d[\nu^D_\bullet(z)]$ and D are ultrafilters over I. For the converse inclusion, if $u \in Uf\mathbb{A}$ satisfies $d[u] = D$, then the set $u_D := \{a/D \mid a \in u\}$ is easily seen to be an ultrafilter of $\mathbb{A}_D$ which satisfies $\nu^D_\bullet(u_D) = u$. This proves (22).

Clearly for each ultrafilter D over I, $Range\left(\nu^D_\bullet\right)$ is (the domain of) a generated subframe of $\mathbb{A}_\bullet$; it now follows from the fact that $d[u] \in Uf(I)$ and (22) that these subframes are mutually disjoint, but jointly cover the full domain $Uf\mathbb{A}$ of $\mathbb{A}_\bullet$. From this the theorem is immediate. ❑

On the basis of the Theorems 76 and 77 we may develop a 'calculus of class operations'. For instance, letting $\mathsf{S_f}$ denote the operation of taking generated subframes, Theorem 76(1) can be read as stating '$\mathsf{CmS_f} \leq \mathsf{HCm}$', meaning that $\mathsf{CmS_f}(\mathsf{C}) \subseteq \mathsf{HCm}(\mathsf{C})$ for every frame class C. There are many constructions of either frames or algebras that have been investigated, and many results, similar to the Theorems 76 and 77, have been obtained. The interested reader is referred to work by Goldblatt, for instance [40, 41].

Unfortunately, we have only space here for one further example (which will be used in the next section).

PROPOSITION 78. *For any class* C *of frames,* $\mathsf{PuCm}(\mathsf{C}) \subseteq \mathsf{SCmPu}(\mathsf{C})$.

Proof. Let $\{\mathbb{S}_i \mid i \in I\}$ be a family of τ-frames, and let D be an ultrafilter over I. Define the map $\eta : \prod_I \mathcal{P}(S_i)/D \to \mathcal{P}(\prod_I \mathbb{S}_i/D)$ by putting, for s/D in $\prod_I \mathbb{S}_i/D$:

$$s/D \in \eta(a/D) \;:\Longleftrightarrow\; \{i \in I \mid s(i) \in a(i)\} \in D.$$

We leave it for the reader to verify that this is a well-defined embedding of $\prod_I \mathbb{S}_i^+/D$ into $(\prod_I \mathbb{S}_i/D)^+$. ❑

We will give one application of the Theorems 76 and 77 here, more use of these results will be made in the next sections. Theorem 79 below, due to Goldblatt & Thomason [47], can be read as a modal dual of Birkhoff's theorem identifying varieties with equational classes. For a definition of Birkhoff's theorem from a *coalgebraic* perspective, the reader is referred to section 14.

THEOREM 79 (Goldblatt-Thomason Theorem). *Let* C *be a class of* τ*-frames. Then*

1. *if* C *is modally definable then it reflects ultrafilter extensions, and is closed under taking bounded morphic images, generated subframes and disjoint unions;*

2. *the converse of (1) holds if* C *is closed under taking ultrapowers, (for instance, if* C *is elementary).*

Proof. First assume that C is modally definable; that is, $\mathsf{C} = \mathsf{Fr}(\Gamma)$ for some set Γ of modal τ-formulas (in fact, we may take Γ to the logic of C, but this is not relevant now). Now suppose that the frame $\mathbb{S}'$ is the bounded morphic image of some $\mathbb{S}$ in C. From $\mathbb{S}$ in C it follows that $\mathbb{S} \Vdash \Gamma$ whence $\mathbb{S}^+ \models \Gamma^{\approx}$; but at the same time we see that by Theorem 76(2), $\mathbb{S}'^+$ is a subalgebra of $\mathbb{S}^+$. Hence also $\mathbb{S}'^+ \models \Gamma^{\approx}$, so $\mathbb{S}' \models \Gamma$ which immediately implies that $\mathbb{S}'$ belongs to C. This shows that C is closed under taking bounded morphic images; the case of generated subframes and disjoint unions is proved similarly.

Now suppose that the ultrafilter extension $\mathbf{ue}\mathbb{S} = (\mathbb{S}^+)_\bullet$ belongs to C. Then $((\mathbb{S}^+)_\bullet)^+ \models \Gamma^{\approx}$, and so $\mathbb{S}^+ \Vdash \Gamma^{\approx}$ since $\mathbb{S}^+$ is a subalgebra of $((\mathbb{S}^+)_\bullet)^+$ by the Jónsson-Tarski Theorem 54. But from $\mathbb{S}^+ \models \Gamma^{\approx}$ it follows that $\mathbb{S} \Vdash \Gamma$ whence $\mathbb{S}$ belongs to C. This shows that C reflects ultrafilter extensions, and thus proves part (1).

For the second part, assume that C enjoys all of the listed closure properties. In order to prove that $\mathsf{C} = \mathsf{Fr}(\mathit{Log}(\mathsf{C}))$, take an arbitrary frame $\mathbb{S}$ such that $\mathbb{S} \Vdash \mathit{Log}(\mathsf{C})$. It suffices to show that $\mathbb{S}$ actually belongs to C.

It follows from $\mathbb{S} \Vdash \mathit{Log}(\mathsf{C})$ that $\mathbb{S}^+$ validates the equational theory of the class $\mathsf{Cm}(\mathsf{C})$, and so by Birkhoff's variety theorem $\mathbb{S}^+$ belongs to the variety $\mathsf{VarCm}(\mathsf{C})$ generated by

the class of complex algebras over C. Then by Tarski's HSP-theorem, $\mathbb{S}^+$ belongs to $\mathsf{HSPCm}(\mathsf{C})$. That is, for some family $\{\mathbb{F}_i \mid i \in I\}$ of frames in C, and some algebra $\mathbb{A}$ we have that

$$\mathbb{S}^+ \twoheadleftarrow \mathbb{A} \rightarrowtail \prod\nolimits_I \mathbb{F}_i^+.$$

Note that $\prod_I \mathbb{F}_i^+ \cong (\sum_I \mathbb{F}_i)^+$ by Theorem 76(5), and that $\mathbb{F} := \sum_I \mathbb{F}_i$ belongs to C. Then using Theorem 76(3) and (4) we find that

$$(\mathbb{S}^+)_\bullet \rightarrowtail \mathbb{A}_\bullet \twoheadleftarrow (\mathbb{F}^+)_\bullet.$$

Now it follows by Theorem 90 in Chapter 5 of this volume that $(\mathbb{F}^+)_\bullet$ is a bounded morphic image of some *ultrapower* $\mathbb{F}^J/D$ of $\mathbb{F}$. Then by the various listed closure properties of C, we show that subsequently, each of the frames $\mathbb{F}^J/D$, $(\mathbb{F}^+)_\bullet$, $\mathbb{A}_\bullet$ and $(\mathbb{S}^+)_\bullet$ belong to C. Finally then, also $\mathbb{S}$ belongs to C since its ultrafilter extension $(\mathbb{S}^+)_\bullet$ does so. ❑

6 LOGICS AND VARIETIES

This section, which forms the heart of the algebra part of this chapter, discusses the connection between normal modal logics (NMLs) and varieties of BAOs. The main part of the section consists in showing how standard properties of a logic turn up on the algebraic side of the picture, but we start with showing how the *lattice* of normal modal logics is dually isomorphic to that of the varieties of BAOs.

DEFINITION 80. Given a normal modal logic L, we say that a normal modal logic L' is a *normal extension* of L simply if $L \subseteq L'$. The lattice of normal extensions of L is denoted as $\mathrm{NExt}(L)$.

We have already seen that with every normal modal τ-logic we may associate a variety $\mathsf{BAO}_\tau(L)$ of τ-BAOs. Conversely, every class of these algebras gives rise to a normal modal logic.

DEFINITION 81. Given a class K of Boolean algebras with τ-operators, we define $Log(\mathsf{K}) := \{\varphi \in Fma_\tau \mid \mathsf{K} \models \varphi^\approx\}$.

The following theorem then describes the intimate connection between normal modal logics and varieties of BAOs. Similar results can be proved about arbitrary modal logics and varieties of BAEs, and about monotone modal logics and varieties of BAMs.

THEOREM 82.

1. *The maps $\mathsf{BAO}_\tau(\cdot)$ and $Log(\cdot)$ form a Galois connection, in the sense that for every set Γ of τ-formulas, and every class K of Boolean algebras with τ-operators, $\Gamma \subseteq Log(\mathsf{K})$ iff $\mathsf{K} \subseteq \mathsf{BAO}_\tau(\Gamma)$.*

2. *The stable formula sets of this connection are precisely the normal modal τ-logics, while the stable classes of algebras are precisely the varieties of Boolean algebras with τ-operators.*

3. *Hence, Log is a dual isomorphism between the lattice of subvarieties of BAO_τ and the lattice $\mathrm{NExt}(\mathbf{K}_\tau)$ of normal modal τ-logics*

Proof. It is not hard to see the Galois connection, since we have $\Gamma \subseteq \mathit{Log}(\mathsf{K})$ iff $\mathbb{A} \models \gamma^{\approx}$ for all $\mathbb{A}$ in K and all $\gamma \in \Gamma$ iff $\mathsf{K} \subseteq \mathsf{BAO}_\tau(\Gamma)$.

Now let Γ be a stable set of formulas of this connection, that is, suppose that $\Gamma = \mathit{Log}(\mathsf{BAO}_\tau(\Gamma))$; one easily infers that such a Γ must be a normal modal logic. Conversely, if L is a normal modal logic, then $L = \mathit{Log}(\mathsf{BAO}_\tau(L))$ by the Algebraization Theorem 17.

At the other side of the connection, it is immediate from the definition that every class $\mathsf{BAO}_\tau(\Gamma)$ is a variety. Conversely, assume that V is a variety of τ-BAOs. Then clearly $\mathsf{V} \subseteq \mathsf{BAO}_\tau(\mathit{Log}(\mathsf{V}))$ since this holds for any class; for the opposite inclusion, by Birkhoff's variety theorem it suffices to show that $\mathsf{BAO}_\tau(\mathit{Log}(\mathsf{V}))$ validates every equation of V. So suppose that $\mathsf{V} \models \varphi \approx \psi$; then $\mathsf{V} \models (\varphi \leftrightarrow \psi) \approx \top$ since V has a Boolean basis; from this it follows that $\varphi \leftrightarrow \psi \in \mathit{Log}(\mathsf{V})$, whence $\mathsf{BAO}_\tau(\mathit{Log}(\mathsf{V}))$ validates the equation $(\varphi \leftrightarrow \psi) \approx \top$, by definition. But $\mathsf{BAO}_\tau(\mathit{Log}(\mathsf{V}))$ also has a Boolean basis, so we find that $\mathsf{BAO}_\tau(\mathit{Log}(\mathsf{V})) \models \varphi \approx \psi$, as required.

The last part of the theorem is then immediate by the general theory of Galois connections. ❑

The dual isomorphism given by Theorem 82, linking the lattice of normal modal logics to that of varieties of BAOs, has yielded a wealth of information on modal logics. For instance, universal algebraic theory on *splitting algebras* led algebraically minded modal logicians to strong results on the *degree of Kripke incompleteness* of a modal logic, see for instance Blok [15]. We will not discuss the lattice of modal logics any further in this chapter, referring the reader to the Chapters 7 and 8 of this volume.

Instead we turn to the question, how standard logical phenomena fit in the algebraic framework presented so far. The answer to this question depends on the issue at stake, so let us consider a number of examples:

completeness is a property not so much of a single logic but rather of a pair of logics. For instance, Kripke completeness of a logic L means that L coincides with the logic of its frame class C. Algebraically, this corresponds to the fact that the variety $\mathsf{BAO}_\tau(L)$ is generated by the class of complex algebras $\mathsf{Cm}(\mathsf{C})$. More details will be provided in subsection 6.1.

canonicity of a modal logic L has, as we will see in subsection 6.2, an algebraic counterpart in the property of a class of algebras being closed under taking canonical extensions.

correspondence is more about formulas, or equations, than about logics, or varieties of algebras. Nevertheless, it has a clear algebraic meaning: We can say that an equation $s \approx t$ *corresponds, over a frame class* C to a first-order formula α in the language of frames, if, for all frames $\mathbb{S}$ in C, we have that $\mathbb{S}^+ \models s \approx t$ iff $\mathbb{S} \models \alpha$.

interpolation is a property of a normal modal logic. In subsection 6.3 we will see that it corresponds to an amalgamation property on the algebraic side.

Let us now move to a more detailed discussion of some of these issues.

6.1 Completeness

As we mentioned already, Theorem 17 can be read as a *general* algebraic *completeness* result. So in this respect the algebraic semantics behaves much better than the relational

one: Classes of Kripke frames are generally not adequate for revealing all distinctions between normal modal logics, see Chapter 7 of this volume for the details. It clearly *means* something for a modal logic to be Kripke complete, so what about the associated algebraic variety? For an answer, recall the notion of a *perfect* BAO from Definition 40.

THEOREM 83. *A normal modal τ-logic L is (Kripke) complete iff* $\mathsf{BAO}_\tau(L)$ *is generated by its perfect members.*

Proof. Straightforward by the observation that any variety V of BAOs is generated by its perfect members iff its equational theory coincides with that of the class $\mathsf{CmStr}(\mathsf{V})$. ❑

This inspires the following definition.

DEFINITION 84. A variety V of Boolean algebras with τ-operators is called *(Kripke) complete* if V is generated by its perfect members.

The phenomenon of Kripke incompleteness of normal modal logics is thus algebraically reflected by the fact that many different varieties of BAOs may share the same class of perfect members.

The formulation of Theorem 83 strongly suggests that Kripke completeness is only one of a *family* of properties pertaining to normal modal logics. In fact, one may wonder whether varieties of Boolean algebras with operators are generated by those of their members that meet any given constraint. For instance, we might consider varieties that are generated by their *finite* members. Since every finite BAO is perfect this gives a strong version of Kripke completeness that is known on the logical side as the *finite model property* of the logic.

In this respect it is also interesting to see what happens if we consider *weakenings* or *variations* of the notion of perfection. For instance, recall that perfection of a BAO is the conjunction of three properties: atomicity and completeness of the underlying Boolean algebra, and complete additivity of the operators. Hence, we may naturally ask which varieties of BAOs are generated by their atomic members, their complete and completely additive members, etc. Recent investigations have provided answers to some of these questions. First however, we mention a result of Buszkowski [18] which has been around for almost twenty years already, but which seems to have received little attention. Call a first-order formula or equation in the language of Boolean algebras with operators *modally guarded* if every variable occurs within the scope of a modality.

THEOREM 85. *Let* V *be a variety of expanded Boolean algebras which is axiomatized by modally guarded equations. Then* V *is generated by its atomic members.*

Proof. Given two BAEs $\mathbb{A}$ and $\mathbb{A}'$, call an embedding $\eta : \mathbb{A} \rightarrowtail \mathbb{A}'$ *guarded* if for all guarded formulas $\varphi(x_1, \ldots, x_k)$, and all $a_1, \ldots, a_k \in A$, it holds that $\mathbb{A} \models \varphi[a_1, \ldots, a_k]$ iff $\mathbb{A}' \models \varphi[\eta a_1, \ldots, \eta a_k]$. Then

$$\text{every BAE } \mathbb{A} \text{ has a guarded embedding into an atomic BAE.} \tag{23}$$

It is straightforward to prove the theorem from (23): Any algebra $\mathbb{A}$ in V can be embedded into an atomic BAE $\mathbb{B}$ that satisfies the same guarded sentences as $\mathbb{A}$, and thus in particular, also belongs to V.

For a proof of (23), let $\mathbb{A}$ be some τ-expanded Boolean algebra. By the Stone representation theorem, we may assume that for some set X, $\mathbb{A}$ is of the form

$$\langle A, X, \varnothing, \sim_X, \cup, \cap, \{\nabla^{\mathbb{A}} \mid \nabla \in \tau\}\rangle.$$

In fact, we may assume that every non-empty $a \in A$ is an *infinite* subset of X. (Otherwise, replace X with the set $X \times \omega$ and, using the natural embedding $P \mapsto P \times \omega$ of the power set algebra of X into that of $X \times \omega$, continue with the image of $\mathbb{A}$ under this map.) Now let B be the collection of those subsets b of X that differ in at most finitely many elements from some element of A; that is,

$$B := \{b \subseteq X \mid (a \cap \sim_X b) \cup (b \cap \sim_X a) \text{ is finite, for some } a \in A\}.$$

It is not hard to see that for every $b \in B$ there is in fact a *unique* element $a \in A$ such that the symmetric difference $(a \cap \sim_X b) \cup (b \cap \sim_X a)$ is finite; this element will be denoted as b^*.

One then easily proves that the structure $\langle B, X, \varnothing, \sim_X, \cup, \cap\rangle$ is an atomic Boolean algebra, so if we define, for $\nabla \in \tau$:

$$\nabla^{\mathbb{B}}(b_1, \ldots, b_n) := \nabla^{\mathbb{A}}(b_1^*, \ldots, b_n^*),$$

we obtain a τ-expanded Boolean algebra $\mathbb{B}$. Finally, a straightforward induction on the complexity of guarded formulas shows that the identity map is the required guarded embedding of $\mathbb{A}$ into $\mathbb{B}$. This proves (23). ❑

However, the restriction to *guarded* axioms in Theorem 85 is essential, as the following result of Venema [106] implies that there are varieties of BAOs that have *no* atomic members.

THEOREM 86. *There are nontrivial varieties of Boolean algebras with operators of which all members are atomless.*

Proof. The basic idea underlying this proof is straightforward: construct a particular, nontrivial, BAO $\mathbb{A}$, and a unary term $\pi(x)$ such that the formula $\alpha \equiv \forall x(\bot \prec x \Rightarrow \bot \prec \pi(x) \prec x)$ holds in $\mathbb{A}$. This shows not only that $\mathbb{A}$ is atomless, but that this atomlessness is witnessed by a *term function.*

Lacking the space for further details concerning the construction of $\mathbb{A}$, we briefly sketch how to prove the theorem from here. Let K be the class of BAOs satisfying α. Without loss of generality, assume that K has a global modality (see section 8.2). It then follows that the class $\mathsf{SP}(\mathsf{K})$ is a variety, and thus, that the formula α, being a universal Horn sentence, holds in every member of this variety. But then every such algebra is atomless, so the theorem follows if we can prove that K is nontrivial. But this is an immediate consequence of the existence of the algebra $\mathbb{A}$. ❑

Regarding the order/lattice theoretic property of completeness, a similar result obtains, due to Litak [81].

THEOREM 87. *There are nontrivial varieties of Boolean algebras with operators without complete members.*

Proof. Consider the similarity type of *tense logic*, as in section 8.1. Let $\mathbb{S} = \langle N, < \rangle$ be the bidirectional frame of the natural numbers with the standard ordering. That is, we interpret the diamonds $\Diamond_F$ and $\Diamond_P$ via the relations $<$ and $>$, respectively. Furthermore, let $\mathbb{A}$ be the subalgebra of $\mathbb{S}^+$ based on the collection of finite and cofinite subsets of $\mathbb{N}$. We claim that $\mathsf{Var}(\mathbb{A})$, the variety generated by $\mathbb{A}$, has no complete members. Suppose for contradiction that $\mathbb{C}$ is a complete member of $\mathsf{Var}(\mathbb{A})$.

Each natural number n is, inside $\mathbb{S}$, the unique point satisfying the variable free formula $\varphi_n := \Diamond_P^n \top \wedge \Box_P^{n+1} \bot$. Observe that the inequalities $\varphi_n \wedge \varphi_m \preceq \bot$ (for $m \neq n$), and $\varphi_n \preceq \Diamond_F \varphi_{n+1}$ hold in $\mathbb{A}$, hence in $\mathsf{Var}(\mathbb{A})$, and therefore, in $\mathbb{C}$. Define $a_n := \varphi_{2n}^{\mathbb{C}}$ and $b_n := \varphi_{2n+1}^{\mathbb{C}}$. It is then immediate that $a_n \leq \Diamond_F b_n$, $b_n \leq \Diamond_F a_{n+1}$, and $a_n \wedge b_m = \bot$, for all m, n (we write $\Diamond_F$ rather than $\Diamond_F^{\mathbb{C}}$). But $\mathbb{C}$ is complete, so it contains elements $a = \bigvee_n a_n$ and $b = \bigvee_n b_n$, for which we easily derive that $a \leq \Diamond_F b$, $b \leq \Diamond_F a$, and $a \wedge b = \bot$. Hence, from the fact that $\mathbb{C} \models \Diamond_F \Diamond_F x \preceq \Diamond_F x$ it follows that $a \leq \Diamond_F a \wedge \Diamond_F -a$, whence $a \wedge (\Box_F a \vee \Box_F -a) = \bot$. Thus $\mathbb{C}$ refutes the inequality $\Diamond_F x \preceq \Diamond_F (x \wedge \Box_F x \vee \Box_F \neg x)$, while a straightforward proof shows this inequality to hold in $\mathbb{A}$, and hence, in $\mathsf{Var}(\mathbb{A})$. This provides the required contradiction. ❑

For more information on such notions of incompleteness that are weaker than Kripke incompleteness, the reader is referred to Litak [81]. To mention one open problem: it is not known whether an analogue of the previous two results can be proved for the notion of completely additivity.

6.2 Canonicity

In Chapter 2 of this volume, a normal modal logic L is defined to be *canonical* if $\mathbb{C}_L \Vdash L$, where $\mathbb{C}_L$ is the canonical frame for the logic L. In order to put this in an algebraic perspective, first note that $\mathbb{C}_L \Vdash L$ is equivalent to the requirement that $\mathbb{C}_L^+ \models L^{\approx}$. Also, recall from Example 52 that the canonical frame for L is isomorphic to the ultrafilter frame of the Lindenbaum-Tarski algebra $\mathbb{F}_L$. Hence, we see that the issue is whether $(\mathbb{F}_L)^\sigma = ((\mathbb{F}_L)_\bullet)^+ \models L^{\approx}$, whereas we know that $\mathbb{F}_L \models L^{\approx}$, cf. Theorem 21. This inspires the following definition.

DEFINITION 88. A class of Boolean algebras with τ-operators is *canonical* if it is closed under taking canonical embedding algebras. Accordingly, an equation η is called *canonical* if the variety $\mathsf{BAO}_\tau(\eta)$ is canonical, that is, if $\mathbb{A} \models \eta$ only if $\mathbb{A}^\sigma \models \eta$, for all BAOs $\mathbb{A}$.

From the definition it is obvious that any normal modal logic is canonical if the variety $\mathsf{BAO}_\tau(L)$ is canonical, but what about the converse implication? Here we need to be a bit more precise about the definition of the canonical frame; in particular, about the size of the set of variables. For, observe that the notion of *maximality* of an L-consistent set of formulas depends on the surrounding set of formulas, and hence, on the set X of variables. Thus the shape of the canonical frame $\mathbb{C}_L$ depends on the *size* of the set X of variables; in order to make this dependence explicit, we will write $\mathbb{C}_L(X)$ for the canonical frame in which the points are maximal L-consistent subsets of $Fma(X)$. A similarly convention applies to Lindenbaum-Tarski algebras. Taking this cardinal subtlety into account, we arrive at a sharpened definition of the logical concept of canonicity.

DEFINITION 89. A normal modal logic L is *canonical* if $\mathbb{C}_L(X) \Vdash L$ for *all* sets X. A formula φ is called canonical if $\mathbb{C}_L(X) \Vdash \varphi$ for all normal modal logics L containing φ.

Fortunately, we can prove that the logical and the algebraic notion of canonicity coincide.

THEOREM 90. *For any normal modal τ-logic L, L is canonical iff* $\mathsf{BAO}_\tau(L)$ *is a canonical variety.*

Proof. Let $\mathbb{A}$ be an arbitrary algebra in $\mathsf{BAO}_\tau(L)$, and let X be a set containing a separate variable x_a for each $a \in A$. Then $\mathbb{A}$ is a homomorphic image of $\mathbb{F}_L(X)$ by the fact that $\mathbb{F}_L(X)$ is the free algebra for $\mathsf{BAO}_\tau(L)$ over the set $[X]_L$, see Theorem 22 for the case of countable X. Now two applications of Theorem 76 show that $(\mathbb{F}_L(X))^\sigma \twoheadrightarrow \mathbb{A}^\sigma$. But $(\mathbb{F}_L(X))^\sigma$ belongs to $\mathsf{BAO}_\tau(L)$ by canonicity of L, and so $\mathbb{A}^\sigma$ is in $\mathsf{BAO}_\tau(L)$ because varieties are closed under taking homomorphic images. ❑

It is not known whether, for the variety $\mathsf{BAO}_\tau(L)$ to be canonical, it suffices that the canonical frames for countable variable sets validate L. Leaving this question as an open problem, we turn to the logical *motivation* of the concept of canonicity. This lies in its applications in modal completeness theory, see Chapter 2 of this volume for details. Algebraically, these applications are connected to the following result.

THEOREM 91. *Let* V *be a variety of Boolean algebras with τ-operators. If* V *is canonical, then* V *is complete.*

Proof. If V is canonical then $\mathsf{V} \subseteq \mathsf{SCmCst}(\mathsf{V})$ so clearly V is generated by its perfect members. ❑

So where do we find canonical varieties? In general there seem to be two roads here, a syntactic and a model-theoretic one. The syntactic approach is the most important one for applications. Basically, the idea is to find out whether a logic is canonical on the basis of the syntactic shape of the axioms. Now in general it is *undecidable* whether a given formula φ is canonical (see Kracht [72] for a proof). Fortunately, however, there are fairly large classes of canonical formulas that occur frequently in practice, and are easily recognized. We confine our attention here to *Sahlqvist formulas* — these are also discussed in the Chapters 1, 5 and 7 of this volume.

In the sequel it will be convenient to assume that the primitive symbols of our language are, besides the Boolean connectives $\top$, $\bot$, $\neg$, $\wedge$ and $\vee$, and the modalities $\{\nabla \mid \nabla \in \tau\}$, also the implication symbol $\to$, and the dual modalities $\{\Delta \mid \nabla \in \tau\}$. Also, recall that boxes are the duals of diamonds, that is, of *unary* modal operators.

DEFINITION 92. Given a modal similarity type τ, we define the following classes of terms/formulas. A *boxed atom* is a variable, possibly preceded by a string of boxes. A formula π is *positive* (*negative*) if all of its variables are in the scope of an even (odd, respectively) number of negation symbols. A *Sahlqvist formula* is a formula of the form $\varphi \to \psi$, where φ is built up from negative formulas, boxed atoms, and constants, using only modalities, $\wedge$ and $\vee$, while ψ is a positive formula.

The following results are some of the most celebrated general results in modal logic. Theorem 93 below, from Sahlqvist [98], put the crown on the work of many contemporary modal logicians.

THEOREM 93 (Sahlqvist Canonicity). *Every Sahlqvist formula is canonical.*

For the *proof*, the reader is referred to section 7. As a corollary of this theorem and the *correspondence* result for Sahlqvist formulas (see Chapter 1 of this volume), we obtain the following.

COROLLARY 94. *Let $L = \mathbf{K}_\tau.\Sigma$ be a normal modal logic axiomatized by a collection Σ of Sahlqvist axioms. Then L is sound and complete with respect to the class of frames defined by the first-order correspondents of the formulas of Σ.*

REMARK 95. Although the Sahlqvist canonicity theorem takes care of most of the canonical formulas that one encounters in practice, it certainly does not cover the concept completely. For instance, Goranko & Vakarelov [49] widen the class to that of so-called *inductive* formulas, see Chapter 5 of this volume for some discussion. Jónsson [69] generalizes an example of Fine [25] to the result that for every positive formula $\varphi(x)$, the equation $\varphi(x \vee y) \approx \varphi(x) \vee \varphi(y)$ is canonical. And of course, there are individual examples of canonical formulas, such as the conjunction of the transitivity axiom 4 and the McKinsey axiom $\Box\Diamond x \leq \Diamond\Box x$, cf. [69] for an algebraic proof.

As we mentioned, a second way to arrive at canonical varieties of BAOs proceeds via a model-theoretic road. The basic idea here is that varieties are canonical if they can be *generated* in a certain way. A first and seminal result in this direction was the following.

THEOREM 96 (Fine). *If K is an elementary class of frames, then $Log(\mathsf{K})$ is a canonical normal modal logic.*

Algebraically, Theorem 96 reads that elementary frame classes generate canonical varieties. This result points at an intriguing connection between elementary frame classes and canonical varieties. In particular, it has been an open problem for a long time whether the converse of Fine's theorem would hold as well, that is, whether every canonical variety would be generated by some elementary frame class. Recently however, this issue has been settled negatively in Goldblatt, Hodkinson & Venema [46].

THEOREM 97. *There is a canonical variety that is not generated by any elementary frame class.*

Proof. The example that we give here is based on a famous graph-theoretic result due to Erdős. Here a *graph* is a pair $\mathbb{G} = (G, E)$ with E an irreflexive, symmetric relation on G. A *k-coloring* of $\mathbb{G}$ is a partition of G into k *independent* sets, i.e., sets containing no pair of neighboring vertices. The *chromatic number* $\chi(\mathbb{G})$ of $\mathbb{G}$ is the smallest number k for which it has a k-coloring, and ∞ if it has no finite coloring. A *cycle* in $\mathbb{G}$ is a path $x_1 E x_2 E \ldots E x_n E x_1$ such that $n \geq 3$ and $x_1, \ldots, x_n$ are all distinct vertices; the length of this cycle is n.

Now intuitively, a lack of short cycles, indicating a certain 'looseness' of the graph, should make it easy to color a graph with few colors, but Erdős [22] reveals the existence of a sequence of finite graphs whose n-th member $\mathbb{G}_n$ has chromaticity bigger than n while $\mathbb{G}_n$ has *no* cycles of length $\leq n$. Fix such a sequence $\{\mathbb{G}_n \mid n \geq 2\}$, under the additional assumption that $|\mathbb{G}_n| > |\mathbb{G}_m|$ if $n > m$. (Here $|\mathbb{G}|$ denotes the number of vertices in $\mathbb{G}$.)

The modal similarity type ϵ of our variety EG will have two diamonds, $\Diamond$ and E. On a graph $\mathbb{G}$, the first of these will be interpreted through the edge relation, and the second, through the *global relation* $\Upsilon_G = G \times G$. That is, E is a *global modality*, cf. section 8.2. In the sequel we will blur the distinction between the structures $\langle G, E, \Upsilon_G \rangle$ and $\langle G, E \rangle$,

for instance calling $\langle G, E, \Upsilon_G\rangle^+$ the complex algebra of $\mathbb{G}$, and denoting it, accordingly, as $\mathbb{G}^+$.

For the definition of EG we extend the notion of chromaticity to arbitrary algebras. An element a of an ϵ-BAO $\mathbb{A}$ is called *independent* if $a \wedge \Diamond a = \bot$; write $\chi(\mathbb{A})$ for the chromatic number of $\mathbb{A}$, that is, for the least k such that there are independent $a_1, \ldots, a_k$ with $a_1 \vee \cdots \vee a_k = \top$ and $a_i \wedge a_j = \bot$ for $i \neq j$, putting $\chi(\mathbb{A}) = \infty$ if there is no finite such k. Note that this definition generalizes the one given earlier, in the sense that for any graph $\mathbb{G}$, $\chi(\mathbb{G}) = \chi(\mathbb{G}^+)$.

Now let $\psi_{n,m}$ be the first order formula in this algebraic language stating that if $\mathbb{A}$ has at least 2^n elements, then $\chi(\mathbb{A}) > m$, and define

$$\begin{array}{rcl}\Psi & := & \{\psi_{1,2}\} \cup \{\psi_{|\mathbb{G}_n|,n} \mid n \geq 2\}, \\ \Gamma & := & \{x \preceq \mathsf{E}x, \mathsf{E}\mathsf{E}x \preceq \mathsf{E}x, \mathsf{E}\neg\mathsf{E}\neg x \preceq x, \Diamond x \preceq \mathsf{E}x\}.\end{array}$$

Note that Γ is the set of equations defining E to be a global modality, cf. Definition 135 for the logical incarnation of Γ. Let C denote the class of algebras satisfying the formulas $\Psi \cup \Gamma$, and let EG denote the variety generated by C. It follows from Theorem 139 that $\mathsf{EG} = \mathsf{SP}(\mathsf{C})$.

We first show that EG is canonical. Note that since C is an elementary class, it suffices by Theorem 98 below to prove that C itself is canonical. Take an arbitrary algebra $\mathbb{A}$ in C. If $\mathbb{A}$ is finite, then $\mathbb{A}^\sigma \cong \mathbb{A}$ is in C by assumption. If $\mathbb{A}$ is infinite, then $|\mathbb{A}| > 2^{|\mathbb{G}_n|}$ for all $n \geq 2$, so by $\mathbb{A} \models \psi_{|\mathbb{G}_n|,n}$ we obtain that $\chi(\mathbb{A}) > n$ for all $n \geq 2$. Clearly then $\chi(\mathbb{A}) = \infty$; from this we may derive that the ultrafilter frame $\mathbb{A}_\bullet$ has a *reflexive* point, which implies that $(\mathbb{A}_\bullet)^+$, being the complex algebra of $\mathbb{A}_\bullet$, has infinite chromaticity as well. But then we see that $\mathbb{A}^\sigma \models \psi_{m,n}$ for all m, n, so we certainly have $\mathbb{A}^\sigma \models \Psi$. It is easily seen that the formulas Γ are canonical, so that we have proved that $\mathbb{A}^\sigma$ belongs to C.

It is left to prove that EG is not elementarily generated. Theorem 4.12 of Goldblatt [40] states that any variety V of BAOs which is elementarily generated, is generated by an elementary frame class K such that $\mathsf{Cst}(\mathsf{V}) \subseteq \mathsf{K} \subseteq \mathsf{Str}(\mathsf{V})$. Hence, for our purpose it suffices to come up with a family of frames in $\mathsf{Cst}(\mathsf{EG})$ that provide an ultraproduct outside $\mathsf{Str}(\mathsf{EG})$, and the obvious candidates for this are the Erdős frames $\{\mathbb{G}_n \mid n \geq 2\}$. It is easy to check that $\mathbb{G}_n^+ \models \Psi$ for each $n \geq 2$, so each $\mathbb{G}_n^+$ belongs to C. But then all Erdős frames belong to $\mathsf{Cst}(\mathsf{C})$, because each $\mathbb{G}_n$, being finite, is isomorphic to $(\mathbb{G}_n^+)_\bullet$. Now take a non-principal ultrafilter D over the set $\omega \setminus \{0,1\}$. Observe that for each k, only finitely many of the $\mathbb{G}_n$ have any cycles of length k; hence, by Łos' theorem, the ultraproduct $\prod_D \mathbb{G}_n$ has no cycles at all, and hence, it is *2-colorable.*

This shows that $\prod_D \mathbb{G}_n$ does not belong to C, since it follows from $\mathsf{C} \models \psi_{1,2}$ that every nontrivial algebra in C has chromaticity at least three. But fairly direct proofs show that $\chi(\prod_I \mathbb{A}_i) \geq \chi(\mathbb{A}_i)$ for all i, and that $\chi(\mathbb{A}) \geq \chi(\mathbb{A}')$ if $\mathbb{A} \rightarrowtail \mathbb{A}'$. This implies that $\chi(\mathbb{A}) > 2$ for all $\mathbb{A}$ in $\mathsf{SP}(\mathsf{C})$, so by the fact that $\mathsf{SP}(\mathsf{C}) = \mathsf{EG}$ it follows that $(\prod_D \mathbb{G}_n)^+$ does not belong to EG. ❑

Nevertheless, the converse of Fine's theorem may fail be true in general, in many interesting cases it does hold — we refer to Goldblatt, Hodkinson & Venema [46] for a state of the art survey. Note that it is still an open problem whether every *finitely axiomatizable* canonical variety is elementarily generated.

Finally, recent work has put Fine's result in a wider algebraic context. We formulate the following theorem for Boolean algebras with operators, but in fact, it holds in a much wider setting, see for instance Gehrke & Harding [28].

THEOREM 98. *Let K be a class of Boolean algebras with τ-operators which is closed under taking ultraproducts and canonical extensions. Then the variety generated by K is canonical.*

Proof. Let $\mathbb{A}$ be in the variety generated by K; we will show $\mathbb{A}^\sigma$ to belong to $\mathsf{Var}(\mathsf{K})$ as well. By Tarski's 'HSP'-theorem, there is a family $\{\mathbb{B}_i \mid i \in I\} \subseteq \mathsf{K}$, and an algebra $\mathbb{B}$ such that $\mathbb{A} \twoheadleftarrow \mathbb{B} \rightarrowtail \prod_I \mathbb{B}_i$. Then it follows from two times two applications of Theorem 76 that $\mathbb{A}^\sigma \twoheadleftarrow \mathbb{B}^\sigma \rightarrowtail (\prod_I \mathbb{B}_i)^\sigma$, so it suffices to show that $(\prod_I \mathbb{B}_i)^\sigma$ belongs to $\mathsf{Var}(\mathsf{K})$. However, we may infer from Theorem 77 and Theorem 76(5) that

$$\left(\prod\nolimits_I \mathbb{B}_i\right)^\sigma \cong \prod_{D \in Uf(I)} \left(\prod\nolimits_D \mathbb{A}_i\right)^\sigma . \tag{24}$$

But by the assumptions on K, each algebra $(\prod_D \mathbb{A}_i)^\sigma$ belongs to K, and so the product (24) is in $\mathsf{P}(\mathsf{K}) \subseteq \mathsf{Var}(\mathsf{K})$, as required. ❑

From the above result we can derive Fine's Theorem as follows. Suppose that C is a frame class, closed under taking ultraproducts; for instance, let C be elementary. Then consider the class $\mathsf{SCm}(\mathsf{C})$ of sub-complex algebras over C. This class can be shown to be closed under taking ultraproducts as a corollary of Proposition 78, and closed under taking canonical extensions as a corollary of Theorem 76 and Theorem 90 in Chapter 5 of this volume. Application of Theorem 98 then yields the desired result.

6.3 Interpolation

In the last part of this section we discuss another fundamental property of logics: interpolation. Interpolation is important for applications because it allows reasoning systems to be set up in a modular way. Since we have confined our attention to logics in the form of sets of theorems, the version of interpolation that we will consider here is the following.

DEFINITION 99. A modal logic L has the *local* or *Craig interpolation property* if for every two formulas φ and ψ such that $\vdash_L \varphi \to \psi$ there is an *interpolant*, that is, a formula χ with $\vdash_L \varphi \to \chi$ and $\vdash_L \chi \to \psi$ and such that each variable of χ occurs both in φ and in ψ.

The algebraic counterpart of interpolation involves the notion of *amalgamation.*

DEFINITION 100. Let K be a class of algebras.

A *V-formation* in K is a quintuple, presented as $\mathbb{B}_1 \overset{e_1}{\leftarrowtail} \mathbb{B}_0 \overset{e_1}{\rightarrowtail} \mathbb{B}_2$, and consisting of three algebras $\mathbb{B}_0$, $\mathbb{B}_1$ and $\mathbb{B}_2$ in K, linked by two embeddings e_0 and e_1. An *amalgam* of this V-formation is a formation $\mathbb{B}_1 \overset{f_1}{\rightarrowtail} \mathbb{B}_{12} \overset{f_1}{\leftarrowtail} \mathbb{B}_2$ such that $f_1 \circ e_1 = f_2 \circ e_2$. Such a amalgam is a *superamalgam* if for all distinct i and j, and all $b_i \in B_i$ and $b_j \in B_j$: $f_i(b_i) \leq_{12} f_j(b_j)$ only if there is some $b_0 \in B_0$ with $b_i \leq_i e_i(b_0)$ and $e_j(b_0) \leq_j b_j$.

$$\begin{tikzcd}
& \mathbb{B}_{12} & \\
\mathbb{B}_1 \arrow[ur, dotted, "f_1"] & & \mathbb{B}_2 \arrow[ul, dotted, "f_2"'] \\
& \mathbb{B}_0 \arrow[ul, "e_1"] \arrow[ur, "e_2"'] &
\end{tikzcd}$$

K is said to have the *(super)amalgamation property* if every V-formation in K has a (super)amalgam in K.

In words, an amalgam is a superamalgam if whenever a $\mathbb{B}_i$-element is smaller (in $\mathbb{B}_{12}$) than a $\mathbb{B}_j$-element, then this is *witnessed* by a $\mathbb{B}_0$-element. The basic result connecting interpolation and amalgamation is from Maksimova [83].

THEOREM 101. *Let L be a normal modal τ-logic. Then L has the local interpolation property if and only if* $\mathsf{BAO}_\tau(L)$ *has superamalgamation.*

Proof. Fix L. In the proof of this theorem we will frequently consider Lindenbaum-Tarski algebras for L over various distinct sets of variables. Our notational convention will be that these sets of variables will always be called X_0, X_1, X_2 and X_{12}, with $X_0 = X_1 \cap X_2$ and $X_{12} = X_1 \cup X_2$; that $\mathbb{F}_i$ denotes the Lindenbaum-Tarski algebra over X_i; that $[\varphi]_i$ denotes the equivalence class of the formula φ under the L-equivalence relation $\equiv_L$ *within* the set $Fma(X_i)$; and, finally, if $X_i \subseteq X_j$, that $\iota_{i,j}$ denotes the map given by $[\varphi]_i \mapsto [\varphi]_j$. We leave it for the reader to verify that $\iota_{i,j}$ is an *embedding* of $\mathbb{F}_i$ into $\mathbb{F}_j$.

It is not hard to prove that L has local interpolation iff for all sets X_1 and X_2 of variables, the formation $\mathbb{F}_1 \overset{\iota_{1,12}}{\rightarrowtail} \mathbb{F}_{12} \overset{\iota_{2,12}}{\leftarrowtail} \mathbb{F}_2$ is a superamalgam of the V-formation $\mathbb{F}_1 \overset{\iota_{0,1}}{\leftarrowtail} \mathbb{F}_0 \overset{\iota_{0,2}}{\rightarrowtail} \mathbb{F}_2$. This observation already takes care of the direction from right to left of the theorem.

For the other direction we have to work harder. Consider a V-formation $\mathbb{B}_1 \overset{e_1}{\leftarrowtail} \mathbb{B}_0 \overset{e_1}{\rightarrowtail} \mathbb{B}_2$ in $\mathsf{BAO}_\tau(L)$. Without loss of generality we may assume that $B_0 = B_1 \cap B_2$. Wanting to use local interpolation of L to find a superamalgam of this V-formation, we translate the V-formation into syntax.

With $X_i := \{x_b \mid b \in B_i\}$ for each $i \in \{0, 1, 2\}$, let $\beta_i : \mathbb{F}_i \to \mathbb{B}_i$ be the unique homomorphism determined by the map $[x_b] \mapsto b$, cf. the picture. Clearly each β_i is surjective, whence by universal algebra, each $\mathbb{B}_i$ is isomorphic to the algebra $\mathbb{F}_i / \ker(\beta_i)$. Let M_i be the modal filter of $\mathbb{F}_i$ associated with the congruence $\ker(\beta_i)$ (as in Theorem 29), and let M be the modal filter of $\mathbb{F}_{12}$ generated by the union of M_1 and M_2, or, to be more precise, by the set $\iota_{1,12}[M_1] \cup \iota_{1,12}[M_1]$. We claim that the algebra $\mathbb{F}_{12}/\Pi_M$ is the required superamalgam, with Π_M the congruence associated with M, again, as in Theorem 29.

$$\begin{tikzcd}
 & \mathbb{B}_1 \arrow[rr, dotted] & & \mathbb{F}_{12}/\Pi_M \\
\mathbb{F}_1 \arrow[ur, "\beta_1"] \arrow[rr, "\iota_{1,12}"] & & \mathbb{F}_{12} \arrow[ur] & \\
 & \mathbb{B}_0 \arrow[uu, "e_1"] \arrow[rr, "e_2"] & & \mathbb{B}_2 \arrow[uu, dotted] \\
\mathbb{F}_0 \arrow[uu, "\iota_{0,1}"] \arrow[ur, "\beta_0"] \arrow[rr, "\iota_{0,2}"] & & \mathbb{F}_2 \arrow[uu, "\iota_{2,12}"] \arrow[ur, "\beta_2"] &
\end{tikzcd}$$

Proving this, the crucial observation is that $[\varphi]_{12}$ belongs to M iff there are formulas $\varphi_1 \in Fma(X_1)$ and $\varphi_2 \in Fma(X_2)$ such that $\vdash_L (\varphi_1 \wedge \varphi_2) \to \varphi$, and $[\varphi_i]_i \in M_i$ for $i = 1, 2$. From this, using local interpolation, it may be derived that for formulas $\psi_1 \in Fma(X_1)$ and $\psi_2 \in Fma(X_2)$, we have $[\psi_1 \to \psi_2]_{12} \in M$ iff there is a $\chi \in Fma(X_0)$ such that $[\psi_1 \to \chi]_1 \in M_1$ and $[\chi \to \psi_2]_2 \in M_2$. And from this the desired properties of $\mathbb{F}_{12}/\Pi_M$ follow almost immediately. ❑

This theorem can be applied to obtain a fairly general interpolation result for *canonical* modal logics that define nice frame classes. We need the following definition.

DEFINITION 102. Let $\mathbb{S}_1$ and $\mathbb{S}_2$ be two τ-frames. The direct product $\mathbb{S}_1 \times \mathbb{S}_2$ of these frames is the frame based on the Cartesian product $S_1 \times S_2$, with the relations defined coordinate-wise (for instance, in the case of a binary relation R, we put $R(s_1, s_2)(t_1, t_2)$ if $R_1 s_1 t_1$ and $R_2 s_2 t_2$). A subframe $\mathbb{Z}$ of $\mathbb{S}_1 \times \mathbb{S}_2$ is called a *zigzag product* of $\mathbb{S}_1$ and $\mathbb{S}_2$ if Z is a hereditary subset of the product frame on which the projection maps are surjective.

Clearly then zigzag products are substructures of direct products. A different perspective is that zigzag products of $\mathbb{S}_1$ and $\mathbb{S}_2$ are given by those bisimulations Z between $\mathbb{S}_1$ and $\mathbb{S}_2$ that are *full*, i.e., have domain S_1 and range S_2.

As an example of a zigzag product, consider two surjective bounded morphisms θ_1, θ_2 with $\theta_i : \mathbb{S}_i \twoheadrightarrow \mathbb{S}_0$. Then the frame $\mathbb{E}(\theta_1, \theta_2)$ based on the set $\{(s_1, s_2) \in S_1 \times S_2 \mid \theta_1(s_1) = \theta_2(s_2)\}$ is a zigzag product of $\mathbb{S}_1$ and $\mathbb{S}_2$. We call this the zigzag product *induced* by θ_1 and θ_2.

The following theorem, which is a generalization from Marx [84] of a result by Németi [87], is useful for proving that a canonical logic has interpolation.

THEOREM 103. *Let* K *be a class of Boolean algebras with* τ*-frames, and* C *a class of* τ*-frames such that* $\mathsf{Cst}(\mathsf{K}) \subseteq \mathsf{C}$*,* $\mathsf{Cm}(\mathsf{C}) \subseteq \mathsf{K}$*, and* C *is closed under taking zigzag products. Then* K *has the superamalgamation property.*

Proof. Suppose that K and C have the listed properties, and consider a V-formation

$$\mathbb{B} \stackrel{\alpha}{\leftarrowtail} \mathbb{A} \stackrel{\alpha'}{\rightarrowtail} \mathbb{B}'. \tag{25}$$

It follows from Theorem 76(3) that $\mathbb{B}_\bullet \stackrel{\alpha_\bullet}{\twoheadrightarrow} \mathbb{A}_\bullet \stackrel{\alpha'_\bullet}{\twoheadleftarrow} \mathbb{B}'_\bullet$. Now let $\mathbb{E}$ be the zigzag product of $\mathbb{B}_\bullet$ and $\mathbb{B}'_\bullet$ induced by the bounded morphisms $\alpha_\bullet$ and $\alpha'_\bullet$. Note that $\mathbb{E}$ belongs to $\mathbb{C}$ by the listed closure properties. Letting π and π' be the (surjective!) bounded morphisms from $\mathbb{E}$ onto $\mathbb{B}_\bullet$ and $\mathbb{B}'_\bullet$, respectively, we see that $\mathbb{B}_\bullet \stackrel{\pi}{\twoheadleftarrow} \mathbb{E} \stackrel{\pi'}{\twoheadrightarrow} \mathbb{B}'_\bullet$. It then follows from Theorem 76(2) and Theorem 54 that

$$\mathbb{B} \stackrel{\widehat{\cdot}}{\rightarrowtail} \mathbb{B}^\sigma \stackrel{\pi^+}{\rightarrowtail} \mathbb{E}^+ \stackrel{\pi'^+}{\leftarrowtail} \mathbb{B}'^\sigma \stackrel{\widehat{\cdot}}{\leftarrowtail} \mathbb{B}' \tag{26}$$

We claim that in fact, (26) is a superamalgam of (25), but leave further proof details for the reader. ❑

As a corollary of this theorem, suppose that Γ is a set of canonical formulas defining an elementary frame class that is closed under taking direct products and substructures — for instance, Γ corresponds to a set of universal Horn sentences. Then $\mathbf{K}_\tau.\Gamma$ has Craig interpolation.

Chapter 8 of this volume contains more information on interpolation. Related properties, such as Beth definability, also have algebraic characterizations; for details we refer to HOOGLAND [59].

7 CASE STUDY: CANONICAL EQUATIONS

7.1 Introduction

In this section we address the question, which equations are *canonical*, that is, remain valid when we move from a BAO $\mathbb{A}$ to its canonical embedding algebra $\mathbb{A}^\sigma$. In other words, we are interested in properties that move to certain *superalgebras*.

Earlier on we defined $\mathbb{A}^\sigma$ via a concrete construction, namely, as the 'double dual' $(\mathbb{A}_\bullet)^+$: the complex algebra of the ultrafilter frame of $\mathbb{A}$. In this section we will take a rather more abstract approach in which we first consider the canonical extension $\mathbb{B}^\sigma$ of the Boolean reduct $\mathbb{B}$ of $\mathbb{A}$; this $\mathbb{B}^\sigma$ is not constructed but axiomatically characterized as the (modulo isomorphism) unique completion of $\mathbb{B}$ in which $\mathbb{B}$ is *dense* and *compact*. Then the property of density suggests a canonical way to extend the interpretation of the operators on $\mathbb{B}$ to operations on $\mathbb{B}^\sigma$, thus providing the canonical extension $\mathbb{A}^\sigma$ of $\mathbb{A}$.

This algebraic method originates with the original BAO paper Jónsson and Tarski [70], but it differs from the duality-based approach of for instance Sambin & Vaccaro [100] that modal logicians usually take. In order to compare the two approaches, consider the following picture, introducing the four main characters of this story:

$$\begin{array}{|c|c|}\hline \mathbb{A} & \mathbb{A}_* \\ \hline \mathbb{A}^\sigma & \mathbb{A}_\bullet \\ \hline \end{array} \tag{27}$$

In the duality-based approach, one compares the frame (frame-based) structures on the right hand side of the picture, cf. the discussion on the notion of *persistence* in Chapter 5 of this volume, while the algebraic method stays purely on the left hand side, basically by encoding the relevant topological concepts into the algebraic framework. An advantage of the duality-based method is that it allows a treatment of canonicity in tandem with correspondence; on the other hand, the more abstract and 'duality-free' nature of the other approach enables its transportation to a much wider setting than that of canonical extensions of Boolean algebras with operators. In recent years, the algebraic approach has proven its use for *lattices* expanded with *arbitrary* operations, and has been applied to other kinds of completions than the perfect extension of Jónsson and Tarski.

Our exposition of this algebraic approach in the sections 7.2 to 7.5 is based on work by Jónsson [69], Gehrke & Jónsson [30, 31, 32] and Gehrke & Harding [28], while the very similar approach by Ghilardi & Meloni [34] should also be mentioned here. In our presentation we try to be as general as possible while keeping the section self-contained, and staying within the framework of Boolean algebras. Almost all our formulations apply to lattice-ordered algebras as well, however; we will come back to this issue towards the end of the section when we discuss further generalizations of the theory presented here.

For an outline, recall that the validity of equations can be formulated using term functions:

$$\mathbb{A} \models s \approx t \text{ iff } s^{\mathbb{A}} = t^{\mathbb{A}}. \tag{28}$$

Hence, for the canonical extension of $\mathbb{A}$, we find that

$$\mathbb{A}^\sigma \models s \approx t \text{ iff } s^{\mathbb{A}^\sigma} = t^{\mathbb{A}^\sigma}. \tag{29}$$

Now suppose that we have developed a canonical way to extend an n-ary map $f : A^n \to A$ to an n-ary map $f^\sigma : (A^\sigma)^n \to A^\sigma$; it then immediately follows from (28) that

$$\mathbb{A} \models s \approx t \text{ only if } (s^{\mathbb{A}})^\sigma = (t^{\mathbb{A}})^\sigma. \tag{30}$$

Hence, in case s and t are *stable* on $\mathbb{A}$, that is, if $(s^{\mathbb{A}})^\sigma = s^{\mathbb{A}^\sigma}$ and $(t^{\mathbb{A}})^\sigma = t^{\mathbb{A}^\sigma}$, then we may infer from $\mathbb{A} \models s \approx t$ that $\mathbb{A}^\sigma \models s \approx t$. This motivates a careful analysis of the relation between the functions $s^{\mathbb{A}^\sigma}$ (the term function of s in $\mathbb{A}^\sigma$) and $(s^{\mathbb{A}})^\sigma$ (the extension to $\mathbb{A}^\sigma$ of the term function $s^{\mathbb{A}}$). This analysis crucially involves the question, which f

and g satisfy $(f \circ g)^\sigma = f^\sigma \circ g^\sigma$. We will see that such cases of $(\cdot)^\sigma$ distributing over function composition admit a satisfactory explanation in terms of 'matching continuity properties' of the maps f^σ and g^σ. For this purpose we will endow canonical extensions of Boolean algebras with topological structure.

7.2 Canonical extensions of Boolean algebras

In this section we define the canonical extension of a Boolean algebra $\mathbb{B}$ as the unique *completion* of $\mathbb{B}$ in which $\mathbb{B}$ is *dense* and *compact*. We introduce these notions one by one.

A Boolean algebra $\mathbb{C}$ is a *completion* of a Boolean algebra $\mathbb{B}$ if $\mathbb{C}$ is complete and $\mathbb{B}$ is a subalgebra of $\mathbb{C}$. If $\mathbb{C}$ agrees with $\mathbb{B}$ on *all* meets and joins, then we call $\mathbb{C}$ a *regular* completion of $\mathbb{B}$, but in general we do not require completions to be regular. Thus the notation $\vee$ for finite joins is unambiguous, but not so for infinite joins. Our convention will be that $\bigvee X$ always denotes $\bigvee^{\mathbb{C}} X$, that is, the join taken in the completion.

For an example of a completion, consider a field of sets $\mathbb{S} = \langle S, A \rangle$ and note that the power set algebra $\mathbb{P}S$ is a completion of $\mathbb{S}^*$.

Before we define the concept of density, we introduce some preliminary notions. Given a completion $\mathbb{C}$ of the Boolean algebra $\mathbb{B}$, we call an element $c \in C$ *closed* (*open*) if c is the meet (join, respectively) in $\mathbb{C}$ of elements in B. We let $K_{\mathbb{C}}(B)$ and $O_{\mathbb{C}}(B)$ denote the collections of closed and open elements, respectively. Objects (such as the elements of B) that are both closed and open are called *clopen*. This terminology is in accordance with the topological perspective on fields of sets as in Remark 60. In the sequel, we may write $K_{\mathbb{C}}$, $K(B)$, or even K, instead of $K_{\mathbb{C}}(B)$, if the suppressed details are clear from context; and similarly for the set $O_{\mathbb{C}}(B)$.

We say that $\mathbb{B}$ is *meet-dense* in $\mathbb{C}$ if $K_{\mathbb{C}}(B) = C$, *join-dense* if $O_{\mathbb{C}}(B) = C$, and *dense* if $K_{\mathbb{C}}(O_{\mathbb{C}}(B)) = O_{\mathbb{C}}(K_{\mathbb{C}}(B)) = C$. In words, A is dense in $\mathbb{C}$ if every element of C is both a meet of open elements, and a join of closed elements. As a simple example of join-density, note that a Boolean algebra is atomic iff the collection of atoms forms a join-dense set. Building on this, we leave it as an exercise for the reader to verify that a field of sets $\mathbb{S} = \langle S, A \rangle$ is differentiated iff $\mathbb{S}^*$ is dense in $\mathbb{P}S$.

Now we turn to the notion of compactness. Given a completion $\mathbb{C}$ of the Boolean algebra $\mathbb{B}$, we say that $\mathbb{B}$ is *compact in* $\mathbb{C}$ if for all sets X and Y of closed and open elements, respectively, $\bigwedge X \leq \bigvee Y$ implies the existence of finite subsets $X_0 \subseteq X$, $Y_0 \subseteq Y$ such that $\bigwedge X_0 \leq \bigvee Y_0$. An alternative (but equivalent) characterization of compactness is that, for any closed p and open u,

$$p \leq u \text{ only if } p \leq b \leq u \text{ for some } b \in B,$$

as can easily be verified. Also note that, again, our definition of compactness coincides with standard topological terminology; this easily follows from the observation that for any pair C, U of collections of subsets of a set S, we have $\bigcap C \subseteq \bigcup U$ iff $S \subseteq \bigcup U \cup \bigcup \{\sim_S c \mid c \in C\}$.

We are now ready to define canonical extensions.

DEFINITION 104. A completion $\mathbb{C}$ of the Boolean algebra $\mathbb{B}$ is called a *canonical extension of* $\mathbb{B}$ if $\mathbb{B}$ is both compact and dense in $\mathbb{C}$.

It is in fact a rather strong property for one Boolean algebra to be the canonical extension of another. To start with, every Boolean algebra has a *unique* canonical extension.

THEOREM 105. *Let $\mathbb{B}$ be some Boolean algebra. Then*

1. *(existence) $\mathbb{B}$ has a canonical extension;*
2. *(unicity) Any two canonical extensions of $\mathbb{B}$ are isomorphic via a unique isomorphism that restricts to the identity on B.*

Proof. Recall from the topological duality that $\mathbb{B}_* = \langle Uf\mathbb{B}, \widehat{B}\rangle$ is a differentiated and compact field of sets. By the comments made above it should be clear that $\mathbb{P}(Uf\mathbb{B})$ is a canonical extension of $\mathbb{B}$.

For unicity, suppose that $\mathbb{C}$ is a canonical extension of $\mathbb{B}$. We leave it as an exercise for the reader to verify that, by compactness, the map $F \mapsto \bigwedge F$ forms a dual (that is, order-reversing) isomorphism between the lattice $\langle Fi(\mathbb{B}), \subseteq\rangle$ and the induced ordering on the set $K(B)$ of closed elements. Its inverse is given by the map $p \mapsto \{a \in B \mid a \geq p\}$. Similarly, there is a dual isomorphism between the lattice of ideals of $\mathbb{B}$, and the induced ordering of the open elements. Also, we have for p closed and u open, that $p \leq u$ iff there is an $a \in B$ with $p \leq a \leq u$, and that $u \leq p$ iff $a \leq b$ for all a and b in A with $a \leq u$ and $p \leq b$. In other words, by *compactness* the induced poset on the set $K \cup O$ of closed or open elements is completely determined by the ordering of $\mathbb{B}$. This suffices to prove the theorem, since by *density*, the elements of $\mathbb{C}$ can be identified with the pairs (L, U) of subsets of C such that L is the collection of closed lower bounds of U, and U is the collection of open upper bounds of L. Summarizing, we see that together, compactness and density completely fix the order relation of the canonical extension. ❑

The above theorem justifies our speaking of 'the' canonical extension of a Boolean algebra $\mathbb{B}$; this algebra will be denoted as $\mathbb{B}^\sigma$. Furthermore, we need the following facts.

PROPOSITION 106. *Let $\mathbb{C}$ be a canonical extension of the Boolean algebra $\mathbb{B}$. Then*

1. *$B = K(B) \cap O(B)$; that is, B coincides with the set of clopen elements of $\mathbb{C}$;*
2. *the set $K(B)$ forms a sublattice of $\mathbb{C}$ which is closed under taking infinitary meets;*
3. *$\mathbb{C}$ is atomic and $At\mathbb{C} \subseteq K(B)$; that is, all atoms are closed.*

We leave the proof of this proposition to the reader; note that by Theorem 105, it suffices to restrict attention to the double dual $\mathbb{P}(Uf\mathbb{B})$ of $\mathbb{B}$. For instance, part (3) follows almost immediately from the identification of atoms of $\mathbb{P}(Uf\mathbb{B})$ with ultrafilters of $\mathbb{B}$.

As a last introductory remark, we note that canonical extensions interact well with finite products and order duals. Concerning the latter notion, recall that the *order dual* of a Boolean algebra $\mathbb{B} = \langle B, \top, \bot, -, \wedge, \vee\rangle$ is the structure $\mathbb{B}^\partial = \langle B, \bot, \top, -, \vee, \wedge\rangle$. The fact, that $\mathbb{B}^\partial$ is a Boolean algebra as well, enables us to shorten quite a lot of definitions and proofs by referring to the *principle of order duality*: Every fact concerning Boolean algebras remains valid after swapping $\top$ with $\bot$, $\wedge$ with $\vee$, etc.

PROPOSITION 107. *Let $\mathbb{B}_1, \ldots, \mathbb{B}_n$ be Boolean algebras. Then*

1. *$(\mathbb{B}_1 \times \cdots \times \mathbb{B}_n)^\sigma \cong \mathbb{B}_1^\sigma \times \cdots \times \mathbb{B}_n^\sigma$;*
2. *$(\mathbb{B}^\partial)^\sigma \cong (\mathbb{B}^\sigma)^\partial$;*

Proof. Both statements can be proved on the basis of Theorem 76. As intermediate steps, one can prove facts like $K(\mathbb{B}_1) \times \cdots \times \mathbb{B}_n) = K(\mathbb{B}_1) \times \cdots \times K(\mathbb{B}_n)$ and $K(\mathbb{B}^\partial) = O(\mathbb{B})$. ❑

7.3 *Extending maps to the canonical extension*

In the introduction to this section we saw that in order to investigate the canonicity of an equation $s \approx t$, it is useful to define extensions of the term functions on a BAO to maps on the canonical extension of the BAO. But in fact, there are canonical ways to extend an *arbitrary* map between two Boolean algebras $\mathbb{A}$ and $\mathbb{B}$, to a map between $\mathbb{A}^\sigma$ and $\mathbb{B}^\sigma$. This general definition will be discussed at the end of this section — for the time being we will confine ourselves to extensions of *monotone* maps.

The easiest way to understand these definitions is to break them down in two steps. For a start, the definition of closed and open elements suggests the following extension of $f : \mathbb{A} \to \mathbb{B}$ to a map $\overline{f}$ defined on $K(A) \cup O(A)$:

$$\begin{array}{rcll} \overline{f}(p) & := & \bigwedge\{f(a) \mid p \leq a \in A\} & \text{for } p \in K(A), \\ \overline{f}(u) & := & \bigvee\{f(a) \mid u \geq a \in A\} & \text{for } u \in O(A). \end{array} \tag{31}$$

Note that this is a correct definition because $K \cap O = A$ by Proposition 106(1), that $\overline{f}(a) = f(a)$ for $a \in A$ by monotonicity of f, and that $\overline{f}$ itself is also order preserving.

Now for the second step of the construction. The fact that every element is both the join of the closed elements below it, and the meet of the opens above it, suggests *two* ways to proceed:

$$\begin{array}{rcl} f^\sigma(x) & := & \bigvee\{\overline{f}(p) \mid x \geq p \in K(A)\}, \\ f^\pi(x) & := & \bigwedge\{\overline{f}(u) \mid x \leq u \in O(A)\}. \end{array} \tag{32}$$

The maps f^σ and f^π are called the *lower* and *upper extension* of f, respectively.

Let us first gather some basic facts concerning these definitions. The following proposition says that the names 'lower', 'upper', and 'extension' are well chosen.

PROPOSITION 108. *Let $f : \mathbb{A} \to \mathbb{B}$ be a monotone map between Boolean algebras. Then*

1. *both f^σ and f^π extend f;*

2. *$f^\sigma \leq f^\pi$, with equality holding on the closed and on the open elements.*

Proof. The first statement is immediate by the definitions and the monotonicity of $\overline{f}$. For the second statement, take, for $x \in A^\sigma$, a closed $p \leq x$ and an open $u \geq x$. By compactness there is an $a \in [p, u] \cap A$. This element satisfies $\overline{f}(p) \leq f(a) \leq \overline{f}(u)$ by definition of $\overline{f}$; hence $f^\sigma(x) \leq f^\pi(x)$ by definition of f^σ and f^π. Finally, for closed p we may derive from the first part of the proposition that $f^\pi(p) \leq \overline{f}(p)$, and from the monotonicity of $\overline{f}$ that $\overline{f}(p) = f^\sigma(p)$. Thus we obtain the desired equality $f^\sigma = f^\pi$ on K. The result for opens follows by order duality. ❑

Maps for which the lower and upper extension coincide are obviously of interest.

DEFINITION 109. A monotone map f between Boolean algebras is called *smooth* if $f^\sigma = f^\pi$.

EXAMPLE 110. As a first example of a smooth operation, consider the *global modality* g on a Boolean algebra $\mathbb{B}$, given by $g(\bot) = \bot$ while $g(b) = \top$ for $b > \bot$, see Definition 131. It is easy to see that $\overline{g}$ satisfies these conditions as well, whence it is equally easy to infer that both g^σ and g^π coincide with the global modality of $\mathbb{B}^\sigma$; smoothness is then immediate. Similarly, one can prove that the *meet* and *join* operations of $\mathbb{B}$ are smooth, and that their extensions coincide with the meet and the join of $\mathbb{B}^\sigma$, respectively.

For an operation that is not smooth, consider the composition of the global modality with the meet operation, i.e., the map $f : B^2 \to B$ given by $f(a, b) = \bot$ if $a \wedge b = \bot$, while $f(a, b) = \top$ otherwise. Now if $\mathbb{B}$ is infinite, then $\mathbb{B}^\sigma$ must contain some element c which is closed but not open; a straightforward verification shows that for such a c, we have that $f^\sigma(c, -c) = \bot$, while $f^\pi(c, -c) = \top$. This shows that not even operators are smooth.

While it may not be the case that the lower and the upper extension agree in all cases, both kinds of extensions generally display good behavior; often they even improve on the original map. For the definitions of the notions mentioned in the theorem below, see Definition 15 and 40.

PROPOSITION 111. *Let $f : \mathbb{A} \to \mathbb{B}$ be a map between Boolean algebras. Then*

1. *if f is monotone then so is f^σ;*
2. *if f is an operator then f^σ is a complete operator;*
3. *if f is additive or multiplicative then f is smooth.*

Proof. The proof of the first statement is easy and hence omitted, while we postpone the proof of the last statement (it is in fact a rather straightforward consequence of the Propositions 116 and 117). For the remaining part, we need to show that if f is normal and additive in each coordinate, then f^σ is normal and completely additive in each coordinate. Leaving the easy proof for normality as an exercise for the reader, concerning additivity, we will prove that if $f : \mathbb{A}_0 \times \mathbb{A}_1 \to \mathbb{B}$ is additive in its first coordinate and monotone in its second, then f^σ preserves all non-empty joins in its first coordinate.

Fix elements $x_0 \in A_0^\sigma$ and $x_1 \in A_1^\sigma$. By atomicity of $\mathbb{B}^\sigma$, and monotonicity of f^σ, it suffices to prove, for an arbitrary atom p of $\mathbb{B}^\sigma$:

$$p \leq f^\sigma(x_0, x_1) \text{ only if there is a } q \in At_0 \text{ with } p \leq f^\sigma(q, x_1), \tag{33}$$

where At_0 denotes the set of atoms in $\mathbb{A}_0^\sigma$ below x_0. Note that since $f^\sigma(x_0, x_1) = \bigvee\{f^\sigma(c_0, c_1) \mid x_i \geq c_i \in K(A_i)\}$ we may safely assume that both x_0 and x_1 are closed.

Now suppose for contradiction that (33) fails. Then for some atom p of $\mathbb{B}^\sigma$ we have $p \leq f^\sigma(x_0, x_1)$ while for each $q \in At_0$ there are, by definition of f^σ, elements $a_{q,0} \in A_0$ above q and $a_{q,1} \in A_1$ above x_1, such that $p \not\leq f^\sigma(a_{q,0}, a_{q,1})$. It follows that $x_0 = \bigvee At_0 \leq \bigvee\{a_{q,0} \mid q \in At_0\}$, whence by compactness $x_0 \leq \bigvee\{a_{q,0} \mid q \in F\}$ for some *finite* set $F \subseteq At_0$.

Now observe that the join $a_0 = \bigvee\{a_{q,0} \mid q \in F\}$ is in A_0, and the meet $a_1 = \bigwedge\{a_{q,1} \mid q \in F\}$ is in A_1. Clearly $p \not\leq f^\sigma(a_{q,0}, a_1)$ for each $q \in F$; since p is an atom this means $p \not\leq \bigvee\{f^\sigma(a_{q,0}, a_1) \mid q \in F\} = f(a_0, a_1)$, where in the last identity we use the additivity of f in its first coordinate.

On the other hand, from $x_0 \leq a_0$ and $x_1 \leq a_1$ it follows that $f^\sigma(x_0, x_1) \leq f(a_0, a_1)$ which gives the desired contradiction. ❑

In the proof above we already used the fact that complete additivity of f^σ means that it is completely determined by its values on the *atoms* of $\mathbb{B}^\sigma$. Now recall that (in the concrete representation of) $\mathbb{B}^\sigma$, the atoms are nothing but the *ultrafilters* of $\mathbb{B}$. From this the following proposition is immediate.

PROPOSITION 112. *Let* $\mathbb{A}$ *be some Boolean algebra with* τ*-operators with underlying Boolean algebra* $\mathbb{B}$*. Then* $\mathbb{A}^\sigma := (\mathbb{A}_\bullet)^+$ *is isomorphic to the algebra* $\mathbb{B}^\sigma$ *expanded with the family* $\{(\nabla^\mathbb{A})^\sigma \mid \nabla \in \tau\}$ *of complete operators.*

This proposition, which can be summarized as '$\nabla^{\mathbb{A}^\sigma} = (\nabla^\mathbb{A})^\sigma$', will be used throughout the sequel, but always implicitly.

7.4 Composite maps

We now investigate the interaction between composing maps between Boolean algebras and taking their canonical extensions. That is, we will take a look at the relation between the maps $(gf)^\sigma$ and $g^\sigma f^\sigma$ for maps $f : \mathbb{A} \to \mathbb{A}'$, and $g : \mathbb{A}' \to \mathbb{A}''$. We are obviously eager to find cases in which we have $(gf)^\sigma = g^\sigma f^\sigma$, but also conditions under which one of the inequalities ($\leq$ or $\geq$) apply will turn out to be of interest. As we will see shortly, many of these conditions can naturally be described in *topological* terms.

For this purpose, we will introduce no less than six topologies on each set A^σ. Fortunately, these topologies can be neatly organized in two families, each consisting of an upper, a lower and a join topology. As a terminological convention, let us call a map between the algebras $\mathbb{A}^\sigma$ and $\mathbb{B}^\sigma$ (ρ, ρ')*-continuous*, if it is a continuous function between the topological spaces $\langle A^\sigma, \rho\rangle$ and $\langle B^\sigma, \rho'\rangle$.

The first family is that of the Scott topologies. Although these can already be defined on arbitrary partial orders, here we will only consider topologies on canonical extensions of BAOs. Recall that a subset D of a partial order is called *up-directed*, if every pair of elements of D has an upper bound in D.

DEFINITION 113. Given a Boolean algebra $\mathbb{B}$, call a subset U of B^σ *Scott open* if U is an up-set such that $U \cap D \neq \varnothing$ for every up-directed set D with $\bigvee D \in U$. The *Scott topology* is defined as the collection $\gamma^\uparrow$ of Scott open sets; the topology $\gamma^\downarrow$ is given by the principle of order duality, and we define $\gamma := \{U \cap V \mid U \in \gamma^\uparrow, V \in \gamma^\downarrow\}$ as the join of $\gamma^\uparrow$ and $\gamma^\downarrow$ in the lattice of topologies over B.

In practice it is sometimes easier to work with the *closed* sets in the Scott topology; these are precisely the down-sets of $\mathbb{C}$ that are closed under taking up-directed unions. From this observation one easily derives the (well-known) fact that a map between partial orders is Scott continuous (that is, $(\gamma^\uparrow, \gamma^\uparrow)$-continuous) iff it preserves up-directed joins. But this implies that a map is completely additive iff it is both additive and Scott continuous, which may help to explain the relevance of the Scott topologies for our purposes.

We now turn to the second family of topologies. Recall from Example 27 that for an arbitrary element b of a Boolean algebra $\mathbb{B}$, the sets $b{\uparrow}$ and $b{\downarrow}$ are defined as $b{\uparrow} = \{a \in B \mid b \leq a\}$ and $b{\downarrow} = \{a \in B \mid a \leq b\}$.

PROPOSITION 114. *For any Boolean algebra* $\mathbb{B}$, *the sets* $\sigma^{\uparrow} := \{p{\uparrow} \mid p \in K\}$ *and* $\sigma^{\downarrow} := \{u{\downarrow} \mid u \in O\}$ *both form a topology on* A^{σ}*; and so does the set* $\sigma := \{p{\uparrow} \cap u{\downarrow} \mid K \ni p \leq u \in O\}$, *which is in fact identical to the join* $\sigma^{\uparrow} \vee \sigma^{\downarrow}$ *in the lattice of topologies on* A^{σ}.

In the sequel, we will write $[p, u]$ for the *interval* between p and u, that is, $[p, u] = p{\uparrow} \cap u{\downarrow}$.

Proof. The fact that $\sigma^{\uparrow}$ is a topology follows from the fact that the set $K(A)$ is closed under finitary joins and arbitrary meets of $\mathbb{A}^{\sigma}$, see Proposition 106(2). ❑

REMARK 115. As suggested by notation, the topology σ is closely connected to the kind of inclusion of $\mathbb{B}$ in $\mathbb{B}^{\sigma}$. Let us just mention a couple of salient facts here. First, it is easy to see that the set $\{[a, b] \mid a, b \in B\}$ is a *basis* for σ. This reveals that the set B is topologically *dense* in σ, in the sense that every σ-open set contains an element of B. But also, B constitutes the collection of *isolated points* of σ — recall that a point x is isolated in a topology if the singleton $\{x\}$ is open. It is the latter two properties that make it possible to extend arbitrary maps between Boolean algebras to their extensions; we will come back to this at the end of this section.

The following proposition, which links the two topological families, will be crucial when it comes to finding the 'matching continuities' mentioned in the introduction.

PROPOSITION 116. *Let* $\mathbb{A}$ *be a Boolean algebra. Then* $\gamma^{\uparrow} \subseteq \sigma^{\uparrow}$, $\gamma^{\downarrow} \subseteq \sigma^{\downarrow}$ *and* $\gamma \subseteq \sigma$.

Proof. Confining ourselves to the first claim, it suffices to prove that $U = \bigcup\{p{\uparrow} \mid p \in U \cap K\}$ for an arbitrary Scott open set $U \subseteq A^{\sigma}$. The crucial observation here is that every $u \in U$ is the *up-directed* join of the closed elements below it. Further proof details are left to the reader. ❑

The following proposition is a first sign that these topologies can be useful.

PROPOSITION 117. *Let* $f : \mathbb{A} \to \mathbb{B}$ *be a monotone map between the Boolean algebras* $\mathbb{A}$ *and* $\mathbb{B}$. *Then*

1. f^{σ} *is the largest monotone* $(\sigma, \gamma^{\uparrow})$*-continuous extension of* f*;*

2. f *is smooth iff* f^{σ} *is* (σ, γ)*-continuous;*

3. *if* f *is an operator then* f^{σ} *is* $(\gamma^{\uparrow}, \gamma^{\uparrow})$*-continuous;*

4. *if* f *is additive then* f^{σ} *is* $(\sigma^{\downarrow}, \sigma^{\downarrow})$*-continuous.*

5. *if* f *is multiplicative then* f^{σ} *is* $(\sigma^{\uparrow}, \sigma^{\uparrow})$*-continuous.*

Proof. Concerning the first part of the proposition, we already know from Proposition 108 that f^{σ} is an extension of f. Now for $x \in A^{\sigma}$ take an arbitrary Scott open set $V \subseteq B^{\sigma}$ with $f^{\sigma}(x) \in V$. That is, $\bigvee\{f^{\sigma}(p) \mid x \geq p \in K(A)\} \in V$. Now it is easy to see that the collection $Q := \{f^{\sigma}(p) \mid x \geq p \in K(A)\}$ is up-directed, so $Q \cap V \neq \varnothing$. In other words, there is a closed $p \leq x$ with $f^{\sigma}(p) \in V$. But then by monotonicity of f^{σ} we have that $f^{\sigma}[p{\uparrow}] \subseteq V$. Since $x \in p{\uparrow} \in \sigma$ this suffices to prove that f^{σ} is $(\sigma, \gamma^{\uparrow})$-continuous, while by Proposition 111 it is monotone.

In order to show that f is the largest such map, take a monotone $(\sigma, \gamma^{\uparrow})$-continuous extension $g : A^{\sigma} \to B^{\sigma}$ of f, and suppose for contradiction that $g(x) \not\leq f^{\sigma}(x)$ for some $x \in A^{\sigma}$. By atomicity of $\mathbb{B}^{\sigma}$ there must be an *atom* p of $\mathbb{B}^{\sigma}$ which lies below $g(x)$, but not below $f^{\sigma}(x)$. Because $g(x) \in p{\uparrow} \in \gamma^{\uparrow}$, the continuity of g provides us with a $c \in K$ such that $c \leq x$ and $g[c{\uparrow}] \subseteq p{\uparrow}$. In other words, we find that $p \leq g(c)$ whence by monotonicity it follows that $p \leq g(a)$ for all $a \in A$ above c. But then by the fact that g extends f, and the definition of f^{σ}, we may infer that $p \leq f^{\sigma}(c)$. From this we obtain, as the required contradiction, that $p \leq f^{\sigma}(x)$.

For part (2), it follows from part (1) by order duality that f^{π} is the smallest monotone $(\sigma, \gamma^{\downarrow})$-continuous extension of f. Hence if f is smooth, then $f^{\sigma} = f^{\pi}$ is both $(\sigma, \gamma^{\uparrow})$- and $(\sigma, \gamma^{\downarrow})$-continuous, and hence, (σ, γ)-continuous. Conversely, if f^{σ} is (σ, γ)-continuous, then it is, a fortiori, $(\sigma, \gamma^{\downarrow})$-continuous. This implies, again by the order dual of part (1), that $f^{\pi} \leq f^{\sigma}$; but then we have equality because of Proposition 108(2).

Concerning part (3), if $f : \mathbb{A}^n \to \mathbb{A}$ is an operator then by Proposition 111(2), $f^{\sigma} : (\mathbb{A}^{\sigma})^n \to \mathbb{A}^{\sigma}$ is additive in each coordinate. From this it is straightforward to derive that f^{σ} preserves up-directed joins.

For part (4), suppose that $f : \mathbb{A} \to \mathbb{B}$ is additive, and take an arbitrary $\sigma^{\downarrow}$-open subset $u{\downarrow}$ of B^{σ}, that is, $u \in O(B)$. It follows by Proposition 111(2) that f^{σ} preserves all non-empty joins. From this one may derive that the set $(f^{\sigma})^{-1}[u{\downarrow}]$ is either empty, in which case it certainly belongs to σ, or else it is of the form $v{\downarrow}$, where $v = \bigvee (f^{\sigma})^{-1}[u{\downarrow}]$ satisfies $f^{\sigma}(v) \leq u$. In order to show that $v{\downarrow}$ is open in σ, it suffices to prove that v is an open element of $\mathbb{A}^{\sigma}$.

Consider an arbitrary closed element $p \leq v$; then $\bigwedge f[p{\uparrow} \cap A] = f^{\sigma}(p) \leq f^{\sigma}(v) \leq u$. Hence by compactness there is a finite set $F \subseteq p{\uparrow} \cap A$ such that $\bigwedge f[F] \leq u$. Putting $a_p := \bigwedge F$ we find that $a_p \in A$, $p \leq a_p$ and $a_p \leq v$ since $f(a_p) \leq \bigwedge f[F]$. Clearly then $v = \bigvee \{p \mid v \geq p \in K\} \leq \bigvee \{a_p \mid v \geq p \in K\} \leq v$ which shows that v is *identical* to the second join, and hence, open.

Finally, part (5) follows from part (4) by order duality. ❑

As we announced already in the introduction to this section, the following properties will be crucial in proving canonicity results further on. The reason for this lies in the observation that for some terms t, we may apply Proposition 118(2) by the fact that the term function $t^{\mathbb{A}^{\sigma}}$ in the canonical extension $\mathbb{A}^{\sigma}$ can be decomposed as $t^{\mathbb{A}^{\sigma}} = g^{\sigma} \circ f^{\sigma}$ where g^{σ} is $(\tau, \gamma^{\uparrow})$-continuous and f^{σ} is (σ, τ)-continuous, for some 'intermediate' topology τ. This is the principle of *matching continuities* that we mentioned in the introduction.

PROPOSITION 118. *Let $f : \mathbb{A} \to \mathbb{B}$ and $g : \mathbb{B} \to \mathbb{C}$ be monotone maps between the Boolean algebras $\mathbb{A}$, $\mathbb{B}$ and $\mathbb{C}$. Then*

1. $(gf)^{\sigma} \leq g^{\sigma} f^{\sigma}$*;*
2. $(gf)^{\sigma} \geq g^{\sigma} f^{\sigma}$ *whenever* $g^{\sigma} f^{\sigma}$ *is* $(\sigma, \gamma^{\uparrow})$*-continuous.*

Proof. Part (2) of the proposition is an immediate consequence of Proposition 117(1) since $g^{\sigma} f^{\sigma}$ is an extension of gf (and gf is monotone). Concerning part (1), we first show that $(gf)^{\sigma}(p) \leq g^{\sigma} f^{\sigma}(p)$ for closed p. Note that

$$\begin{aligned} (gf)^{\sigma}(p) &= \bigwedge \{gf(a) \mid p \leq a \in A\}, \\ g^{\sigma} f^{\sigma}(p) &= \bigwedge \{g(b) \mid f^{\sigma}(p) \leq b \in B\}. \end{aligned}$$

where the latter identity holds because $f^\sigma(p)$ is closed in $\mathbb{A}^\sigma$. Now take a $b \in B$ with $f^\sigma(p) \leq b$. As $f^\sigma(p) = \bigwedge\{f(a) \mid p \leq a \in A\}$ is a down-directed meet, compactness provides some $a \in A$ with $p \leq a$ and $f(a) \leq b$. Then $(gf)^\sigma(p) \leq gf(a) \leq gb$; and hence, $(gf)^\sigma(p) \leq g^\sigma f^\sigma(p)$.

Now we turn to arbitrary $x \in A^\sigma$. Note that

$$\begin{aligned} (gf)^\sigma(x) &= \bigvee\{(gf)^\sigma(p) \mid x \geq p \in K(A)\}, \\ g^\sigma f^\sigma(x) &= \bigvee\{g^\sigma(q) \mid f^\sigma(x) \geq q \in K(B)\}. \end{aligned}$$

Take an arbitrary $p \in K(A)$ with $p \leq x$; then $(gf)^\sigma(p) \leq g^\sigma f^\sigma(p)$, as we just saw. Since $f^\sigma(x) \geq f^\sigma(p) \in K(B)$, this shows that every joinand $(gf)^\sigma(p)$ of $(gf)^\sigma(x)$ is below some joinand $g^\sigma(q)$ of $g^\sigma f^\sigma(x)$. This suffices to prove the desired inequality. ❑

7.5 Canonical equations

Time to harvest. The key idea for proving canonicity results for an equation $s \approx t$ will be to use properties of the *term functions* $s^\mathbb{A}$ and $t^\mathbb{A}$. Recall that for a term $t(x_1, \ldots, x_n)$, the term function $t^\mathbb{A} : A^n \to A$ is inductively defined as follows:

$$\begin{aligned} x_i^\mathbb{A} &:= \pi_i^n, \\ (\heartsuit(t_1, \ldots, t_n))^\mathbb{A} &:= \heartsuit^\mathbb{A} \circ \langle t_1^\mathbb{A}, \ldots, t_n^\mathbb{A}\rangle. \end{aligned}$$

where $\pi_i^n : (a_1, \ldots, a_n) \mapsto a_i$ is the i-th *projection* function, and, for maps $f_1, \ldots, f_n : X \to Y$, the map $\langle f_1, \ldots, f_n\rangle : X \to Y^n$ is given by $\langle f_1, \ldots, f_n\rangle(x) = (f_1(x), \ldots, f_n(x))$.

In the context of canonical extensions the following definitions are crucial.

DEFINITION 119. A term t is *expanding* on an expanded Boolean algebra $\mathbb{A}$ if $(t^\mathbb{A})^\sigma \leq t^{\mathbb{A}^\sigma}$, *contracting* if $(t^\mathbb{A})^\sigma \geq t^{\mathbb{A}^\sigma}$, and *stable* if $(t^\mathbb{A})^\sigma = t^{\mathbb{A}^\sigma}$. We let these properties apply to classes of algebras in case they apply to all members of the class.

PROPOSITION 120. *Let s and t be two τ-terms, and K a class of τ-expanded Boolean algebras. If s is contracting and t is expanding on K, then the inequality $s \preceq t$ is canonical on K.*

Proof. Consider an algebra $\mathbb{A}$ in K such that $\mathbb{A} \models s \preceq t$. In other words, we have $s^\mathbb{A} \leq t^\mathbb{A}$, so that $(s^\mathbb{A})^\sigma \leq (t^\mathbb{A})^\sigma$. But then by the assumptions on s and t it follows that $s^{\mathbb{A}^\sigma} \leq (s^\mathbb{A})^\sigma \leq (t^\mathbb{A})^\sigma \leq t^{\mathbb{A}^\sigma}$, which shows that $\mathbb{A}^\sigma \models s \preceq t$. ❑

So which terms are contracting, and which ones are expanding? Here the topologies prove their value. Before moving on to these results, we need to get one technicality out of the way. Basically, the following proposition states that the product map $\langle f_1, \ldots, f_n\rangle$ behaves as well as one could hope for.

PROPOSITION 121. *Let $f_1, \ldots, f_n$ be monotone maps between the Boolean algebras $\mathbb{A}$ and $\mathbb{B}$. Then*

$$\langle f_1, \ldots, f_n\rangle^\sigma = \langle f_1^\sigma, \ldots, f_n^\sigma\rangle,$$

and for all $\rho, \rho' \in \{\gamma^\downarrow, \gamma^\uparrow, \gamma, \sigma^\downarrow, \sigma^\uparrow, \sigma\}$ it holds that

$$\langle f_1, \ldots, f_n\rangle^\sigma \textit{ is } (\rho, \rho')\textit{-continuous iff each } f_i^\sigma \textit{ is } (\rho, \rho')\textit{-continuous.}$$

We leave the rather tedious but not very difficult proof of this proposition to the reader, and move on to more interesting facts. First we associate topological properties with term functions.

PROPOSITION 122. *Let $\mathbb{A}$ be a τ-expanded Boolean algebra, and t a τ-term. Then*

1. *If $\mathbb{A}$ interprets all connectives in t as operators, then $t^{\mathbb{A}^\sigma}$ is $(\gamma^\uparrow, \gamma^\uparrow)$-continuous.*
2. *If $\mathbb{A}$ interprets all connectives in t as additive maps, then $t^{\mathbb{A}^\sigma}$ is $(\sigma^\downarrow, \sigma^\downarrow)$-continuous.*
3. *If $\mathbb{A}$ interprets all connectives in t as multiplicative maps, then $t^{\mathbb{A}^\sigma}$ is $(\sigma^\uparrow, \sigma^\uparrow)$-continuous.*

Proof. All three statements can be proved by a straightforward term induction, using the Propositions 117 and 121 for the induction step. For the induction base, note that the projection maps are both join- and meet preserving, and hence, their canonical extensions have all the continuity properties mentioned in the statements of this proposition. ❑

Here we arrive at the core of the algebraic approach towards the canonicity of equations. On the basis of the syntactic shape of some terms we can see whether it is expanding or stable. In Theorem 123 we give some sample results; observe that the key idea in the proof of part (3) is the principle of 'matching continuities' as described before Proposition 118.

THEOREM 123. *Let $\mathbb{A}$ be a τ-expanded Boolean algebra, and t a τ-term. Then*

1. *If $\mathbb{A}$ interprets all connectives in t as monotone maps, then t is expanding.*
2. *If $\mathbb{A}$ interprets all connectives in t as operators or dual operators, then t is stable.*
3. *If t is of the form $s(u_1, \ldots, u_n)$ such that $\mathbb{A}$ interprets all connectives in s as operators, and all connectives in each of the u_i as meet-preserving operations, then t is stable.*

Proof. Part (1) is proved by term induction. The base case is immediate from the definitions. For the inductive step, suppose that $t \equiv \nabla(t_1, \ldots, t_n)$, then

$$
\begin{array}{rcl}
(t^{\mathbb{A}})^\sigma & = & (\nabla^{\mathbb{A}} \circ \langle t_1^{\mathbb{A}}, \ldots, t_n^{\mathbb{A}} \rangle)^\sigma \\
& \leq & (\nabla^{\mathbb{A}})^\sigma \circ \langle t_1^{\mathbb{A}}, \ldots, t_n^{\mathbb{A}} \rangle^\sigma \\
& = & \nabla^{\mathbb{A}^\sigma} \circ \langle (t_1^{\mathbb{A}})^\sigma, \ldots, (t_n^{\mathbb{A}})^\sigma \rangle \\
& \leq & \nabla^{\mathbb{A}^\sigma} \circ \langle t_1^{\mathbb{A}^\sigma}, \ldots, t_n^{\mathbb{A}^\sigma} \rangle \\
& = & t^{\mathbb{A}^\sigma}.
\end{array}
$$

Here the first and last step are by definition, the second step is by Proposition 118(1) and monotonicity, the third step is by definition of $\nabla^{\mathbb{A}^\sigma} = (\nabla^{\mathbb{A}})^\sigma$ and by Proposition 121, and the fourth step is by the inductive hypothesis and the monotonicity of $\nabla^{\mathbb{A}^\sigma}$.

For part (2) and (3) it suffices to prove that $t^{\mathbb{A}^\sigma} \leq (t^{\mathbb{A}})^\sigma$, since the opposite inequality holds by part (1). In the case of part (2) this follows from a straightforward induction, whereas for part (3) we need the principle of matching topologies.

Let t be as described in part (3), then

$$t^{\mathbb{A}^\sigma} = s^{\mathbb{A}^\sigma} \circ \langle u_1^{\mathbb{A}^\sigma}, \ldots, u_n^{\mathbb{A}^\sigma} \rangle = (s^{\mathbb{A}})^\sigma \circ \langle (u_1^{\mathbb{A}})^\sigma, \ldots, (u_n^{\mathbb{A}})^\sigma \rangle$$

with the second identity holding by part (2). Also, note that by Proposition 117, the term function $s^{\mathbb{A}^\sigma}$ is $(\gamma^\uparrow, \gamma^\uparrow)$-continuous, and each $u_i^{\mathbb{A}^\sigma}$ is $(\sigma^\uparrow, \sigma^\uparrow)$-continuous. From this we infer by Proposition 121 that the map $\langle (u_1^{\mathbb{A}})^\sigma, \ldots, (u_n^{\mathbb{A}})^\sigma \rangle = \langle u_1^{\mathbb{A}}, \ldots, u_n^{\mathbb{A}} \rangle^\sigma$ is $(\sigma^\uparrow, \sigma^\uparrow)$-continuous as well, whence by $\gamma^\uparrow \subseteq \sigma^\uparrow$ it is $(\sigma^\uparrow, \gamma^\uparrow)$-continuous. Thus the $(\gamma^\uparrow, \gamma^\uparrow)$-continuity of $s^{\mathbb{A}^\sigma}$ *matches* with the $(\sigma^\uparrow, \gamma^\uparrow)$-continuity of $\langle u_1^{\mathbb{A}}, \ldots, u_n^{\mathbb{A}} \rangle^\sigma$. Hence, we may apply Proposition 118(2), and find that $t^{\mathbb{A}^\sigma} = (s^{\mathbb{A}})^\sigma \circ \langle u_1^{\mathbb{A}}, \ldots, u_n^{\mathbb{A}} \rangle^\sigma \leq (s^{\mathbb{A}} \circ \langle u_1^{\mathbb{A}}, \ldots, u_n^{\mathbb{A}} \rangle)^\sigma = (t^{\mathbb{A}})^\sigma$, as desired. ❑

As a sample application, we show how Sahlqvist canonicity is an easy consequence of the previous theorem.

COROLLARY 124. *Sahlqvist equations are canonical over the class of all Boolean algebras with τ-operators.*

Proof. First we treat inequalities of the form $\varphi(\beta_1, \ldots, \beta_n) \leq \psi$, where φ only uses $\wedge$, $\vee$ and modalities, all β_i are boxed atoms, and ψ is positive. But then it is immediate by the previous proposition that $\varphi(\beta_1, \ldots, \beta_n)$ is stable, while ψ is expanding. Hence the result follows from Proposition 120.

Now consider an arbitrary Sahlqvist inequality. Without loss of generality we may assume that it is in fact an equation of the form

$$\varphi(\beta_1, \ldots, \beta_n, \neg\psi_1, \ldots, \neg\psi_k) \approx \bot, \tag{34}$$

where φ and the β's are as before, while all ψ_j are positive formulas. It is easy to see that this equation is equivalent to the quasi-equation

$$\left(\mathop{\&}_{1 \leq i \leq n} x_i \leq \neg\psi_i \right) \;\Rightarrow\; \varphi(\beta_1, \ldots, \beta_n, x_1, \ldots, x_k) \approx \bot,$$

which in its turn is equivalent to

$$\left(\mathop{\&}_{1 \leq i \leq n} x_i \wedge \psi_i \approx \bot \right) \;\Rightarrow\; \varphi(\beta_1, \ldots, \beta_n, x_1, \ldots, x_k) \approx \bot. \tag{35}$$

Now suppose that we *add* a diamond E to the language, and interpret this diamond as the global modality on every algebra (see section 8.2). Then clearly the quasi-equation (35) is equivalent to the formula

$$\varphi(\beta_1, \ldots, \beta_n, x_1, \ldots, x_k) \preceq \bigvee_{1 \leq i \leq n} \mathsf{E}(x_i \wedge \psi_i). \tag{36}$$

(Note that this reduction of a quasi-equation to an equivalent equation is a specific example of Proposition 138.)

The result then follows by the observation that (36) is a Sahlqvist inequality of the kind already treated, together with the fact that the canonical extension of the global modality is again the global modality (see Remark 110). ❑

7.6 Further remarks

The ideas described in this section allow for variations and generalizations in at least two directions.

To start with, the algebraic approach has already been put to work for a far wider class of structures than just Boolean algebras with operators. In particular, nothing in the theory crucially depends on the *Boolean* nature of the underlying order of the algebras. The notion of a canonical extension, with all the results in section 7.2 pertaining to them, has been extended to (first distributive and then) arbitrary lattices, with work on partial orders under way.

Furthermore, the restriction to monotone operations is not necessary either; *arbitrary* maps between lattices can be extended to maps between their canonical extensions. First suppose that we are dealing with a dense set X' in a topology $\langle X, \rho\rangle$, and let $f : X' \to C$ be a map from X' to the carrier C of a complete lattice $\mathbb{C}$. Then define

$$\begin{array}{rcl} f^{\sigma}(x) & := & \bigvee\{\bigwedge f[U \cap X'] \mid x \in U \in \rho\}, \\ f^{\pi}(x) & := & \bigwedge\{\bigvee f[U \cap X'] \mid x \in U \in \rho\}. \end{array} \tag{37}$$

In order to apply this definition for the canonical extension of a map f between two lattices $\mathbb{L}$ and $\mathbb{M}$, note that (just like in the case for Boolean algebras, see Remark 115) the carrier L of $\mathbb{L}$ forms a dense subset of the σ-topology over the carrier $\mathbb{L}^{\sigma}$. Also observe that f^{σ} and f^{π} are *extensions* of f because all elements of L are *isolated* points of f, and that for *monotone* f, (37) agrees with (32).

Finally, it is not just the definitions that translate to the more general setting of lattice expansions (that is, lattices with additional operations), the same holds for the theory. To mention just one example: one may prove that any equation $s \approx t$ is canonical provided that all the primitive symbols (including the join operation $\wedge$) occurring in s and t are interpreted as operators. Details can be found in for instance Gehrke & Harding [28].

The second generalization that we want to mention involves other ways of completing lattices and lattice expansions, such as the *MacNeille completion*, which generalizes Dedekind's construction of the reals from the rationals to arbitrary partial orders. For a characterization in the style of this section, one may start by proving that any lattice $\mathbb{L}$ has a (modulo isomorphism) unique completion $\mathbb{L}^{\mu}$, its *MacNeille completion*, in which $\mathbb{L}$ is both join- and meet dense. This way of extending lattices is obviously similar to that of the canonical extension, but a substantial difference is that the MacNeille completion agrees with the original lattices on *all* meets and joins, whereas the canonical extension only agrees on the *finite* ones.

In any case, it follows from join- and meet density, that any map between two lattices can be extended to a map between their MacNeille completions, in two ways. In the case of a *monotone* operation f between two lattices $\mathbb{L}$ and $\mathbb{M}$, we define the *lower extension* $\check{f}$ and the *upper extension* $\hat{f}$ by

$$\begin{array}{rcl} \check{f}(x) & := & \bigvee\{f(a) \mid x \geq a \in L\} \\ \hat{f}(x) & := & \bigwedge\{f(a) \mid x \leq a \in L\} \end{array}$$

Clearly then, almost all questions concerning canonical extensions have an obvious counterpart for MacNeille completions. Generally speaking, MacNeille completions are less

well-behaved than canonical extensions; for instances, unary operators (diamonds) are no longer smooth, and the variety of modal algebras is not closed under taking lower MacNeille completions. Probably for this reason, Monk [85] introduced the notion of the MacNeille completion of a BAO only for Boolean algebras with *complete* operators. On the other hand, in case the primitive operations are *residuated* (see Proposition 129), the situation improves; for instance, Givant & Venema [36] show that the validity of all Sahlqvist equations is preserved under taking MacNeille completions of *tense* algebras. As a final remark, there are interesting connections between the MacNeille completion and the canonical extension of a lattice expansion: for instance, Gehrke, Harding & Venema [29] prove that the canonical extension of lattice expansion $\mathbb{A}$ can be embedded in the MacNeille completion of some ultrapower of $\mathbb{A}$. As a consequence, every variety of lattice expansions that is closed under taking MacNeille completions, is also canonical in the sense of canonical extensions.

8 SPECIAL ALGEBRAIC TOPICS

In this final section on algebra we discuss the algebraic perspective on two further issues in modal logic.

8.1 Tense logic

Our first example concerns *tense logic*; as its name already indicates, this branch of modal logic originates in the formal semantics of natural language, cf. Chapter 19 of this volume.

DEFINITION 125. The modal similarity type ϑ of *tense logic* is fixed by its two diamonds, $\Diamond_F$ and $\Diamond_P$.

The letters $\Diamond_F$ and $\Diamond_P$ are mnemonic of **f**uture and **p**ast, respectively. This already indicates that the standard interpretation of this language is in frames representing a flow of time, such that $\Diamond_F$ obtains the meaning 'sometime in the future', and dually $\Diamond_P$ means 'sometime in the past'. Tense logic thus forms a rather simple example of *temporal* logic, cf. Chapter 11 of this volume. Here we abstract from the temporal interpretations of tense logics; what is then left is that in the intended frames for this language, the two diamonds of the language are interpreted along the two directions of a *single* binary relation.

DEFINITION 126. A ϑ-frame $\mathbb{S} = \langle S, R_F, R_P\rangle$ is called *bidirectional* if R_F and R_P are each other's converse.

This definition explains why a ϑ-frame is often represented simply as the pair $\langle S, R_F\rangle$. Turning to logic, we define the following.

DEFINITION 127. A modal ϑ-logic L is a *tense logic* if both formulas $p \to \Box_F \Diamond_P p$ and $p \to \Box_P \Diamond_F p$ are theorems of L; the minimal tense logic is denoted as $\mathbf{K}_t$. Algebraically, a *tense algebra* is a Boolean algebra expanded with monotone ϑ-operations satisfying the corresponding equations $x \preceq \Box_F \Diamond_P x$ and $x \preceq \Box_P \Diamond_F x$.

It is easy to see that $\mathbb{S}^+$ is a tense algebra if and only if $\mathbb{S}$ is a bidirectional frame. In the other direction, it is not a priori clear whether we can extract a useful frame from

an arbitrary tense algebra: First we must show that tense algebras are Boolean algebras with operators. In fact, already Jónsson & Tarski [70] show something better.

THEOREM 128. *Let* $\mathbb{A} = \mathbb{A} = \langle A, \top, \bot, -, \wedge, \vee, \Diamond_F, \Diamond_P \rangle$ *be a tense algebra. Then*

1. *the operations* $\Diamond_F$ *and* $\Diamond_P$ *are complete operators;*
2. *the structure* $\mathbb{A}_\bullet$ *is a bidirectional frame, and the algebra* $\mathbb{A}^\sigma$ *is again a tense algebra.*

Proof. For part 1 of the Theorem, let $a \in A$ be the least upper bound of some subset X of A. Then by monotonicity, $\Diamond_F a$ is an upper bound of the set $\Diamond_F[X]$. Now suppose that b is also an upper bound of this set, that is, $\Diamond_F x \leq b$ for all $x \in X$. From this it follows, for each $x \in X$, that $x \leq \Box_P \Diamond_F x \leq \Box_P b$ (here we use monotonicity of $\Box_P$, which is easily proven). Thus we see that $a \leq \Box_P b$ by our assumption on a. But then by monotonicity of $\Diamond_F$ we obtain that $\Diamond_F a \leq \Diamond_F \Box_P b \leq b$. This proves that $\Diamond_F a$ is in fact the least upper bound of the set $\Diamond_F[X]$.

Concerning the second part of the theorem, that $\mathbb{A}^\sigma$ is a tense algebra is a special of the Sahlqvist Canonicity Theorem 93; the bidirectionality of $\mathbb{A}_\bullet$ is then immediate since $\mathbb{A}^\sigma = (\mathbb{A}_\bullet)^+$. ❑

There is a lot more to say about the complete additivity of the diamonds in tense algebras. To start with, the definition of tense algebras can be reformulated using either of the algebraically more familiar notions of *conjugation* or *residuation.*

PROPOSITION 129. *Let* $\mathbb{A} = \langle A, \top, \bot, -, \wedge, \vee, \Diamond_F, \Diamond_P \rangle$ *be a monotone* ϑ*-expanded Boolean algebra. Then the following are equivalent:*

1. $\mathbb{A}$ *is a tense algebra,*
2. $\Diamond_F$ *and* $\Diamond_P$ *are conjugated operations, that is, they satisfy the following:*
$$\mathbb{A} \models \forall xy\, (x \wedge \Diamond_F y \approx \bot \Leftrightarrow y \wedge \Diamond_P x \approx \bot), \tag{38}$$
3. $\Diamond_F$ *and* $\Box_P$ *form a residual pair, that is,*
$$\mathbb{A} \models \forall xy\, (\Diamond_F x \preceq y \Leftrightarrow x \preceq \Box_P y). \tag{39}$$

This connection with residuation shows that from a general mathematical perspective, tense logic is not just *any* bimodal logic: It provides the modal logic manifestation of the fundamental category theoretic concept of *adjoint functors.* Theorem 128(1) is thus a rather special case of the category theoretic fact that left adjoint functors preserve all (existing) colimits.

Another nice property of tense logic that should be mentioned here is that somehow, tense algebras are *richer* than ordinary Boolean algebras with operators. For instance, consider an atomic modal algebra $\mathbb{A}$, and suppose that $\mathbb{A}$ satisfies some Sahlqvist equation η. Then it is *not* guaranteed that the atom structure $\mathbb{A}_\bullet$ (see Definition 41) satisfies the first-order correspondent c_η of η, not even if the diamond of $\mathbb{A}$ is completely additive. However, in case $\mathbb{A}$ is a *tense* algebra, it contains sufficient information to enforce this.

THEOREM 130. *Let* $\mathbb{A}$ *be an* atomic *tense algebra. Then for every Sahlqvist equation* η*:* $\mathbb{A} \models \eta$ *iff* $\mathbb{A}_+ \models c_\eta$ *iff* $(\mathbb{A}_\bullet)^+ \models \eta$.

Proof. Clearly, the equivalence of the last two statements follows from Sahlqvist correspondence theory. For the implication from right to left, it suffices to observe that $\mathbb{A}$ is a subalgebra of $(\mathbb{A}_\bullet)^+$ because of the complete additivity of the operators. This follows from (12) in the proof of Proposition 42.

The remaining implication is a special case of the preservation of Sahlqvist equations under taking (lower) MacNeille completions of tense algebras, see the end of section 7 for some discussion, and Givant & Venema [36] for proofs. ❑

Finally, tense algebras play a role in other part of universal algebra as well. For instance, any *lattice* can be represented as the sublattice of a tense algebra that has the solution set of the equation $x \approx \Box_P \Diamond_F x$ as its carrier. This idea basically goes back to Birkhoff [12]; for more details, the reader is referred to Harding [56].

Nevertheless, despite their rather special characteristics, just like all bimodal logics, tense logics can be *simulated* by monomodal ones; for details we refer to Chapter 8 of this volume.

8.2 Global modality & discriminator varieties

Recent years have witnessed an increasing interest in formalisms that enhance the expressive power of standard modal languages, see for instance Chapter 14 of this volume. In such a pursuit, one naturally arrives at the *global* or *universal* modality E which has the global relation $S \times S$ of a frame $\mathbb{S}$ as its (intended) accessibility relation, see Goranko & Passy [48]. But also, a large number of standard logics come with an intended semantics in which the global relation interprets some more complex term of the language: as an example we mention the compound modality $\Diamond_F \Diamond_P$ in the tense logic over any linear flow of time.

DEFINITION 131. Algebraically, we define the *global modality* or *unary discriminator* over a Boolean algebra (with operators) $\mathbb{B}$ as the function given by

$$b \mapsto \begin{cases} \bot & \text{if } b = \bot, \\ \top & \text{if } b > \bot. \end{cases}$$

The term $\gamma(x)$ is called a *global modality* or *unary discriminator term* over an expanded Boolean algebra $\mathbb{A}$ if it is interpreted as the global modality on $\mathbb{A}$.

This notion can be seen as the BAO manifestation of the well-known algebraic concept of a *discriminator*, see Jipsen [67] for a first explicit discussion of the connections.

DEFINITION 132. We call a ternary term d a *discriminator term* over an algebra $\mathbb{A}$ if it is interpreted as the discriminator function on A, that is, if $d^{\mathbb{A}}(a,b,c) = a$ if $a \neq b$, and $d^{\mathbb{A}}(a,b,c) = c$ if $a = b$. Any variety V generated by a class of algebras with a common discriminator term, is called a *discriminator* variety.

PROPOSITION 133. *Let $\mathbb{A}$ be a τ-expanded Boolean algebra.*

1. *If γ is a global modality for $\mathbb{A}$, then the term $(\gamma(\neg(x \leftrightarrow y)) \wedge x) \vee (\gamma(\neg(x \leftrightarrow y)) \wedge z)$ is a discriminator term for $\mathbb{A}$.*

2. *If $d(x,y,z)$ is a discriminator term for $\mathbb{A}$, then the term $\neg d(\bot, x, \top)$ is a global modality for $\mathbb{A}$.*

Before going into further detail of the connection with the global modality, let us, for future reference, list some of the many nice properties that discriminator varieties have.

THEOREM 134. *Let* K *be a class of algebras with a discriminator term* d*. Then*

1. *all algebras in* K *are simple;*
2. $\mathsf{Var}(\mathsf{K})$ *is congruence-distributive and congruence-permutable;*
3. *all subdirectly irreducible algebras in* $\mathsf{Var}(\mathsf{K})$ *are simple, and vice versa;*
4. $\mathsf{Var}(\mathsf{K})$ *is semi-simple; that is, every algebra in* $\mathsf{Var}(\mathsf{K})$ *is a subdirect product of simple algebras.*
5. d *is a discriminator term for every simple algebra in* $\mathsf{Var}(\mathsf{K})$*.*

Proof. For the first statement of the theorem, define the term

$$s(x, y, u, v) := d(d(x, y, u), d(x, y, v), v).$$

It is easy to see that s is a so-called *switching term* for K; that is, for every $\mathbb{A}$ in K, and for all a, b, c and d in $\mathbb{A}$:

$$s^{\mathbb{A}}(a, b, c, d) = \begin{cases} c & \text{if } a = b, \\ d & \text{if } a \neq b. \end{cases}$$

Now let $\Theta \neq \Delta_A$ be a congruence of $\mathbb{A}$; then there are two elements $a \neq b$ with $(a, b) \in \Theta$. But then we find $(c, d) = (s^{\mathbb{A}}(a, a, c, d), s^{\mathbb{A}}(a, b, c, d)) \in \Theta$ for every c and d in Θ. In other words, such a Θ must be the trivial congruence $A \times A$. But this clearly means that $\mathbb{A}$ is simple. Details of the proof of the second statement, which is similar to that of Theorem 25, are left to the reader.

For the third part of the theorem, it is not hard to verify that d is a discriminator term for $\mathsf{SPu}(\mathsf{K})$ as well, whence $\mathsf{SPu}(\mathsf{K})$ consists of simple algebras by part (1). So by definition of simplicity, we find that $\mathsf{HSPu}(\mathsf{K}) = \mathsf{SPu}(\mathsf{K})$; hence, all algebras in $\mathsf{HSPu}(\mathsf{K})$ are simple. However, by part 2 we may apply Jónsson's Lemma, which states that all s.i. members of $\mathsf{Var}(\mathsf{K})$ belong to $\mathsf{HSPu}(\mathsf{K})$. Thus every s.i. algebra in $\mathsf{Var}(\mathsf{K})$ is simple.

Part (4) is immediate from part (3) by Birkhoff's subdirect indecomposability theorem, while the final statement follows from the fact that every simple algebra belongs to $\mathsf{SPu}(\mathsf{K})$, and thus shares the discriminator term of K. ❑

In particular, since the notions of simplicity and subdirect irreducibility coincide in a discriminator variety, its subvarieties are completely determined by its simple members. Let us now see how these issues are axiomatized in normal modal logics.

DEFINITION 135. A τ-formula $\gamma(x)$ is a *global modality* for a normal modal τ-logic L if the formulas Γ

- $\nabla(x_1, \ldots, x_n) \rightarrow \gamma(x_i)$ for every $\nabla \in \tau$, and every $i \in \{1, \ldots, n\}$;
- $x \rightarrow \gamma(x)$, $\gamma(\gamma(x)) \rightarrow \gamma(x)$ and $\gamma(\neg\gamma(\neg x)) \rightarrow x$;

are theorems of L.

That is, L defines a global modality iff there is a term $\gamma(x)$ that satisfies the **S5** axioms, plus the inclusion axiom $\nabla^i x \to \gamma(x)$ for every induced diamond ∇^i. It is not hard to derive that such an axiomatically defined global modality $\gamma(x)$ also has $\gamma(\neg\gamma(x)) \to \neg\gamma(x)$, and $\vdash_L \blacklozenge x \to \gamma(x)$ for all compound diamonds $\blacklozenge$.

The terminology of Definition 135 is justified by the following Proposition, which is essentially taken from Jipsen [67].

PROPOSITION 136. *Let L be a normal modal τ-logic, and $\gamma(x)$ a τ-formula. Then $\gamma(x)$ is a global modality for L if and only if $\mathsf{BAO}_\tau(L) = \mathsf{Var}(\mathsf{K})$ for some class K of algebras sharing γ as a global modality.*

Proof. The direction from right to left is immediate by the fact that any unary discriminator term satisfies all the formulas listed in Definition 135.

For the other direction, by Theorem 34 it suffices to show that γ is a unary discriminator term on subdirectly irreducible algebras in $\mathsf{BAO}_\tau(L)$. In order to prove this, suppose for contradiction that $\mathbb{A}$ has a radical element ρ, while $\gamma^{\mathbb{A}}$ is not the global modality on $\mathbb{A}$. That is, some $a \in A$ satisfies $a \neq \bot$ while $\gamma^{\mathbb{A}}(a) \neq \top$, whence $-\gamma^{\mathbb{A}}(a) \neq \bot$. Since ρ is radical in $\mathbb{A}$ there are compound diamonds $\blacklozenge_1$ and $\blacklozenge_2$ such that $\rho \leq \blacklozenge_1 a$ and $\rho \leq \blacklozenge_2 -\gamma^{\mathbb{A}}(a)$. However, from $\rho \leq \blacklozenge_1 a$ we obtain $\rho \leq \gamma^{\mathbb{A}}(a)$, while from $\rho \leq \blacklozenge_2 -\gamma^{\mathbb{A}}(a)$ we may infer that $\rho \leq \gamma^{\mathbb{A}}(-\gamma^{\mathbb{A}}(a)) \leq -\gamma^{\mathbb{A}}(a)$. This contradicts the fact that $\rho > \bot$, and so we may conclude that γ is the global modality on $\mathbb{A}$. ❑

A very useful property of discriminators is that they allow the effective replacement of universal sentences with equations. In the case of BAOs, this works out as follows.

DEFINITION 137. Suppose that $\gamma(x)$ is a global modality term for K. Inductively we define a function λ mapping quantifier-free formulas (in the first order language of BAOs) to τ-terms:

$$\begin{array}{rcl} s \approx t & \mapsto & (s \wedge \neg t) \vee (\neg s \wedge t), \\ \sim P & \mapsto & \neg\gamma(\lambda_P), \\ P \mathbin{\&} Q & \mapsto & \lambda_P \vee \lambda_Q. \end{array}$$

THEOREM 138. *Let K be a class of Boolean algebras with τ-operators with a discriminator term γ. Then any universal formula P is equivalent over K to the equation $\lambda_{P'} \approx \bot$, where P' is the quantifier-free part of P.*

Proof. A straightforward induction shows that for any algebra $\mathbb{A}$ in K, any assignment α on $\mathbb{A}$ and any quantifier-free formula P it holds that

$$\mathbb{A} \models_\alpha P \text{ iff } \mathbb{A} \models_\alpha \lambda_P \approx \bot.$$

From this, the statement of the theorem is immediate. ❑

Working with discriminator classes has many advantages. For instances, if K is a discriminator class, then we may generate $\mathsf{Var}(\mathsf{K})$ from K just by taking products and subalgebras (that is, homomorphic images are not needed). The result in this generality is due to Givant [35].

THEOREM 139. *Let K be a class of Boolean algebras with a common global modality term $\gamma(x)$.*

1. *If* $\mathsf{Pu}(\mathsf{K}) \subseteq \mathsf{S}(\mathsf{K})$*, then* $\mathsf{SP}(\mathsf{K})$ *is a variety and* $\mathsf{S}(\mathsf{K})$ *is the universal class of simple algebras in* $\mathsf{SP}(\mathsf{K})$.

2. *If* K *is axiomatized by a set* Φ *of universal formulas, then* $\mathsf{SP}(\mathsf{K})$ *is axiomatized by the set* $\{\lambda_P \approx \bot \mid P \in \Phi\}$*, together with the set* Γ *of Definition 135.*

Proof. Assume that $\mathsf{Pu}(\mathsf{K}) \subseteq \mathsf{S}(\mathsf{K})$, then it is easy to see that the class $\mathsf{S}(\mathsf{K})$ is closed under taking ultraproducts and subalgebras. It then follows by standard universal algebra, see [17, Theorem 2.20], that $\mathsf{S}(\mathsf{K})$ is a universal class, that is, an elementary class axiomatized by universal formulas.

By assumption, the algebras in K have a common discriminator term, and, hence, we find, reasoning as in the proof of Theorem 134(3), that $\mathsf{SirVar}(\mathsf{K}) = \mathsf{SPu}(\mathsf{K})$, where $\mathsf{SirVar}(\mathsf{K})$ denotes the class of s.i. members in $\mathsf{Var}(\mathsf{K})$. Thus by the assumption we find that $\mathsf{SirVar}(\mathsf{K}) = \mathsf{S}(\mathsf{K})$ and therefore, $\mathsf{S}(\mathsf{K})$ is the class of simple algebras in $\mathsf{Var}(\mathsf{K})$, since the notions of simplicity and subdirect irreducibility coincide. Finally then, by Birkhoff's and Jónsson's theorems, the variety $\mathsf{Var}(\mathsf{K})$ is the class of subdirect products of algebras in $\mathsf{HSPu}(\mathsf{K}) = \mathsf{S}(\mathsf{K})$; a straightforward calculation then will show that $\mathsf{Var}(\mathsf{K}) = \mathsf{SP}(\mathsf{K})$.

Part two of the theorem is a straightforward consequence of Proposition 136 and Theorem 138. ❑

Finally, for more information on the global modality, the reader is referred to Chapter 8 of this volume.

9 COALGEBRAS: AN INTRODUCTION

This section forms a brief introduction to the field of *Coalgebra.* While certain kinds of coalgebras had already been studied in the sixties, the field really took off after it was realized that coalgebra can be conceived as a general and uniform theory of dynamic systems, taken in a broad sense.

Many structures in mathematics and theoretical computer science can naturally be represented as coalgebras. Probably the first example was provided by Aczel [2], who models transition systems and non-well-founded sets as coalgebras. On the basis of Aczel's work, Barwise & Moss [11] discuss a wide range of phenomena involving the notions of circularity and self-reference, with applications ranging from theoretical economics to the semantics of natural language. A second paradigmatic specimen of coalgebras in computer science is given by (deterministic) automata, see Rutten [96]. Further important examples include the representation of infinite data structures, and the formal modeling of objects and classes in object oriented programming, see Reichel [92] or Jacobs [61]. But for modal logicians, it will be Kripke frames and models that provide the prime examples of coalgebras; this link goes back to at least Abramsky [1]. In fact, the model theory of modal logic is coalgebraic in nature, so modal logicians entering the field will have much the same experience as group theorists learning about universal algebra, in that they will recognize many familiar notions and results, lifted to a higher level of generality and abstraction.

For readers that want to learn more about coalgebras, the literature harbors some well written introductions and surveys (although at the time of writing there is no text book or monograph available). We refer the reader to Jacobs & Rutten [65] for a very accessible

introduction, and to Rutten [97] or Gumm [50] for comprehensive surveys. Ihringer [60] has an appendix on coalgebras by Gumm. For more details on the connection between coalgebra and modal logic, the reader may consult Kurz [75] or Pattinson [90].

What then are coalgebras? The most concrete, state-based specimens, called *systems*, simply consist of a set S endowed with some kind of transition, formally modeled as some map σ from S to another set ΩS. Here Ω is some functor constituting the *type* or *signature* of the coalgebra at stake. The transition map provides some kind of structure on S, but whereas *algebraic* operations are ways to *construct* complex objects out of simple ones, coalgebraic operations, going *out of* the carrier set, should be seen as ways to *unfold* or *observe* objects. This explains the central role of the notion of *behavior* in the theory of coalgebras.

More generally, given an endofunctor Ω on some base category C, an Ω-*coalgebra* is a pair $\mathbb{C} = \langle C, \gamma \rangle$, with C an arbitrary object in C, and γ a C-arrow from C to ΩC. The full functorial power of Ω comes in when we turn Ω-coalgebras into a category $\mathsf{Coalg}(\Omega)$ by introducing morphisms: A homomorphism from $\langle C, \gamma \rangle$ to $\langle C', \gamma' \rangle$ is an arrow $f : C \to C'$ such that $\gamma' \circ f = (\Omega f) \circ \gamma$. This set-up enables the canonical definition of two notions of equivalence between coalgebras, namely, bisimulation and behavioral equivalence. As we will see as well, the definitions make the concept of a coalgebra very similar to that of an algebra. However, if one makes this connection mathematically precise, it turns out that coalgebras over the base category C are *dual* to algebras over the *opposite* category C^{op}. This explains not only the name 'coalgebra', but, as we will see, also many of the peculiarities of *universal coalgebra*, that is, the general coalgebraic theory of systems.

Given the nature of coalgebra as a very general model of state-based dynamics, there is a natural place for *modal logic* as a formalism for reasoning about behavior. It was Moss [11, 86] who realized that one may generalize the concept of modal logic from Kripke frames and models to coalgebras over arbitrary set functors. Over subsequent years, the development and study of modal languages for the specification of properties of coalgebras has been actively pursued and studied by various authors, including Jacobs [62, 64], Kurz [77, 76], Pattinson [88, 89], and Rößiger [95]. In fact, as we will see, the link between modal logics and coalgebra is so tight, that one may even claim that modal logic is the natural logic for coalgebras — just like equational logic is that for algebra.

We now turn to the technical development of the topic, starting with the definition of a *coalgebra*.

DEFINITION 140. Given an endofunctor Ω on a category C, an Ω-*coalgebra* is a pair $\mathbb{A} = (A, \alpha)$, where A is an object of C called the *carrier* of $\mathbb{A}$, and $\alpha : A \to \Omega A$ is an arrow in C, called the *transition map* of $\mathbb{A}$. In case Ω is an endofunctor on Set, Ω-coalgebras may also be called Ω-*systems*; a *pointed* Ω-*system* is a triple $\langle A, \alpha, a \rangle$ such that $\langle A, \alpha \rangle$ is an Ω-system, and a is a state in $\mathbb{A}$, that is, an element of A.

As we mentioned already, the action of the functor Ω on the *arrows* of the category C will be needed when we introduce, in Definition 148 below, homomorphisms between Ω-coalgebras. First we consider some examples of systems.

EXAMPLE 141. Probably the simplest example of a system is that of an C-colored set, that is, a pair $\langle S, \gamma : S \to C \rangle$. No matter where we start, this system can only display the color of the current state, and halt after doing so.

A slightly more interesting example is provided by a black box machine which may be prompted to display a value, or color, from C, and to move on to a next state. These

states are internal to the machine, that is, invisible to an outside observer. Such a machine can abstractly be modeled as a coalgebra $\mu : M \to C \times M$, with $\pi_0(\mu(s)) \in C$ denoting the current value of the machine, and $\pi_1(\mu(s)) \in M$ representing the machine's next internal state. (Here $\pi_0 : C \times M \to C$ and $\pi_1 : C \times M \to M$ are the projection functions.)

EXAMPLE 142. For our second example, we turn to automata theory. Recall that *deterministic automata* are usually modeled as quintuples $\mathbb{A} = \langle A, a_I, C, \delta, F\rangle$ such that A is the state space of the automaton $\mathbb{A}$, $a_I \in A$ is its initial state, C its *alphabet*, $\delta : A \times C \to A$ its *transition function* and finally, $F \subseteq A$ its collection of *accepting states*.

Now observe that we may represent F by its characteristic map $\chi_F : A \to 2$ (with 2 denoting the set $\{0, 1\}$) which maps $a \in A$ to 1 if $a \in F$, and to 0 if $a \notin F$. Furthermore, we can and will view δ as a map from $A \to A^C$, where A^C denotes the collection of maps from C to A. Thus we see that we may represent a deterministic automaton over the alphabet C as a pointed system over the functor $S \mapsto 2 \times S^C$.

EXAMPLE 143. Our third example provides the crown witness when it comes to the connection between coalgebra and modal logics: We will now see that *frames* and *models* are in fact coalgebras in disguise. The crucial observation is here that a binary relation $R \subseteq S \times S$ can be represented by the function $R[\cdot] : S \to \mathcal{P}(S)$ mapping a point s to the collection $R[s]$ of its successors. Thus frames for the basic modal similarity type correspond to coalgebras over the covariant power set functor $\mathcal{P}$. (This functor maps a set S to its power set $\mathcal{P}(S)$ and a function $f : S \to S'$ to the image map $\mathcal{P}f$ given by $(\mathcal{P}f)(X) := f[X](= \{f(x) \mid x \in X\})$.)

Similarly, a ternary relation $T \subseteq S^3$ can be modeled as the function $T[\cdot] : S \to \mathcal{P}(S^2)$ given by $T[s] = \{(t_1, t_2) \in S^2 \mid Tst_1t_2\}$. Thus for any modal similarity type τ, we can represent τ-frames as coalgebras for the functor $S \mapsto \prod_{\nabla\in\tau} \mathcal{P}(S^{ar(\nabla)})$. Also note that *image finite frames*, that is, frames in which $R[s]$ is a finite set for all points s, correspond to coalgebras over the *finitary* power set functor $\mathcal{P}_\omega$.

Concerning models, in this section we let Prop denote the set of propositional variables. It is easy to see that a valuation $V : \mathsf{Prop} \to \mathcal{P}(S)$ on a frame $\mathbb{S} = \langle S, R\rangle$ could equivalently have been defined as a $\mathcal{P}(\mathsf{Prop})$-coloring of S, that is, as the map sending a state s to the collection $V^{-1}[s] = \{p \in \mathsf{Prop} \mid s \in V(p)\}$ of proposition letters holding at s. Thus models for the basic modal similarity type can be identified with coalgebras of the functor Ω given by $X \mapsto \mathcal{P}(\mathsf{Prop}) \times \mathcal{P}(X)$.

EXAMPLE 144. For our last example, let $\breve{\mathcal{P}}$ denote the *contravariant* power set functor. This functor agrees with the covariant power set functor on objects, while on arrows $\breve{\mathcal{P}}$ takes *inverse* images. That is, for $f : A \to A'$, the function $\breve{\mathcal{P}}f : \mathcal{P}A' \to \mathcal{P}A$ is given by $(\breve{\mathcal{P}}f)(X') := f^{-1}[X'](= \{x \in A \mid f(x) \in X'\})$. Note that $\breve{\mathcal{P}}$ is not a functor from Set to Set, and thus does not produce coalgebras. Its composition with itself, however, *is* an endofunctor on Set, so that we may consider $\breve{\mathcal{P}} \circ \breve{\mathcal{P}}$-coalgebras. Because the transition function σ of such a coalgebra $\langle S, \sigma\rangle$ is a function $\sigma : S \to \mathcal{P}\mathcal{P}S$, the structure $\langle S, \sigma\rangle$ may also be seen as a *neighborhood frame*, as discussed in Chapter 1 of this volume.

Some variants of the functor $\breve{\mathcal{P}} \circ \breve{\mathcal{P}}$ are of interest as well — we discuss the examples $\mathcal{U}_{\breve{\mathcal{P}}}$ and $\mathcal{F}_{\breve{\mathcal{P}}}$. Recall that $\breve{\mathcal{P}} \circ \breve{\mathcal{P}}(S) = \mathcal{P}\mathcal{P}(S)$ is the set of *all* collections of subsets of S. $\mathcal{U}_{\breve{\mathcal{P}}}(S)$ denotes the set of all *upward closed* collections of subsets of S, while $\mathcal{F}_{\breve{\mathcal{P}}}(S)$ denotes the set of all *filters* of S. On arrows, these functors coincide with $\breve{\mathcal{P}} \circ \breve{\mathcal{P}}$; more precisely, for $f : S \to S'$, we set $\mathcal{U}_{\breve{\mathcal{P}}}f$ and $\mathcal{F}_{\breve{\mathcal{P}}}f$ as the restrictions of $(\breve{\mathcal{P}} \circ \breve{\mathcal{P}})f$ to $\mathcal{U}_{\breve{\mathcal{P}}}S$

and $\mathcal{F}_{\breve{\mathcal{P}}}S$, respectively.

It is not hard to show that $\mathcal{U}_{\breve{\mathcal{P}}}$ and $\mathcal{F}_{\breve{\mathcal{P}}}$ are indeed functors $\mathsf{Set} \to \mathsf{Set}$. The reader may in fact be familiar with (some) coalgebras for these functors. It can easily be verified that the $\mathcal{U}_{\breve{\mathcal{P}}}$-coalgebras correspond exactly to the *monotonic neighborhood frames* that were mentioned in Chapter 1 as the superset closed neighborhood frames. Prime examples of $\mathcal{F}_{\breve{\mathcal{P}}}$-coalgebras are the topological spaces (that were also mentioned in Chapter 1, be it rather implicitly under the name of *topological semantics*). To see this, represent the topology σ on the set S by the function mapping a point $s \in S$ to the collection $\{U \in \sigma \mid s \in U\}$ of its neighborhoods.

EXAMPLE 145. For each set functor Ω, the empty set $\varnothing$, with the unique map from $\varnothing$ to $\Omega\varnothing$, provides an Ω-coalgebra.

The functors mentioned in the Examples 141, 142 and 143, are examples of so-called *Kripke polynomial functors* which share some pleasant properties as we will see further on.

DEFINITION 146. The collection of *polynomial functors* is inductively defined as follows:

$$K \;::=\; \mathcal{I} \mid C \mid K_0 + K_1 \mid K_0 \times K_1 \mid K^D. \tag{40}$$

Here $\mathcal{I}$ denotes the identity functor on the category Set; C the constant functor $X \mapsto C$; $K_0 + K_1$ the coproduct functor $X \mapsto K_0(X) + K_1(X)$; $K_0 \times K_1$ the product functor; and K^D denotes the exponent functor $X \mapsto K(X)^D$.

Similarly, the collection of *Kripke polynomial functors* is given by

$$K \;::=\; \mathcal{I} \mid C \mid K_0 + K_1 \mid K_0 \times K_1 \mid K^D \mid \mathcal{P}K, \tag{41}$$

where $\mathcal{P}K$ is the composition of K with the power set functor $\mathcal{P}$. Replacing $\mathcal{P}$ with the *finite power set functor* $\mathcal{P}_\omega$, and demanding the exponent D in K^D to be finite, we obtain the collection of *finitary Kripke polynomial functors*.

In each of these cases, the set $Ing K$ of *ingredient functors* of a (Kripke) polynomial functor K is defined by an obvious induction, with clauses $Ing(\mathcal{I}) := \{\mathcal{I}\}$, $Ing(\mathcal{P}K) := \{\mathcal{P}K\} \cup Ing(K)$, etc.

With the notation of this definition, Example 141 provides examples of coalgebras for the functors C and $\mathcal{I} \times C$. Deterministic automata over the alphabet C are $2 \times \mathcal{I}^C$-coalgebras. Kripke frames are $\mathcal{P}\mathcal{I}$-coalgebras, and Kripke models are coalgebras for the functor $\mathcal{P}\mathsf{Prop} \times \mathcal{P}\mathcal{I}$. (Note that in the format (41), the power set functor as such is not a Kripke polynomial functor: It has to be represented as the functor $\mathcal{P}\mathcal{I}$. In the sequel, we will keep working with Kripke frames as $\mathcal{P}$-coalgebras, unless explicitly mentioned otherwise.)

After Set, the base category for coalgebras that carries most interest to modal logicians, is probably that of *Stone spaces*.

EXAMPLE 147. Recall from Remark 60 that a Stone space is pair $\mathbb{S} = (S, \sigma)$ such that σ is a compact Hausdorff space with a basis of clopens. Let Stone denote the category with Stone spaces as objects, and continuous maps as arrows. We will show that *descriptive general frames* can be viewed as Stone-coalgebras for the so-called *Vietoris functor* $\mathcal{V}$ — for details on this observation, which is due to Abramsky [1], see Kupke, Kurz & Venema [74].

This functor, which forms the topological counterpart of the power set functor, is defined as follows. Given a topological space $\mathbb{S} = \langle S, \sigma\rangle$, let $K(\mathbb{S})$ denote the collection of closed subsets of S, and let $\ni \subseteq K(\mathbb{S}) \times S$ denote the converse membership relation. Then (in accordance with our earlier notation), we define, for any subset $U \subseteq S$, the sets $\langle\ni\rangle U = \{F \in K(\mathbb{S}) \mid F \cap U \neq \varnothing\}$ and $[\ni]U = \{F \in K(\mathbb{S}) \mid F \subseteq U\}$. The topology on $K(\mathbb{S})$, generated by taking the collection $\{\langle\ni\rangle U, [\ni]U \mid U \in \sigma\}$ as a subbasis, is called the *Vietoris topology* of σ, and the resulting space, the *Vietoris space* $\mathcal{V}(\mathbb{S})$ associated with $\mathbb{S}$.

The Vietoris construction preserves several properties of topological spaces; in particular, if $\mathbb{S}$ is a Stone space, then so is $\mathcal{V}(\mathbb{S})$. Also, we may extend it to a functor, by defining, for a continuous map $f : \mathbb{S} \to \mathbb{S}'$, the function $\mathcal{V}f$ as the image map given by $(\mathcal{V}f)(X) := f[X]$. Here we omit the proof that $\mathcal{V}f$ is indeed an arrow in the category Stone, i.e., that it is a *continuous* map from $\mathcal{V}(\mathbb{S})$ to $\mathcal{V}(\mathbb{S}')$.

Now let $\mathbb{G} = \langle G, R, A\rangle$ be a descriptive general frame (cf. Definition 64), with associated Stone space σ_A. Recall from Remark 65 that the map $R[\cdot]$ mapping a point in G to the collection of its successors, is a function from G to $K(\langle G, \sigma_A\rangle)$. It is not too hard to prove that this is in fact a *continuous* map from $\langle G, \sigma_A\rangle$ to its Vietoris space. Thus we may represent $\mathbb{G}$ as the Stone coalgebra $\langle\langle G, \sigma_A\rangle, R[\cdot]\rangle$.

Obviously, coalgebras are not studied in isolation; the following definition provides a natural notion of a map between coalgebras that preserves the transition structure.

DEFINITION 148. Let $\mathbb{A} = \langle A, \alpha\rangle$ and $\mathbb{A}' = \langle A', \alpha'\rangle$ be two coalgebras for the functor $\Omega : \mathsf{C} \to \mathsf{C}$. Then a *homomorphism* from $\mathbb{A}$ to $\mathbb{A}'$ is an arrow $f : A \to A'$ for which the following diagram commutes:

$$\begin{tikzcd} A \arrow[r, "f"] \arrow[d, "\alpha"'] & A' \arrow[d, "\alpha'"] \\ \Omega A \arrow[r, "\Omega f"] & \Omega A' \end{tikzcd}$$

EXAMPLE 149. The homomorphisms for $\mathcal{P}$-coalgebras coincide with the bounded morphisms between Kripke frames. To see this, let $\mathbb{S} = \langle S, R\rangle$ and $\mathbb{S}' = \langle S', R'\rangle$ be two frames (for the basic modal similarity type), and consider their respective coalgebraic representations $\langle S, \sigma\rangle$ and $\langle S', \sigma'\rangle$, as in Example 143.

Now consider a map $f : S \to S'$. It is straightforward to show that

$$\begin{array}{lll} f \text{ satisfies the forth condition} & \text{iff} & (\mathcal{P}f) \circ \sigma(s) \subseteq \sigma' \circ f(s) \text{ for all } s \in S, \\ f \text{ satisfies the back condition} & \text{iff} & (\mathcal{P}f) \circ \sigma(s) \supseteq \sigma' \circ f(s) \text{ for all } s \in S. \end{array}$$

This shows that f is a bounded morphism from $\mathbb{S}$ to $\mathbb{S}'$ if and only if it is a coalgebra homomorphism from $\langle S, \sigma\rangle$ to $\langle S', \sigma'\rangle$, and provides perhaps the most convincing argument that the notion of a bounded morphism is a natural one.

EXAMPLE 150. Let $\mathbb{X}$ and $\mathbb{X}'$ be two topological spaces, represented as coalgebras $\mathbb{X} = \langle X, \xi\rangle$ and $\mathbb{X}' = \langle X', \xi'\rangle$ for the filter functor $\mathcal{F}_{\breve{\mathcal{P}}}$ of Example 144. We leave it for the reader to check that a map $f : S \to S'$ is an $\mathcal{F}_{\breve{\mathcal{P}}}$-coalgebra homomorphism iff f is continuous and open (i.e., not only do we require $f^{-1}[U']$ to be open in $\mathbb{X}$ if U' is open in $\mathbb{X}'$, but also $f[U]$ must be open in $\mathbb{X}'$ for all $\mathbb{X}$-open U).

Likewise, one can prove that the coalgebraic notion of a homomorphism between monotone neighborhood frames, represented as coalgebras for the functor $\mathcal{U}_{\breve{\mathcal{P}}}$, corresponds to that of a bounded morphism for these structures as defined in section 2.

It is easy to check that the collection of coalgebra homomorphisms contains all identity arrows and is closed under arrow composition. Hence, the Ω-coalgebras with their homomorphisms form a category.

DEFINITION 151. For any functor $\Omega : \mathsf{C} \to \mathsf{C}$, we let $\mathsf{Coalg}(\Omega)$ denote the category with Ω-coalgebras as objects and the corresponding homomorphisms as arrows. The category C is called the *base category* of $\mathsf{Coalg}(\Omega)$.

The reader will already be familiar with a number of (isomorphic copies of) these categories. For instance, Example 149 shows in fact that the category Fr (of frames with bounded morphisms) is *isomorphic* to the category $\mathsf{Coalg}(\mathcal{P})$ of $\mathcal{P}$-coalgebras. Likewise, elaborating Example 147, one can prove that the category DGF (of descriptive general frames with continuous bounded morphisms, see Definition 66) is isomorphic to the category of Stone coalgebras for the Vietoris functor. Of course, it is these isomorphisms that justify our classification of modal structures as coalgebras, not so much the simple fact that the objects in isolation can be presented in coalgebraic format.

REMARK 152. Recall that an *algebra* over a signature Ω is a set A with an Ω-indexed collection $\{f^{\mathbb{A}} \mid A^{ar(f)} \to A\}$ of operations. These operations may be combined into a single map $\alpha : \sum_{f\in\Omega} A^{ar(f)} \to A$, where $\sum_{f\in\Omega} A^{ar(f)}$ denotes the *coproduct* (or *sum*, or *disjoint union*) of the sets $\{A^{ar(f)} \mid f \in \Omega\}$. It is not hard to verify that a map $g : A \to A'$ is an algebraic homomorphism between the algebras $\mathbb{A} = \langle A, \alpha\rangle$ and $\mathbb{A}' = \langle A', \alpha'\rangle$ iff the following diagram commutes:

$$\begin{tikzcd}
A \arrow[r, "f"] & A' \\
\Omega A \arrow[u, "\alpha"] \arrow[r, "\Omega f"] & \Omega A' \arrow[u, "\alpha'"']
\end{tikzcd}$$

where we now view the signature Ω as the polynomial set *functor* $\sum_{f\in\Omega} \mathcal{I}^{ar(f)}$. That is, Ω operates as well on functions between sets. This naturally suggests the following generalization.

Given an endofunctor Ω on a category C, an Ω-algebra is a pair $\mathbb{A} = \langle A, \alpha\rangle$ where $\alpha : \Omega A \to A$ is an arrow in C. A homomorphism from an Ω-algebra $\mathbb{A}$ to an Ω-algebra $\mathbb{A}'$ is an arrow $f : A \to A'$ such that $f \circ \alpha = \alpha' \circ (\Omega f)$. The induced category is denoted as $\mathsf{Alg}(\Omega)$.

Now the obvious similarities between the notions of algebra and coalgebra can be made very precise. The basic observation, which also explains the name 'coalgebra', is that a coalgebra $\mathbb{C} = \langle C, \gamma : C \to \Omega C\rangle$ over a base category C can also be seen as an algebra in the *opposite* category C^{op} — we will come back to this issue in section 15. Note however, that universal coalgebra, dealing with arbitrary set functors, is more general than (what is usually called) universal algebra, which involves only polynomial functors.

10 FINAL COALGEBRAS

DEFINITION 153. A functor $\Omega : \mathsf{C} \to \mathsf{C}$ is said to *admit a final* or *terminal coalgebra* if the category $\mathsf{Coalg}(\Omega)$ has a final object, that is, a coalgebra $\mathbb{Z}$ such that from every coalgebra $\mathbb{A}$ in $\mathsf{Coalg}(\Omega)$ there is a unique homomorphism $!_{\mathbb{A}} : \mathbb{A} \to \mathbb{Z}$.

Functors admitting a final coalgebra are of special interest. In the case of state-based coalgebras, one reason for this is that final coalgebras often provide an intuitive encoding of the notion of *behavior*. And in fact, many interesting and well-known mathematical objects can be naturally associated with the final coalgebra of some functor.

EXAMPLE 154. Consider a black box machine $\mathbb{M} = \langle M, \mu \rangle$ as in Example 141. Starting from, say, state x_0, the machine makes a transition $\mu(x_0) = (c_0, x_1)$ and continues with $\mu(x_1) = (c_1, x_2)$, $\mu(x_2) = (c_2, x_3)$, etc. Since the states x_0, x_1, ... are internal to the machine, the only observable part of this dynamics is the infinite sequence or *stream* $beh(x_0) = (c_0, c_1, c_2, \ldots) \in C^\omega$ of values in the data set C.

The collection C^ω of all infinite words over C forms itself a system for the functor $C \times \mathcal{I}$. Simply endow the set C^ω with the transition structure γ splitting an infinite stream $u = c_0c_1c_2\ldots$ into its *head* $h(u) = c_0$ and its *tail* $t(u) = c_1c_2c_3\ldots$ Putting $\gamma(u) = (h(u), t(u))$, one easily proves that the behavior map $x \mapsto beh(x)$ is the unique homomorphism from $\mathbb{M}$ to this coalgebra $\langle C^\omega, \gamma \rangle$. This shows that $\langle C^\omega, \gamma \rangle$ is the final object in the category $\mathsf{Coalg}(C \times \mathcal{I})$.

EXAMPLE 155. For a second example, consider again the coalgebraic representation of a deterministic automaton over the alphabet C as a $2 \times \mathcal{I}^C$-coalgebra. Now we will see that the collection $\mathcal{P}(C^*)$ of all *languages* over C provides (the carrier of) the final coalgebra. We can turn this set $\mathcal{P}(C^*)$ into a coalgebra by imposing on it the following transition function $\lambda : \mathcal{P}(C^*) \to 2 \times \mathcal{P}(C^*)^C$. Writing $\lambda(L) = (\lambda_0(L), \lambda_1(L))$, we define $\lambda_0(L) := 1$ iff the empty string belongs to L, and $\lambda_1(L)(c) := \{w \in C^* \mid cw \in L\}$. (The latter set is sometimes called the *c-derivative* of L.)

We leave it for the reader to verify that with this definition, the structure $\langle \mathcal{P}(C^*), \lambda \rangle$ forms the final object in $\mathsf{Coalg}(2 \times \mathcal{I}^C)$. Given a $2 \times \mathcal{I}^C$-coalgebra $\mathbb{A}$, the unique homomorphism $!_{\mathbb{A}} : \mathbb{A} \to \langle \mathcal{P}(C^*), \lambda \rangle$ maps a state $a \in A$ to the language that is accepted by the automaton that we obtain by taking a as initial state of $\mathbb{A}$.

EXAMPLE 156. An interesting example in modal logic is provided by the final coalgebra for the Vietoris functor $\mathcal{V}$ of Example 147. The existence of a final $\mathcal{V}$-coalgebra is in fact an immediate consequence of the isomorphism $\mathsf{Coalg}(\mathcal{V}) \cong \mathsf{DGF}$, and the duality between DGF and MA (the category of modal algebras with homomorphisms). MA has an initial object (namely, the Lindenbaum-Tarski algebra generated by the empty set of variables, or, equivalently, the free modal algebra over zero generators), and so by duality, $\mathsf{Coalg}(\mathcal{V})$ must have a final object. In fact, the *canonical* descriptive general frame, based on the set of maximal consistent closed formulas, fulfills this role — a nice and perhaps quite unexpected application of this construction.

An important application of final coalgebras is provided by the principle of *coinduction*, which is one of the fundamental coalgebraic notions. There are two sides to this principle: it serves both as an important proof tool and as an elegant means of providing definitions. As a definition principle, coinduction is based on the existence of unique homomorphisms into the final Ω-system $\mathbb{Z} = \langle Z, \zeta \rangle$. For, suppose that we can endow a set S with an Ω-

coalgebra map $\sigma : S \to \Omega S$, thus obtaining the Ω-system $\mathbb{S}$. Then there is a unique function $f_\sigma = !_{\mathbb{S}} : S \to Z$ which is consistent with the coalgebra specification σ, in the sense that it is a coalgebraic homomorphism from $\langle S, \sigma \rangle$ to $\mathbb{Z}$. Thus the function f_σ is *defined* by coinduction from (the specification) σ.

EXAMPLE 157. For instance, take the function that merges two streams by taking elements from either stream in turn. For a coinductive definition of this map, define the transition map $zip : C^\omega \times C^\omega \to C \times (C^\omega \times C^\omega)$ as follows:

$$zip(u, v) := (h(u), (v, t(u))),$$

where h and t are the head and tail maps of Example 154. Then by finality there is a unique homomorphism $f_{zip} : C^\omega \times C^\omega \to C^\omega$. One may verify that this indeed defines the map that zips two streams together.

The previous example is fairly typical in that it uses coinduction to define a function from a product of the final system to itself. It should also be noted that coinduction works particularly well for structures that combine algebraic and coalgebraic features, such as streams of data objects which are subject themselves to algebraic operations.

Unfortunately, final coalgebras do not exist for every functor Ω. For instance, Set-endofunctors involving the power set functor in a nontrivial way, will generally not admit a final coalgebra; in particular, there is no final Kripke frame or model. By Cantor's theorem, these results are immediate consequence of the following proposition, which is due to Lambek [79].

PROPOSITION 158. *Let $\Omega : \mathsf{C} \to \mathsf{C}$ be some functor admitting a final system $\mathbb{Z} = \langle Z, \zeta \rangle$. Then ζ is an isomorphism (in C) between Z and ΩZ.*

Proof. Suppose that $\mathbb{Z} = \langle Z, \zeta \rangle$ is the final object of $\mathsf{Coalg}(\Omega)$. It can easily be verified that ζ is in fact a coalgebra homomorphism from $\mathbb{Z}$ to $\mathbb{Z}_2 := \langle \Omega Z, \Omega\zeta \rangle$. But then the composition $!_{\mathbb{Z}_2} \circ \zeta$ is a coalgebra homomorphism from $\mathbb{Z}$ to itself, just like the identity arrow id_Z on Z. Thus by uniqueness it follows that $!_{\mathbb{Z}_2} \circ \zeta = id_Z$. For the reverse composition $\zeta \circ !_{\mathbb{Z}_2}$ we have, by the fact that $!_{\mathbb{Z}_2}$ is a homomorphism, that $\zeta \circ !_{\mathbb{Z}_2} = \Omega !_{\mathbb{Z}_2} \circ \Omega\zeta = \Omega(!_{\mathbb{Z}_2} \circ \zeta) = \Omega(id_Z) = id_{\Omega Z}$. From this the result is immediate. ❑

So which functors admit final coalgebras? Some good sufficient conditions are known.

DEFINITION 159. Let Ω be some set functor, and κ some cardinal. Call Ω *κ-small* if

$$\Omega(S) = \bigcup \{(\Omega\iota)[\Omega(A)] \mid \iota : A \hookrightarrow S, |A| < \kappa\},$$

for all sets $S \neq \varnothing$. Ω is *small* if it is small for some cardinal κ.

In words, the definition requires every element of $\Omega(S)$ to be in the range of $\Omega\iota$ for an appropriate inclusion map $\iota : A \to S$. In case Ω is a *standard* functor (meaning that Ω maps inclusions $\iota : A \hookrightarrow B$ to inclusions $(\Omega\iota) : \Omega A \hookrightarrow \Omega B$), the definition boils down to the requirement that $\Omega(S) = \bigcup\{\Omega(A) \mid A \subseteq S, |A| < \kappa\}$. The notion of smallness is easily seen to be equivalent to the instantiation in Set of the more general notion of *accessibility*, and it is also equivalent to the concept of *boundedness*, cf. Adámek & Porst [6] for details.

Examples of small functors abound; for instance, whenever we replace, in a Kripke polynomial functor, the power set functor by a bounded variant such as the finite power

set functor, the result is a small functor. For instance, the finite power set functor $\mathcal{P}_\omega$ is ω-small. The following result, due to Aczel & Mendler [3] and Barr [9], witnesses the importance of the notion.

FACT 160. Every small set functor admits a final coalgebra.

As one of the immediate corollaries of this fact, the categories of image finite frames and image finite models, which can be represented as coalgebras for the functor $\mathcal{P}_\omega$, and $\mathcal{P}\mathsf{Prop} \times \mathcal{P}_\omega$, respectively, have final objects.

REMARK 161. For Set-based functors that do not admit a final coalgebra, one may *create* a final coalgebra — at least, if one is willing to allow coalgebras with a class rather than a set as their carrier. Let SET be the category that has classes as objects, and set-continuous functions as arrows. These are functions $f : \mathsf{C} \to \mathsf{C}'$ between classes with the property that $f(\mathsf{C}) = \bigcup\{f(S) \mid S \subseteq \mathsf{C}$ and S is a set$\}$. An endofunctor on SET is *set-based* if for each class C and each $c \in \Omega(C)$ there is a set $S \subseteq C$ such that $c \in (\Omega\iota)[\Omega(S)]$, where $\iota : S \to C$ is the inclusion map. (If the set functor is standard, this boils down to requiring that Ω is a set-continuous map on objects.) Now Aczel & Mendler [3] proved that every set-based endofunctor $\Xi : \mathsf{SET} \to \mathsf{SET}$ admits a final coalgebra. The similarity to Fact 160 is no coincidence: Barr [9] showed that the result of Aczel & Mendler can in fact be reformulated as Fact 160.

This fact can be used as follows. Given an endofunctor Ω on Set, there is a *unique* way to extend Ω to a set based endofunctor Ω^+ on SET. (On objects, simply put $\Omega^+(\mathsf{C}) := \bigcup\{(\Omega\iota)[\Omega(S) \mid \iota : S \hookrightarrow \mathsf{C}, S \text{ a set}\}$.) The theorem of Aczel & Mendler then guarantees the existence of a final object $\mathbb{Z}$ in $\mathsf{Coalg}(\Omega^+)$. This coalgebra will be class-based if Ω does not admit a final coalgebra, but it will be final, not only with respect to the set-based coalgebras in $\mathsf{Coalg}(\Omega^+)$, but also with respect to the class-based ones. As an important instance of this idea, Aczel [2] showed that the class of non-well-founded sets provides the final coalgebra for (the SET-based extension of) the power set functor.

REMARK 162. Whether the functor admits a final coalgebra or not, one may always (try to) approximate it. The *final* or *terminal sequence* associated with a given set functor Ω, is an ordinal indexed sequence of objects $\langle Z_\alpha \rangle$ with maps $p^\alpha_\beta : Z_\alpha \to Z_\beta$ for $\beta \leq \alpha$, such that (i) $Z_{\alpha+1} = \Omega Z_\alpha$ and $p^{\alpha+1}_{\beta+1} = \Omega p^\alpha_\beta$, (ii) $p^\alpha_\alpha = id_{Z_\alpha}$ and $p^\beta_\gamma \circ p^\alpha_\beta = p^\alpha_\gamma$, (iii) if λ is a limit ordinal, then Z_λ with $\{p^\lambda_\alpha \mid \alpha < \lambda\}$ is a limit of the diagram with objects $\{Z_\alpha \mid \alpha < \lambda\}$ and arrows $\{p^\alpha_\beta \mid \alpha, \beta < \lambda\}$. (In particular, taking 0 to be a limit ordinal, we find that $Z_0 = 1$ is some initial object 1 of the category Set.) It is not hard to prove that, modulo isomorphism, the final sequence is uniquely determined by these conditions.

Intuitively, it can be seen as an approximation of the final coalgebra for Ω. That is, where elements of the final coalgebra represent 'complete' behavior, elements of Z_α represent behavior that can be performed in α steps. To make this precise and formal, observe that for any Ω-coalgebra $\mathbb{S}$ there is a *unique* ordinal-indexed class of functions $!_\alpha : S \to Z_\alpha$ such that $!_0$ is fixed by the finality of Z_0 in Set, $!_{\alpha+1} = (\Omega !_\alpha) \circ \sigma$, and for limit λ, $!_\lambda$ is given as the unique map $!_\lambda : S \to Z_\lambda$ such that $!_\lambda = p^\lambda_\alpha \circ !_\alpha$ for all $\alpha < \lambda$. It is not hard to prove that, for instance, $\mathbb{S}, s \equiv_\Omega \mathbb{S}', s'$ implies that $!_\alpha(s) = !_\alpha(s')$ for all α.

The relation with final coalgebras can be made precise, as follows. On the one hand, if the final sequence converges, in the sense that some arrow $p^{\alpha+1}_\alpha$ is a bijection, then the coalgebra $\langle Z_\alpha, (p^{\alpha+1}_\alpha)^{-1}\rangle$ is a final coalgebra for Ω. And conversely, under some constraints on Ω, Adámek & Koubek [5] proved that if Ω admits a final coalgebra, then

the final sequence converges to it. More information on the final sequence of set functors can be found in Worrell [109].

11 BISIMULATION & BEHAVIORAL EQUIVALENCE

In this section we discuss the most important notions of equivalence between systems: behavioral equivalence and bisimulation. Both of these generalize the concept of a bisimulation between two Kripke models.

Probably the most intuitive notion of equivalence between systems is that of *behavioral*, or *observational*, equivalence. The idea here is to consider two states to be similar if we cannot distinguish them by observations, because they display the same behavior. For instance, we call two deterministic automata (pointed $2 \times \mathcal{I}^C$-coalgebras) equivalent if they recognize the same language. In case the functor Ω admits a final coalgebra $\mathbb{Z}$, this idea is easily formalized by making state s_0 in coalgebra $\mathbb{S}_0$ equivalent to state s_1 in coalgebra $\mathbb{S}_1$ if $!_{\mathbb{S}_0}(s_0) = !_{\mathbb{S}_1}(s_1)$. In case the functor does not admit a final coalgebra, we generalize this demand as follows.

DEFINITION 163. Let $\mathbb{S} = \langle S, \sigma \rangle$ and $\mathbb{S}' = \langle S', \sigma' \rangle$ be two systems for the set functor Ω. Then $s \in S$ and $s' \in S'$ are *behaviorally equivalent*, notation: $\mathbb{S}, s \equiv_\Omega \mathbb{S}', s'$ if there is an Ω-system $\mathbb{X} = \langle X, \xi \rangle$ and homomorphisms $f : \mathbb{S} \to \mathbb{X}$ and $f' : \mathbb{S}' \to \mathbb{X}$ such that $f(s) = f'(s')$.

REMARK 164. It is easily checked that in case Ω admits a final coalgebra, then indeed $\mathbb{S}, s \equiv_\Omega \mathbb{S}', s'$ iff $!_{\mathbb{S}}(s) = !_{\mathbb{S}'}(s')$. In the case that Ω does not admit a final coalgebra, then one may show that behavioral equivalence is captured in the same way by the final coalgebra of the extension Ω^+ of Ω to the category SET, see Remark 161.

REMARK 165. As a variation of behavioral equivalence, the final sequence can be used to study behavior, in a way that is not unlike modal logic. For instance, call two pointed Ω-systems $(\mathbb{S}, s)$ and $(\mathbb{S}', s')$ *α-equivalent* if $!_\alpha(s) = !_\alpha(s')$. In the case of Kripke models, this notion coincides with that of bounded bisimilarity, see Chapter 5 of this volume. One may prove that behavioral equivalence itself coincide with the intersection of α-equivalence for all ordinals α.

In almost all cases of interest, behavioral equivalence can be characterized via the equally fundamental concept of *bisimilarity*, which is due to Aczel & Mendler [3]. The definition of bisimilarity and bisimulations may not be so intuitive at first sight, but, as we will see, these notions have some rather elegant mathematical properties.

DEFINITION 166. Let $\mathbb{S} = \langle S, \sigma \rangle$ and $\mathbb{S}' = \langle S', \sigma' \rangle$ be two systems for the set functor Ω. A relation $B \subseteq S \times S'$ is called a *bisimulation between* $\mathbb{S}$ and $\mathbb{S}'$, if we can endow it with a coalgebra map $\beta : B \to \Omega B$, in such a way that the two projections $\pi : B \to S$ and $\pi' : B \to S'$ are homomorphisms from $\langle B, \beta \rangle$ to $\mathbb{S}$ and $\mathbb{S}'$, respectively:

$$
\begin{tikzcd}
S \arrow[d, "\sigma"'] & B \arrow[l, "\pi"'] \arrow[r, "\pi'"] \arrow[d, dotted, "\beta"'] & S' \arrow[d, "\sigma'"'] \\
\Omega S & \Omega B \arrow[l, "\Omega\pi"'] \arrow[r, "\Omega\pi'"] & \Omega S'
\end{tikzcd}
$$

If there exists a bisimulation B with $(s, s') \in B$, we say that s and s' are *bisimilar*,

notation: $\mathbb{S}, s \leftrightarroweq \mathbb{S}', s'$ (or $B : \mathbb{S}, s \leftrightarroweq \mathbb{S}', s'$ in case we want to make the bisimulation B explicit).

Finally, if $\mathbb{S} = \mathbb{S}'$ we say that B is a bisimulation *on* $\mathbb{S}$; if this B happens to be an equivalence relation, we call it a *bisimulation equivalence* on $\mathbb{S}$.

REMARK 167. Intuitively, bisimulation equivalences correspond to *congruences* in universal algebra. To make this analogy somewhat more precise, call a relation $R \subseteq A_0 \times A_1$, linking the carrier sets of two Ω-algebras $\mathbb{A}_0$ and $\mathbb{A}_1$, *substitutive* if there exists an *algebraic structure* $\rho : \Omega R \to R$, such that the two projections $\pi_i : R \to A_i$ are (algebraic) homomorphisms. This is clearly an algebraic *analogue* (rather than a dual version) of a bisimulation, so that the correspondence between congruences and bisimulation equivalences obtains through the observation that a congruence is nothing but a substitutive equivalence relation.

EXAMPLE 168. Let $\mathbb{S}_0 = \langle S_0, \sigma_0 \rangle$ and $\mathbb{S}_1 = \langle S_1, \sigma_1 \rangle$ be two coalgebras over the functor $\mathcal{P}\mathsf{Prop} \times \mathcal{P}$. That is, $\mathbb{S}_0$ and $\mathbb{S}_1$ are Kripke models in coalgebraic shape; write $\sigma_i(s) = (\lambda_i(s), R_i[s])$, where $\lambda_i(s)$ is the collection of proposition letters true at s in $\mathbb{S}_i$, and $R_i[s]$ is the successor set of s in $\mathbb{S}_i$, as in the examples 143 and 149. Now consider an arbitrary relation $B \subseteq S_0 \times S_1$. It is a very instructive exercise to check that B is a bisimulation in the coalgebraic sense if and only if it is a bisimulation in the sense of Kripke models. Recall that the latter property means that for any pair $(s_0, s_1) \in B$:

(atom) $p \in \lambda_0(s)$ iff $p \in \lambda_1(s)$, for all $p \in \mathsf{Prop}$;

(forth) for all $t_0 \in R_0[s_0]$ there is some $t_1 \in R_1[s_1]$ with $(t_0, t_1) \in B$;

(back) for all $t_1 \in R_1[s_1]$ there is some $t_0 \in R_0[s_0]$ with $(t_1, t_0) \in B$.

One way to prove this equivalence uses the fact that bounded morphisms coincide with coalgebra morphisms, cf. Example 149. Details are left to the reader.

EXAMPLE 169. Recall from Example 142 that deterministic automata over an alphabet C can be represented as $2 \times \mathcal{I}^C$-coalgebras. Now let $\mathbb{A} = (A, o, \nu)$ and $\mathbb{A}' = (A', o', \nu')$ be two such automata. We leave it for the reader to verify that $B \subseteq A \times A'$ is a bisimulation between $\mathbb{A}$ and $\mathbb{A}'$ iff every pair $(s, s') \in B$ satisfies (i) $o(s) = o'(s')$ and (ii) $(\nu(s)(c), \nu'(s')(c)) \in B$ for every $c \in C$. In this case it is easy to see that bisimilar states are also behaviorally equivalent.

EXAMPLE 170. For an arbitrary set functor Ω, it is easy to see that for any coalgebra $\mathbb{S}$, the diagonal relation Δ_S is a bisimulation equivalence on $\mathbb{S}$. Furthermore, the converse of a bisimulation is again a bisimulation. However, the collection of bisimulations is not in general closed under taking relational composition.

Finally, homomorphisms can be seen as functional bisimulations. To be more precise, let $f : S_0 \to S_1$ be a function between the carriers of two Ω-coalgebras $\mathbb{S}_0$ and $\mathbb{S}_1$. Recall that the *graph* of f is the relation $G_f := \{(s, f(s)) \mid s \in S\}$. Then it holds that

$$f \text{ is a coalgebraic homomorphism iff its graph is a bisimulation.} \tag{42}$$

In order to see why this is so, first suppose that $G_f : \mathbb{S}_0 \leftrightarroweq \mathbb{S}_1$. Since the projection map $\pi_0 : G_f \to S_0$ is a bijective homomorphism, its inverse π_0^{-1} is also a homomorphism. But then $f = \pi_1 \circ \pi_0^{-1}$, as the composition of two homomorphisms, is also a homomorphism. For the other direction, suppose that f is a homomorphism; then it is straightforward

to verify that the map $(\Omega\pi_0)^{-1} \circ \sigma \circ \pi_0$ equips the set G_f with the required coalgebraic structure.

Bisimulations admit an elegant alternative characterization which involves the notion of *relation lifting*. As an example, consider the power set functor $\mathcal{P}$. Recall that $B \subseteq S_0 \times S_1$ is a bisimulation between $\mathbb{S}_0 = \langle S_0, R_0[\cdot]\rangle$ and $\mathbb{S}_1 = \langle S_1, R_1[\cdot]\rangle$ iff B satisfies the conditions *(back)* and *(forth)* of Example 168. Now suppose that we define, for an arbitrary relation $R \subseteq S_0 \times S_1$, the relation $\overline{\mathcal{P}}(R) \subseteq \mathcal{P}(S_0) \times \mathcal{P}(S_1)$ by putting

$$\overline{\mathcal{P}}(R) := \{(Q_0, Q_1) \mid \forall q_0 \in Q_0\, \exists q_1 \in Q_1.\, (q_0, q_1) \in R \text{ and } \forall q_1 \in Q_1\, \exists q_0 \in Q_0.\, (q_0, q_1) \in R\}. \tag{43}$$

In other words, we *lift* the relation R to the level of the power sets of S_0 and S_1. The definition of a bisimulation between $\mathcal{P}$-coalgebras can now be nicely characterized as follows:

$$B : \mathbb{S}_0 \leftrightarroweq \mathbb{S}_1 \text{ iff } (R_0[s_0], R_1[s_1]) \in \overline{\mathcal{P}}(B) \text{ for all } (s_0, s_1) \in B.$$

This nice way of characterizing bisimulation via relation lifting is not limited to the power set functor — it applies in fact to *every* set functor.

DEFINITION 171. Let $\mathbb{S}_0$ and $\mathbb{S}_1$ be two coalgebras for some set functor Ω. Given a relation $R \subseteq S_0 \times S_1$, consider the following diagram, where $\pi_i : R \to S_i$ and $p_i : \Omega S_0 \times \Omega S_1 \to \Omega S_i$ denote the projection maps.

$$\begin{tikzcd}
S_0 \arrow[d, "\sigma_0"'] & R \arrow[l, "\pi_0"'] \arrow[r, "\pi_1"] & S_1 \arrow[d, "\sigma_1"] \\
\Omega S_0 & \Omega R \arrow[l, "\Omega\pi_0"'] \arrow[r, "\Omega\pi_1"] \arrow[d, dotted, "\rho_R"'] & \Omega S_1 \\
 & \Omega S_0 \times \Omega S_1 \arrow[ul, "p_0"] \arrow[ur, "p_1"'] &
\end{tikzcd}$$

It follows from the category theoretic properties of the product $\Omega S_0 \times \Omega S_1$ that there is a unique map $\rho_R = \langle \Omega\pi_0, \Omega\pi_1\rangle$ from ΩR to $\Omega S_0 \times \Omega S_1$ such that $p_i \circ \rho_R = \Omega\pi_i$ for $i = 0, 1$. We define the *relation lifting* of R as the relation

$$\overline{\Omega} R := \{((\Omega\pi_0)(u), (\Omega\pi_1)(u)) \mid u \in \Omega R\}, \tag{44}$$

that is, $\overline{\Omega} R$ is the image of ΩR under ρ_R.

The results listed in the following theorem, which summarize the most important properties of bisimulations, basically date back to Aczel & Mendler [3].

THEOREM 172. *Let $\mathbb{S}_0$ and $\mathbb{S}_1$ be two coalgebras for some set functor Ω.*

1. *$B : \mathbb{S}_0 \leftrightarroweq \mathbb{S}_1$ iff $(\sigma_0(s_0), \sigma_1(s_1)) \in \overline{\Omega}(B)$ for all $(s_0, s_1) \in B$.*

2. *The collection of bisimulations between $\mathbb{S}_0$ and $\mathbb{S}_1$ forms a complete lattice under the inclusion order, with joins given by unions.*

3. *The bisimilarity relation $\leftrightarroweq$ is the largest bisimulation between $\mathbb{S}_0$ and $\mathbb{S}_1$.*

Proof. The first part of the theorem is an almost immediate consequence of the definitions, so we leave the details to the reader.

The crucial observation in the proof of the other two parts is that

$$\overline{\Omega} : \mathcal{P}(S_0 \times S_1) \to \mathcal{P}(\Omega S_0 \times \Omega S_1) \text{ is a monotone operation.} \tag{45}$$

For a proof, let $R \subseteq R'$ be two relations between S_0 and S_1, with $\iota : R \to R'$ denoting the inclusion map. By definition of $\overline{\Omega}$, we may without loss of generality represent an arbitrary element of $\overline{\Omega}(R)$ as a pair $\rho_R(u) = ((\Omega\pi_0)(u), (\Omega\pi_1)(u))$ for some $u \in \Omega R$. Define $u' := (\Omega\iota)(u)$, then u' belongs to $\Omega R'$, and for each i we find that $(\Omega\pi'_i)(u') = (\Omega\pi'_i \circ \Omega\iota)(u) = (\Omega(\pi'_i \circ \iota)(u) = (\Omega\pi_i)(u)$. That is, $\rho_R(u) = \rho_{R'}(u')$, which shows that $\rho_R(u)$ belongs to $\overline{\Omega}R'$. This proves (45).

Now for the proof of part 2, recall that a partial order is a complete lattice if it closed under arbitrary joins. Hence, it suffices to prove that the union B of a collection $\{B_j \mid j \in J\}$ of bisimulations is again a bisimulation. Take an arbitrary pair $(s_0, s_1) \in B$. Then (s_0, s_1) belongs to B_j for some $j \in J$. Hence, by part 1, we find (s_0, s_1) in $\overline{\Omega}(B_j)$, so $(s_0, s_1) \in \overline{\Omega}(B)$ by the monotonicity of $\overline{\Omega}$. But then B is a bisimulation by part 1.

Finally, for part 3, note that it is an immediate consequence of part 2 that $\leftrightarroweq$, being the union of all bisimulations between $\mathbb{S}_0$ and $\mathbb{S}_1$, is a bisimulation itself. Hence, by definition, it is the greatest bisimulation between $\mathbb{S}_0$ and $\mathbb{S}_1$. In fact, it follows by the Knaster-Tarski theorem (on fixed points of monotone operations on complete lattices), that $\leftrightarroweq$ is in fact the greatest fixed point of the map $\Lambda : R \mapsto \{(s_0, s_1) \mid (\sigma_0(s_0), \sigma_1(s_1)) \in \overline{\Omega}(R)\}$. ❑

In the case of Kripke polynomial functors, relation lifting can be characterized using *induction* on the construction of the functor, cf. Jacobs [63].

PROPOSITION 173. *Let S and S' be two sets, and $R \subseteq S \times S'$ a binary relation between S and S'. Then the following induction defines the relation lifting $\overline{K}(R) \subseteq KS \times KS'$, for each Kripke polynomial functor K:*

$$\begin{array}{rcl}
\overline{\mathcal{I}}(R) & := & R, \\
\overline{C}(R) & := & \Delta_C, \\
\overline{K_0 \times K_1}(R) & := & \{((x_0, x_1), (x'_0, x'_1)) \mid (x_0, x'_0) \in \overline{K_0}(R) \text{ and } (x_1, x'_1) \in \overline{K_1}(R)\}, \\
\overline{K_0 + K_1}(R) & := & \{(\kappa_0 x_0, \kappa_0 x'_0) \mid (x_0, x'_0) \in \overline{K_0}(R)\} \cup \{(\kappa_1 x_1, \kappa_1 x'_1) \mid (x_1, x'_1) \in \overline{K_1}(R)\}, \\
\overline{K^D}(R) & := & \{(f, f') \mid (f(d), f'(d)) \in \overline{K}(R) \text{ for all } d \in D\}, \\
\overline{\mathcal{P}K}(R) & := & \{(Q, Q') \mid \forall q \in Q\, \exists q' \in Q'.\, (q, q') \in \overline{K}(R) \text{ and} \\
& & \qquad \forall q' \in Q'\, \exists q \in Q.\, (q, q') \in \overline{K}(R)\}.
\end{array}$$

Now that we have defined these two notions of equivalence between coalgebras, the obvious question is how they relate to each other. One direction is clear: bisimilarity is a sufficient condition for behavioral equivalence.

PROPOSITION 174. *Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ be some functor, and let s_0 and s_1 be states of the Ω-coalgebras $\mathbb{S}_0$ and $\mathbb{S}_1$, respectively. Then $\mathbb{S}_0, s_0 \leftrightarroweq \mathbb{S}_1, s_1$ implies $\mathbb{S}_0, s_0 \equiv_\Omega \mathbb{S}_1, s_1$.*

Proof. The proof of this proposition is, in the general case, similar to the one of Theorem 177 below (with an application of *pushouts* instead of pullbacks), so we omit details.

In the special case that Ω admits a final coalgebra, a very simple proof obtains. Assume that $B : \mathbb{S}_0 \leftrightarroweq \mathbb{S}_1$, and let $\beta : B \to \Omega B$ be a coalgebra map witnessing this. It follows from the definitions that both $!_{\mathbb{S}_0} \circ \pi_0$ and $!_{\mathbb{S}_1} \circ \pi_1$ are coalgebraic homomorphisms from $\langle B, \beta \rangle$ to the final coalgebra, so from finality it follows that $!_{\mathbb{S}_0} \circ \pi_0 = !_{\mathbb{S}_1} \circ \pi_1$. From this it is immediate that $B \subseteq \equiv_\Omega$. Hence in particular, since $\leftrightarroweq$ is itself a bisimulation, we see that $\leftrightarroweq \subseteq \equiv_\Omega$. ❑

In general however, bisimilarity is a strictly stronger notion than behavioral equivalence. For instance, the two notions do not coincide in the case of monotone neighborhood frames (coalgebras for the functor $\mathcal{U}_{\breve{\mathcal{P}}}$ of Example 144). The reader is referred to Hansen & Kupke [55] for details. Here we just mention that behavioral equivalence, which for monotone neighborhood frames is formulated exactly like the *topobisimilarity* defined in Chapter 1 of this volume, seems to be the more natural notion.

For a constraint on the functor that guarantees the two notions to coincide, consider the following.

DEFINITION 175. A *weak pullback* of two arrows $f_0 : A_0 \to B$, $f_1 : A_1 \to B$ in a category C is a pair of arrows $p_0 : W \to A_0$, $p_1 : W \to A_1$ such that (i) $f_0 \circ p_0 = f_1 \circ p_1$, while (ii) for every pair $p_0' : W' \to A_0$, $p_1' : W' \to A_1$ that also satisfies $f_0 \circ p_0' = f_1 \circ p_1'$, there is a mediating arrow $w' : W' \to W$ such that $p_0 \circ w' = p_0'$ and $p_1 \circ w' = p_1'$.
A functor $\Omega : \mathsf{C} \to \mathsf{C}'$ *preserves weak pullbacks* if for any weak pullback (p_0, p_1) of any (f_0, f_1) in C, the pair $(\Omega p_0, \Omega p_1)$ is a weak pullback of $(\Omega f_0, \Omega f_1)$ in C'.

$$\begin{tikzcd}
& A_0 \arrow[r, "f_0"] & B \\
& W \arrow[u, "p_0"] \arrow[r, "p_1"] & A_1 \arrow[u, "f_1"'] \\
W' \arrow[uur, "p_0'"] \arrow[urr, "p_1'"'] \arrow[ur, dotted]
\end{tikzcd}$$

Note that the mediating arrow w' need not be unique: adding this requirement to the definition would give the more familiar, and stronger, notion of a *pullback*. The category Set has pullbacks: for $f_0 : A_0 \to B$ and $f_1 : A_1 \to B$, we can take the projections to A_0 and A_1 from the set $pb(f_0, f_1) := \{(a_0, a_1) \in A_0 \times A_1 \mid f_0(a_0) = f_1(a_1)\}$.

Many but not all endofunctors on Set in fact preserve weak pullbacks.

PROPOSITION 176. *All polynomial functors preserve pullbacks, and all Kripke polynomial functors preserve weak pullbacks.*

This prima facie rather exotic property is of great importance in the theory of universal coalgebra. The main reason for this is that Ω preserving weak pullbacks is equivalent to $\overline{\Omega}$ commuting with relational composition, that is, satisfying $\overline{\Omega}(R \circ R') = \overline{\Omega}(R) \circ \overline{\Omega}(R')$. In fact, one may show that any set functor Ω preserves weak pullbacks if and only if $\overline{\Omega}$ is an endofunctor on the category with sets as objects and binary relations as arrows. This result is often attributed to Carboni, Kelly & Wood [19], but it already follows from earlier work by Trnková [104, 105] and Barr [10]. In any case, the importance of the notion in the theory of coalgebras lies in the results from Rutten [97] that are given in the next theorem.

THEOREM 177. *Assume that the functor* $\Omega : \mathsf{Set} \to \mathsf{Set}$ *preserves weak pullbacks. Then the collection of bisimulations is closed under taking relational composition, and the notions of bisimilarity and behavioral equivalence coincide.*

Proof. We leave the proof of the first statement as an exercise for the reader, and concentrate on the second statement. Let s_0 and s_1 be states of the Ω-coalgebras $\mathbb{S}_0$ and $\mathbb{S}_1$, respectively. We need to prove that $\mathbb{S}_0, s_0 \leftrightarroweq \mathbb{S}_1, s_1$ iff $\mathbb{S}_0, s_0 \equiv_\Omega \mathbb{S}_1, s_1$. Because of Proposition 174 it suffices to prove the direction from right to left.

Let $f_0 : \mathbb{S}_0 \to \mathbb{X}$ and $f_1 : \mathbb{S}_1 \to \mathbb{X}$ be two homomorphisms such that $f_0(s_0) = f_1(s_1)$. Then in Set, the set $B := \{(s_0, s_1) \in S_0 \times S_1 \mid f_0(s_0) = f_1(s_1)\}$, together with the projection functions $\pi_0 : B \to S_0$ and $\pi_1 : B \to S_1$ constitutes a pullback of f_0 and f_1, cf. the square in the foreground of the picture. Because Ω preserves weak pullbacks, the diagram in the background of the picture is a weak pullback diagram in Set.

Now consider the two arrows $\sigma_i \circ \pi_i : B \to \Omega(S_i)$. First observe that $\Omega f_i \circ \sigma_i = \xi \circ f_i$ for each i, because each f_i is a coalgebra homomorphism. Hence, chasing the diagram we find that

$$\Omega f_0 \circ \sigma_0 \circ \pi_0 = \xi \circ f_0 \circ \pi_0 = \xi \circ f_1 \circ \pi_1 = \Omega f_1 \circ \sigma_1 \circ \pi_1.$$

Since $\Omega\pi_0$ and $\Omega\pi_1$ form a weak pullback of Ωf_0 and Ωf_1, this implies the existence of a mediating function $\beta : B \to \Omega B$ such that $\Omega\pi_i \circ \beta = \sigma_i \circ \pi_1$. In other words, $\mathbb{B} := \langle B, \beta \rangle$ is an Ω-coalgebra, and the projection maps π_0 and π_1 are homomorphisms from $\mathbb{B}$ to $\mathbb{S}_0$ and $\mathbb{S}_1$, respectively.

$$\begin{tikzcd}
 & \Omega S_0 \arrow[rr, "\Omega f_0"] & & \Omega X \\
S_0 \arrow[ur, "\sigma_0"] \arrow[rr, "f_0"] & & X \arrow[ur, "\xi"'] & \\
 & \Omega B \arrow[uu, "\Omega\pi_0"] \arrow[rr, "\Omega\pi_1"'] & & \Omega S_1 \arrow[uu, "\Omega f_1"'] \\
B \arrow[uu, "\pi_0"] \arrow[ur, dotted, "\beta"'] \arrow[rr, "\pi_1"'] & & S_1 \arrow[uu, "f_1"'] \arrow[ur, "\sigma_1"'] &
\end{tikzcd}$$

❑

We finish the section with a brief discussion of *coinduction* as a coalgebraic proof principle. This principle states, for a system $\mathbb{S}$, that $\leftrightarroweq \subseteq \Delta_S$; or equivalently, that every bisimulation is a subset of the diagonal Δ_S. The importance of this principle is that, when applicable to $\mathbb{S}$, in order to prove the identity of two states in $\mathbb{S}$, it suffices to show that they are linked by some bisimulation. It is not hard to prove that *final coalgebras*, if existing, satisfy the principle of coinduction. This principle has surprisingly powerful applications. For instance, since the class of non-well-founded sets is (in $\mathsf{Coalg}(\mathcal{P}^+)$, cf. Remark 161) the final coalgebra of the power set functor, bisimilarity may serve as a notion of identity between sets, see Aczel [2]. As a second example, Rutten [96] is a presentation of the theory of deterministic automata and (regular) languages in which coinduction on the final coalgebra of Example 155 is the basic proof principle.

12 COVARIETIES

What is the coalgebraic analog of a variety? In other words, what are natural closure operations on classes of coalgebras? We start with homomorphic images.

DEFINITION 178. Let Ω be some endofunctor on Set. If $\varphi : \mathbb{A} \to \mathbb{B}$ is a surjective homomorphism between the Ω-coalgebras $\mathbb{A}$ and $\mathbb{B}$, then we say that $\mathbb{B}$ is a *homomorphic image* of $\mathbb{A}$.

In universal algebra, one finds a one-one correspondence between homomorphic images and congruences. Something similar applies here, but the analogy is perfect only in the case of functors that preserve weak pullbacks.

PROPOSITION 179. *Let $\mathbb{S} = \langle S, \sigma \rangle$ be an Ω-coalgebra for some set functor Ω. Then*

1. *Given a bisimulation equivalence E on $\mathbb{S}$, there is a unique coalgebra structure σ' on S/E such that the quotient map $\nu : S \to S/E$ is a homomorphism.*
2. *If Ω preserves weak pullbacks, then $\ker(\varphi)$ is a bisimulation equivalence for any homomorphism $\varphi : \mathbb{S} \to \mathbb{S}'$.*

Proof. For part 1, the coalgebra map σ' can be defined by putting $\sigma'([s]_E) := (\Omega\nu)\circ\sigma(s)$. Further proof details can be found in Rutten [97]. For the second part of the proposition, observe that $\ker(\varphi)$ is the relational composition of the graph of φ with its converse. The result then follows from Theorem 177. ❑

The next class operation that we consider is that of taking subcoalgebras.

DEFINITION 180. Let $\mathbb{A} = \langle A, \alpha \rangle$ and $\mathbb{S} = \langle S, \sigma \rangle$ be two Ω-coalgebras, such that S is a subset of A. If the inclusion map $\iota : S \to A$ is a homomorphism from $\langle S, \sigma \rangle$ to $\langle A, \alpha \rangle$, then we say that S is *open* with respect to $\mathbb{A}$, and we call the structure $\langle S, \alpha{\restriction}_S \rangle$ a *subcoalgebra* of $\mathbb{A}$.

Interestingly enough, the transition map of a subcoalgebra is completely determined by the underlying open set:

PROPOSITION 181. *Let $\mathbb{S}_0 = \langle S, \sigma_0 \rangle$ and $\mathbb{S}_1 = \langle S, \sigma_1 \rangle$ be two subcoalgebras of the coalgebra $\mathbb{A}$. Then $\sigma_0 = \sigma_1$.*

Proof. The case of S being empty is trivial, so suppose otherwise. Then from the assumption that $\mathbb{S}_0$ and $\mathbb{S}_1$ are subcoalgebras of $\mathbb{A}$, we may infer that $(\Omega\iota) \circ \sigma_0 = \alpha \circ \iota = (\Omega\iota) \circ \sigma_1$, where ι is the inclusion map of S into A. It follows from the functoriality of Ω that $\Omega\iota$ is an injection, so that we may conclude that $\sigma_0 = \sigma_1$. ❑

Some further observations concerning subcoalgebras are in order. First of all, the topological terminology is justified by the following proposition.

PROPOSITION 182. *Given a coalgebra $\mathbb{A}$ for some set functor Ω, the collection $\tau_{\mathbb{A}}$ of $\mathbb{A}$-open sets forms a topology.*

Proof. Closure of $\tau_{\mathbb{A}}$ under taking (arbitrary) unions follows from Theorem 172, together with the observation that

$$S \subseteq A \text{ is open with respect to } \mathbb{A} \text{ iff } \Delta_S \text{ is a bisimulation on } \mathbb{A}, \tag{46}$$

which in its turn is an immediate consequence of (42). We skip the proof of the fact that the *intersection* of two opens is open, since it requires a little more work. We refer the reader to Gumm & Schröder [54] for the details. ❑

It follows from the Proposition above that, given a subset S of (the carrier of) a coalgebra $\mathbb{A}$, there is a largest subcoalgebra of $\mathbb{A}$ (of which the carrier is) contained in S: Its universe is given as the union of all open subsets of S. It also follows from Proposition 182 that the collection $\tau_{\mathbb{A}}$ of open subsets of A forms a *complete* lattice under set inclusion. Hence, given a subset S of A, there is an open set $U \subseteq A$ which is the *meet* of the collection $\{Q \in \tau_{\mathbb{A}} \mid S \subseteq Q\}$. However, there is no guarantee that U is

also the *intersection* of this collection, or, indeed, that S is actually a subset of U. Thus we may not in general speak of the smallest subcoalgebra containing a given subset, as the following example from Gumm [50] witnesses.

EXAMPLE 183. Consider the standard Euclidean topology on the real numbers, seen as a coalgebra for the filter functor $\mathcal{F}_{\breve{\mathcal{P}}}$, cf. Example 144. One can show, that a set S of reals is open in the topological sense iff it is open in the sense of Definition 180 — in fact, this holds for any topology. Now take an arbitrary point r in $\mathbb{R}$. Obviously, we have that the *meet* of all open neighborhoods containing r is the empty set.

Before we turn to further coalgebraic constructions, consider the following natural link between homomorphic images and subcoalgebras.

PROPOSITION 184. *Given a coalgebraic homomorphism $\varphi : \mathbb{A} \to \mathbb{B}$, there is a (unique) subcoalgebra $\varphi[\mathbb{A}]$ of $\mathbb{B}$ such that $\varphi : \mathbb{A} \to \varphi[\mathbb{A}]$ is a surjective homomorphism.*

Proof. For a proof of this proposition, let $S := \varphi[A]$ be the (set-theoretic) image of A under φ, and let $f : S \to A$ be a right inverse of φ, that is, $\varphi(f(s)) = s$ for all $s \in S$. Now define $\sigma : S \to \Omega S$ by $\sigma := \Omega\varphi \circ \alpha \circ f$. It can be shown that the resulting structure $\mathbb{S}$ is always a subcoalgebra of $\mathbb{B}$, and that $\varphi : \mathbb{A} \to \mathbb{S}$ is a surjective homomorphism; for details the reader is referred to Rutten [97]. ❑

Our last example of a coalgebraic construction concerns the straightforward generalization of the disjoint union of Kripke models and frames. The idea is as follows. Recall that in Set, a concrete representation of the coproduct of a collection $\{A_i \mid i \in I\}$ of sets is given by the disjoint union $\biguplus_I A_i$, together with the inclusions/embeddings $e_i : A_i \to \biguplus_I A_i$. Hence, the defining property of coproducts provides the key ingredient of the coalgebraic notion of a coproduct, or sum of a family of coalgebras.

DEFINITION 185. The *sum* $\coprod_I \mathbb{A}_i$ of a family $\{\mathbb{A}_i \mid i \in I\}$ of coalgebras for some set functor Ω, is defined by endowing the disjoint union $A := \biguplus_I A_i$ with the unique map $\alpha : A \to \Omega A$ which turns all embeddings $e_i : A_i \to A$ into homomorphisms.

We have now gathered all the basic class operations needed to define the notion of a covariety, which was introduced in Rutten [97] as the natural dual of a variety in universal algebra.

DEFINITION 186. Let Ω be some endofunctor on Set. A class of Ω-coalgebras is a *covariety* if it closed under taking homomorphic images, subcoalgebras and sums. The smallest covariety containing a class K of Ω-coalgebras is called the covariety *generated* by K, notation: $\mathsf{Covar}(\mathsf{K})$.

As in the case of universal algebra, in order to obtain a more succinct characterization of the covariety generated by a class of coalgebras, one may develop a calculus of class operations.

DEFINITION 187. Let H, S and Σ denote the class operations of taking (isomorphic copies of) homomorphic images, subcoalgebras, and sums, respectively.

On the basis of these (and other) operations one may investigate the validity of 'inequalities' like $\mathsf{HS} \leq \mathsf{SH}$ (meaning that $\mathsf{HS}(\mathsf{K}) \subseteq \mathsf{SH}(\mathsf{K})$ for all classes K of coalgebras). Results of these kind lead to the following coalgebraic analog of Tarski's HSP-theorem in universal algebra, due to Gumm & Schröder [53].

THEOREM 188. *Let* K *be a class of* Ω*-coalgebras for some set functor* Ω*. Then*

$$\mathsf{Covar}(\mathsf{K}) = \mathsf{SH\Sigma}(\mathsf{K}).$$

Proof. It is straightforward to prove the theorem on the basis of the idempotency of the class operations H, S and Σ, together with the following three 'inequalities': $\mathsf{HS} \leq \mathsf{SH}$, $\Sigma\mathsf{S} \leq \mathsf{S}\Sigma$, and $\Sigma\mathsf{H} \leq \mathsf{H}\Sigma$. For proofs of these (and more) inequalities, the reader is referred to Gumm & Schröder [53]. ❑

As in the case of varieties, one may wonder about the basic building blocks of varieties. Dualizing the notion of subdirect irreducibility, we arrive at the following definition. It uses the notion of a conjunct sum, which is known, in the case of Kripke frames, under the name of *bounded union.*

DEFINITION 189. Let $\mathbb{A}$ be some Ω-coalgebra for some set functor Ω. A *conjunct representation* $\mathbb{A}$ by a family $\{\mathbb{A}_i \mid i \in I\}$ of coalgebras is a family of embeddings $\{e_i : \mathbb{A}_i \to \mathbb{A} \mid i \in I\}$ such that $A = \bigcup_{i \in I} e_i[A_i]$. In this case we call $\mathbb{A}$ a *conjunct sum* of the $\mathbb{A}_i$. A coalgebra $\mathbb{A}$ is called *conjunctly irreducible* if each of its conjunct representations is trivial in the sense that one of the embeddings is an isomorphism.

Covarieties are easily seen to be closed under taking conjunct sums — we will use this fact without further notice.

Given the results on dualizing the notion of subdirect irreducibility in section 5, in particular, Theorem 68, one would expect that conjunct irreducibility can be explained in terms of roots. Call a state s of a system $\mathbb{S}$ a *root* of $\mathbb{S}$ if $\mathbb{S}$ itself is the only subcoalgebra of $\mathbb{S}$ that contains s. It is then fairly easy to prove that a coalgebra is conjunctly irreducible if and only if it has a root. However, Gumm [50] proves that there is no analog of Birkhoff's s.i. theorem here, at least not for an arbitrary functor. For instance, expanding Example 183, one easily shows that a topological coalgebra will generally not be a conjunct sum of rooted coalgebras.

13 MODAL LOGIC AND COALGEBRAS

If coalgebras are mathematical structures that represent the essence of dynamics, then there is an obvious need for logics to represent and reason about properties of such structures. This is of particular importance for computer scientists who are interested in the formal specification and verification of the behavior of a system. The *kind* of properties that one wants to describe formally may differ from one application to another, but it seems natural to restrict attention to properties that are invariant under behavioral equivalence. Moss [11, 86] was the first to realize that such properties can be conveniently formalized in a version of *modal logic*, properly generalized from Kripke structures to systems for an arbitrary set functor. This connection between modal logic and coalgebra has provided a quite active research area. At the time of writing, quite a few proposals for coalgebraic modal logics are around; most of them are roughly based on one of the approaches to be discussed in this section.

We start with Moss' original approach, which is also the most general. In order to introduce his formalism, we first put ordinary modal logic in a slightly different perspective by introducing a new connective ∇. The *meaning* of this modality, which takes a

set of formulas as its argument, can be summarized by presenting the formula $\nabla\Phi$, with Φ a set of formulas, as the following abbreviation:

$$\nabla\Phi := \Box \bigvee \Phi \wedge \bigwedge \Diamond\Phi, \tag{47}$$

where $\Diamond\Phi$ denotes the set $\{\Diamond\varphi \mid \varphi \in \Phi\}$, and $\bigvee$ and $\bigwedge$ denote disjunction and conjunction. We do not want to exclude the possibility that Φ is an infinite set — coalgebraic logic is generally of an infinitary nature. The operator ∇ pops up in a number of areas in modal logic, cf. for instance the characteristic formulas of Chapter 5. We may also decide to treat this ∇ as a *primitive* connective. As long as we keep $\vee$ and $\top$ in our language, both the standard diamond and box connective are definable in terms of ∇, since we have the following equivalences:

$$\begin{array}{rcl} \Diamond\varphi & \equiv & \nabla\{\varphi, \top\}, \\ \Box\varphi & \equiv & \nabla\varnothing \vee \nabla\{\varphi\}, \end{array}$$

so that we may in fact *replace* the diamond and box with this new modality.

Spelling out the truth definition of $\nabla\Phi$, we see that it can in fact be expressed in terms of the *relation lifting* that we defined in section 11. For, let $\mathbb{S} = \langle S, \lambda, R[\cdot]\rangle$ be a modal model in coalgebraic shape. Then it is straightforward to verify that $\mathbb{S}, s \Vdash \nabla\Phi$ if and only if the pair $(R[s], \Phi)$ belongs to the relation lifting $\overline{\mathcal{P}}(\Vdash_{\mathbb{S}})$ of the satisfaction relation $\Vdash_{\mathbb{S}} \subseteq S \times \Phi$: Every $\varphi \in \Phi$ must hold at some successor $t \in R[s]$, and at every successor t of s some $\varphi \in \Phi$ must hold, see (43). This fundamental insight paves the way for Moss' development of *coalgebraic logic*, in which the same principle is applied to an arbitrary (but fixed) set functor Ω. Basically, the idea is to have

$$\mathbb{S}, s \Vdash_{\mathbb{S}} \nabla P \text{ iff } (P, \sigma(s)) \in \overline{\Omega}(\Vdash_{\mathbb{S}}).$$

Note that in this perspective, the satisfaction relation is much like a bisimulation between a language and a coalgebra; this observation was first made and exploited in Baltag [8].

In order to provide a more precise definition, recall from Remark 161 that we may uniquely extend Ω to a set based endofunctor Ω^+ on the category SET that has classes as objects, and set-continuous functions as arrows. For convenience, we follow Moss [86] in that we confine our attention to *standard* set functors, that is, functors that map inclusions to inclusions.

DEFINITION 190. Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ be a standard set functor that preserves weak pullbacks. Then $\mathcal{L}_\Omega$, the language of *coalgebraic formulas for* Ω, is defined as the least class C such that (i) $\bigwedge \Phi \in \mathcal{L}_\Omega$ if $\Phi \subseteq \mathcal{L}_\Omega$ is a *set* of formulas, and (ii) $\nabla P \in \mathcal{L}_\Omega$ for any $P \in \Omega^+(\mathcal{L}_\Omega)$.

Categorically, $\langle \mathcal{L}_\Omega, \bigwedge, \nabla\rangle$ can be characterized as the *initial algebra* of the functor $(\mathcal{P} + \Omega)^+$. This explains our move to the category SET: if we want to guarantee the *existence* of such a structure, for reasons similar as given in the discussion following Proposition 158, we need to allow class-based algebras.

DEFINITION 191. Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ preserve weak pullbacks. Given an Ω-coalgebra $\mathbb{S} = \langle S, \sigma\rangle$, define $\Vdash_{\mathbb{S}} \subseteq S \times \mathcal{L}_\Omega$ as the least relation satisfying

$$\begin{array}{rcl} s \Vdash_{\mathbb{S}} \bigwedge \Phi & \text{if} & s \Vdash_{\mathbb{S}} \varphi \text{ for all } \varphi \in \Phi, \\ s \Vdash_{\mathbb{S}} \nabla P & \text{if} & (P, \sigma(s)) \in \overline{\Omega}(W) \text{ for some set } W \subseteq \Vdash_{\mathbb{S}}. \end{array}$$

EXAMPLE 192. Consider the functor $\mathcal{P}\mathsf{Prop} \times \mathcal{P}$ of Kripke models. Unraveling the definitions, we find that an arbitrary element of $\Omega^+(\mathcal{L}_\Omega)$ must be of the form (A, Φ) with $A \subseteq \mathsf{Prop}$ a set of proposition letters, and $\Phi \subseteq \mathcal{L}_\Omega$ a set of formulas. It is not hard to verify that

$$\mathbb{S}, s \Vdash \nabla(A, \Phi) \text{ iff } \mathbb{S}, s \Vdash \bigwedge A \wedge \bigwedge \neg(\mathsf{Prop} \setminus A) \wedge \Box \bigvee \Phi \wedge \bigwedge \Diamond\Phi,$$

where $\bigwedge \neg(\mathsf{Prop} \setminus A)$ denotes the formula $\bigwedge\{\neg p \mid p \in P \setminus A\}$. It is instructive to observe the difference between this and (47) which displays an arbitrary ∇-formula for the functor $\mathcal{P}$ of Kripke frames as opposed to models.

EXAMPLE 193. For another example, an arbitrary element of the class $\Omega^+(\mathcal{L}_\Omega)$, where Ω is now the functor $\mathcal{I} \times \mathcal{I}$, must be a *pair* of formulas, say, (φ_0, φ_1). Clearly then we have

$$\mathbb{S}, s \Vdash \nabla(\varphi_0, \varphi_1) \text{ iff } \mathbb{S}, \pi_0(\sigma(s)) \Vdash \varphi_0 \text{ and } \mathbb{S}, \pi_1(\sigma(s)) \Vdash \varphi_1.$$

This in fact implies that *all* formulas are true at *all* states of *all* coalgebras; in other words, in the absence of propositions, the language $\mathcal{L}_\Omega$ may be rather uninteresting.

Obviously, many variations of this language exist, or may be defined. For instance, it is easy to develop finitary versions of the language, while independently of this, one may add Boolean connectives like negation or (infinitary) disjunction. Interestingly, $\mathcal{L}_\Omega$ on its own is already powerful enough to characterize behavior. Theorem 194 below shows that it has the *Hennessy-Milner property* (cf. Chapter 5 of this volume): non-bisimilarity of two points is witnessed by some formula in the language.

THEOREM 194. *Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ preserves weak pullbacks, and let $\mathbb{S}$ and $\mathbb{S}'$ be two Ω-coalgebras. Then for any pair of states $s \in S$, $s' \in S'$:*

$$\mathbb{S}, s \leftrightarroweq \mathbb{S}', s' \textit{ iff } s \textit{ and } s' \textit{ satisfy the same } \mathcal{L}_F\textit{-formulas.}$$

Proof. The direction from left to right is proved by induction on the complexity of formulas. That is, we define Θ to be the class of formulas on which all bisimilar points in $\mathbb{S}$ and $\mathbb{S}'$ agree. Then we prove that $\Theta = \mathcal{L}_\Omega$ by showing that Θ is closed under $\bigwedge$ and ∇ (in the sense that $\bigwedge \Phi \in \Theta$ for all subsets $\Phi \subseteq \Theta$, and that $\nabla P \in \Theta$ for all $P \in \Omega(\Theta)$). We leave the fairly straightforward details as an exercise for the reader.

The proof for the other direction is analogous to that of Karp's Theorem for modal logic (see Chapter 5 of this volume), so we confine ourselves to a brief sketch here. Given an Ω-system $\mathbb{S}$, by ordinal induction we define a family $\varphi^{\mathbb{S}}_\alpha : S \to \mathcal{L}_\Omega$ as follows (we omit the superscript):

$$\begin{array}{rcl}\varphi_0(s) & := & \top \\ \varphi_{\alpha+1}(s) & := & \nabla(\Omega\varphi_\alpha)(\sigma(s)), \\ \varphi_\lambda(s) & := & \bigwedge\{\varphi_\alpha(s) \mid \alpha < \lambda\}.\end{array}$$

One approach to the proof would then be to show that the relation $\equiv_\varphi$, defined via $s \equiv_\varphi t$ if $\varphi_\alpha(s) = \varphi_\alpha(t)$ for all α, is itself a bisimulation. ❑

Moss' definition provides powerful languages, of which syntax and semantics uniformly depend on the coalgebraic signature, but his systems are not very welcoming to our intuitions on modal languages as extensions of propositional logic with diamonds and boxes

that are interpreted via accessibility relations. Baltag [8] introduces variants of Moss' language in which the connectives $\Box \bigvee \Phi$ and $\bigwedge \Diamond \Phi$ of (47) are (separately) generalized from Kripke frames to arbitrary functors, but also his formalism is far too abstract for practical purposes. It therefore seems worthwhile to develop more 'concrete' and practical alternatives to $\mathcal{L}_\Omega$.

In the case of Kripke polynomial functors, the concrete, inductive definition of the functor allows for more down to earth modal languages, as was first observed by Kurz [77]. Here we present a formalism that was introduced in Rößiger [95], and studied by Jacobs [62]. From the perspective of modal logic, its only non-standard feature is that both its syntax and semantics are *sorted* by the set $IngK$ of ingredient functors of K.

DEFINITION 195. Fix a Kripke polynomial functor K. We define the language $Fma_K = \bigcup_{\Lambda \in Ing(K)} Fma_K(\Lambda)$ of *K-sorted modal formulas*, by the following induction. (All functors appearing in the definition below are supposed to be ingredient functors of K.)

- $\bot \in Fma_K(\Lambda)$ for every $\Lambda \in Ing(K)$;
- if $\varphi, \psi \in Fma_K(\Lambda)$ then $\neg\varphi, \varphi \vee \psi \in Fma_K(\Lambda)$;
- if $c \in C$ then $c \in Fma_K(C)$;
- if $\varphi \in Fma_K(\Lambda_i)$ then $\Diamond_{\kappa_i}\varphi \in Fma_K(\Lambda_0 + \Lambda_1)$;
- if $\varphi \in Fma_K(\Lambda_i)$ then $\Diamond_{\pi_i}\varphi \in Fma_K(\Lambda_0 \times \Lambda_1)$;
- if $\varphi \in Fma_K(\Lambda)$ then $\Diamond_d\varphi \in Fma_K(\Lambda^D)$ for all $d \in D$;
- if $\varphi \in Fma_K(\Lambda)$ then $\Diamond_\ni\varphi \in Fma_K(\mathcal{P}\Lambda)$;
- if $\varphi \in Fma_K(K)$ then $\odot\varphi \in Fma_K(\mathcal{I})$.

We say that φ is *of sort* Λ if $\varphi \in Fma_K(\Lambda)$ — note that this sort need not be unique.

How do we interpret these formulas in coalgebras? Intuitively, with each K-coalgebra $\mathbb{S}$, we associate a multi-sorted frame based on the set $\bigcup_{\Lambda \in Ing(K)} \Lambda(S)$. The accessibility relations of this frame (which we will not make explicit) are completely determined by the shape of the functor. For instance, to link the set $(\Lambda_0 + \Lambda_1)(S)$ to $\Lambda_0(S)$, we lay down the relation $R_{\kappa_0} = \{(\kappa_0 s_0, s_0) \mid s_0 \in \Lambda_0(S)\}$. Likewise, the converse membership relation $\ni$ provides the accessibility relation from $\mathcal{P}\Lambda(S)$ to $\Lambda(S)$.

DEFINITION 196. Let $\mathbb{S} = \langle S, \sigma \rangle$ be a K-coalgebra for some Kripke polynomial functor K. By formula induction we define a sorted satisfaction relation $\Vdash = \bigcup_{\Lambda \in Ing(K)} \Vdash_\Lambda$,

with $\Vdash_\Lambda \subseteq \Lambda(S) \times Fma_K(\Lambda)$:

$$\begin{array}{rcl}
s \Vdash_\Lambda \bot & : & \text{never}, \\
s \Vdash_\Lambda \neg\varphi & \text{if} & s \not\Vdash_\Lambda \varphi \text{ (but } s \in \Lambda(S)), \\
s \Vdash_\Lambda \varphi \vee \psi & \text{if} & s \Vdash_\Lambda \varphi \text{ or } s \Vdash_\Lambda \psi, \\
s \Vdash_C c & \text{if} & s = c, \\
s \Vdash_{\Lambda_0+\Lambda_1} \Diamond_{\kappa_i}\varphi & \text{if} & s = \kappa_i(t) \text{ for some } t \in \Lambda_i(S) \text{ with } t \Vdash_{\Lambda_i} \varphi, \\
s \Vdash_{\Lambda_0\times\Lambda_1} \Diamond_{\pi_i}\varphi & \text{if} & s = (s_0, s_1) \text{ and } s_i \Vdash_{\Lambda_i} \varphi, \\
s \Vdash_{\Lambda^D} \Diamond_d\varphi & \text{if} & s(d) \Vdash_\Lambda \varphi, \\
s \Vdash_{\mathcal{P}\Lambda} \Diamond_\ni\varphi & \text{if} & \text{there is some } t \in s \text{ with } t \Vdash_\Lambda \varphi, \\
s \Vdash_{\mathcal{I}} \odot\varphi & \text{if} & \sigma(s) \Vdash_K \varphi.
\end{array}$$

Furthermore we employ the usual terminology concerning validity, etc.

EXAMPLE 197. Consider the functor $\Omega = \mathcal{P}\mathsf{Prop} \times \mathcal{P}(\mathcal{I} \times \mathcal{I})$ corresponding to Kripke models based on frames with a ternary accessibility relation T. In the standard modal language for such models, we would be working with a binary modality $\Diamond$, whereas here, we are dealing with four unary modalities: $\odot$, $\Diamond_\ni$, $\Diamond_{\pi_1}$ and $\Diamond_{\pi_2}$. We leave it for the reader to verify that the modal formula $\varphi_1\Diamond\varphi_2$ in the first language can be rendered as $\odot\Diamond_\ni(\Diamond_{\pi_0}\varphi_1 \wedge \Diamond_{\pi_1}\varphi_2)$ in the second. That is, we have

$$\mathbb{S}, s \models \odot\Diamond_\ni(\Diamond_{\pi_0}\varphi_1 \wedge \Diamond_{\pi_1}\varphi_2) \text{ iff there are } t_1, t_2 \text{ with } Tst_1t_2 \text{ and } \mathbb{S}, t_i \Vdash \varphi_i.$$

Bisimulation invariance of this language is easily proved:

PROPOSITION 198. *Assume that K is some Kripke polynomial functor, and let $\mathbb{S}$ and $\mathbb{S}'$ be two K-coalgebras. Then for any pair of states $s \in S$, $s' \in S'$:*

$$\mathbb{S}, s \leftrightarroweq \mathbb{S}', s' \textit{ only if } s \textit{ and } s' \textit{ satisfy the same formulas in } Fma_K.$$

Proof. Fix a bisimulation B between $\mathbb{S}$ and $\mathbb{S}'$. We claim that for any formula φ of type $\Lambda \in Ing(K)$, it holds for any pair $(s, s') \in \Lambda(S) \times \Lambda(S')$ that

$$\mathbb{S}, s \Vdash_\Lambda \varphi \text{ iff } \mathbb{S}', s' \Vdash_\Lambda \varphi,$$

provided that (s, s') belong to the relation lifting $\overline{\Lambda}(B)$ of B. The proof is by a straightforward formula induction. ❑

The basic modal theory of this formalism has been developed. For instance, analogous to Theorem 38 in Chapter 5 of this volume, one may prove that if K is a *finitary* Kripke polynomial functor, then the language Fma_K has the Hennessy-Milner property. Also, results concerning completeness and decidability are known. The interested reader is referred to Rößiger [95] and Jacobs [62].

We now move to the third approach towards coalgebraic modal logic. Pattinson [89] combines the generality of the first formalism with the concreteness of the second. That is, the approach applies to arbitrary set functors, but provides languages with standard diamonds and boxes. First we present a simplified version, which is based on the idea

to *extract diamonds out of the natural transformations* from the coalgebra functor Ω to the power set functor $\mathcal{P}$. Recall that a natural transformation $\lambda : \Omega \to \mathcal{P}$ provides an arrow $\lambda_S : \Omega(S) \to \mathcal{P}(S)$ for each set S, in such a way that for each function $f : S \to S'$, the following diagram commutes:

$$\begin{tikzcd} S \arrow[d, "f"'] & \Omega S \arrow[r, "\lambda_S"] \arrow[d, "\Omega f"'] & \mathcal{P}S \arrow[d, "\mathcal{P}f"'] \\ S' & \Omega S' \arrow[r, "\lambda_{S'}"] & \mathcal{P}S' \end{tikzcd}$$

Thus if we have an Ω-coalgebra $\mathbb{S} = \langle S, \sigma \rangle$, we may define a relation $R_\lambda \subseteq S \times S$ for such a λ by putting $R_\lambda st$ if $t \in \lambda_S(\sigma(s))$. We may then introduce a diamond $\Diamond_\lambda$ which takes this R_λ as its accessibility relation. Natural transformations $\lambda : \Omega \to \mathcal{P}$ thus literally transform Ω-coalgebras into $\mathcal{P}$-coalgebras, that is, Kripke frames.

Similarly, if we want to have *atomic propositions* in our language, consider any natural transformation ν from Ω to the constant functor Prop. We then make $p \in \mathsf{Prop}$ true at s depending on whether p is an element of the set $\nu_S(\sigma(s))$ or not. It is as if we add the valuation V_ν to $\mathbb{S}$ given by $V_\nu(p) := \{s \in \mathbb{S} \mid p \in \nu_S(\sigma(s))\}$.

DEFINITION 199. Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ be some functor, $\nu : \Omega \to \mathsf{Prop}$ some natural transformation, and Λ some collection of natural transformations $\Omega \to \mathcal{P}$. Then $\mathcal{L}_{\nu,\Lambda}$ is the standard modal language we obtain by taking Prop as the collection of propositional variables, and $\tau_\Lambda := \{\Diamond_\lambda \mid \lambda \in \Lambda\}$ as the modal similarity type.

It will now be obvious how these formulas are interpreted in Ω-coalgebras. We confine ourselves to the following clauses of the inductive truth definition:

$$\begin{array}{rll} \mathbb{S}, s \Vdash p & \text{if} & p \in \nu(\sigma(s)), \\ \mathbb{S}, s \Vdash \Diamond_\lambda \varphi & \text{if} & \mathbb{S}, t \Vdash \varphi \text{ for some } t \in \lambda_S(\sigma(s)). \end{array}$$

In other words, an Ω-coalgebra $\mathbb{S}$ is treated as the Kripke model $\langle S, \{R_\lambda \mid \lambda \in \Lambda\}, V_\nu \rangle$. The reason to require the transformations to be *natural* is to guarantee invariance under behavioral equivalence.

PROPOSITION 200. *Let Ω, ν and Λ be as in Definition 199. Then for any pair $\mathbb{S}$, $\mathbb{S}'$ of Ω-coalgebras, and any pair of states $s \in S$, $s' \in S'$:*

$$\mathbb{S}, s \equiv_\Omega \mathbb{S}', s' \textit{ only if } s \textit{ and } s' \textit{ satisfy the some } \mathcal{L}_{\nu,\Lambda}\textit{-formulas.}$$

Proof. It suffices to prove that for any coalgebraic homomorphism $f : \mathbb{S} \to \mathbb{S}'$, each state s in $\mathbb{S}$ satisfies the same $\mathcal{L}_{\nu,\Lambda}$-formulas as $f(s)$ in $\mathbb{S}'$. This inductive proof is in fact straightforward, the crucial observation being that the naturality of the transformations guarantees that f is a bounded morphism between the Kripke models associated with $\mathbb{S}$ and $\mathbb{S}'$. ❑

For the more general picture, Pattinson uses *predicate liftings* (from $\mathcal{P}S$ to $\mathcal{P}\Omega S$) to obtain modal operators. In order to introduce these, note that the semantics of the modal operator $\Diamond_\lambda$ could have been expressed as follows:

$$\mathbb{S}, s \Vdash \Diamond_\lambda \varphi \text{ iff } \sigma(s) \in \mu_S^\lambda([\![\varphi]\!]),$$

where $\mu^{\lambda}_S : \mathcal{P}S \to \mathcal{P}\Omega S$ is given by $A \mapsto \{\Gamma \in \Omega S \mid \lambda_S(\Gamma) \cap A \neq \varnothing\}$, and $[\![\varphi]\!]$ denotes the extension of φ in $\mathbb{S}$. In fact, it can be shown that μ^{λ} is a natural transformation from the contravariant power set functor $\breve{\mathcal{P}}$ to the functor $\breve{\mathcal{P}} \circ \Omega$. Generalizing this, we arrive at the following definition.

DEFINITION 201. A *predicate lifting* for a set functor Ω is a natural transformation $\mu : \breve{\mathcal{P}} \to \breve{\mathcal{P}} \circ \Omega$. With each predicate lifting we can associate a modal operator $\Diamond_{\mu}$, with the following semantics:

$$\mathbb{S}, s \Vdash \Diamond_{\lambda}\varphi \text{ iff } \sigma(s) \in \mu_S([\![\varphi]\!]).$$

And as before, it is the naturality of the transformation that ensures that this language is invariant under behavioral equivalence.

In order to finish this section, a number of remarks are in order. First, the above mentioned versions of coalgebraic logic are open for the standard expressive enhancements that we know from extended modal logic. As examples we mention Jacobs [64], who adds past operators (as in section 8.1) to a variant of the formalism defined in the Definitions 195 and 196, and Venema [107], who develops a finitary fixed point version of Moss' logic.

Second, it should be mentioned that for certain *polynomial* functors, coalgebraic specification languages have been developed of an *equational* rather than modal nature. Very roughly, the idea is that coalgebras for such a polynomial functor K can be represented by a structured collection of partial functions on the carrier of the coalgebra. From the perspective of Definition 196, this can be explained by the observation that in the absence of the power set functor, each and every accessibility relation of the multi-sorted frame is in fact (the graph of) a partial function. Lacking the space for an appropriate survey of this more equational perspective, we only mention one interesting idea which adds some *modal flavor* to equational logic. In coalgebraic approaches towards specification theory, such as that of *hidden algebra*, a *state equation* $t_1 \simeq t_2$ holds of a state s in a coalgebra $\mathbb{S}$ if $t_1^{\mathbb{S}}(s)$ and $t_2^{\mathbb{S}}(s)$ evaluate to *bisimilar* (rather than identical) states in $\mathbb{S}$. We refer the reader to Goldblatt [42, 43] and Roşu [94] for more details; in particular, Goldblatt [43] contains a clear discussion of this overlap area between modal and equational logic.

Third, Kurz & Pattinson [78] establish a link between coalgebraic predicates and the *final sequence*, see Remark 162: they argue that finitary predicates correspond to subsets of some set Z_n (n finite) occurring in the final sequence. This work is in fact closely related to that of Ghilardi [33], even though the word 'coalgebra' is not mentioned in the latter work.

Finally, there is an interesting connection between Hennessy-Milner results and final coalgebras: Goldblatt [45] proves that a set functor Ω admits a final coalgebra iff there is a coalgebraic modal language for Ω, which has the Hennessy-Milner property and is based on a *set* (rather than a proper class) of formulas.

14 CO-BIRKHOFF THEOREMS AND COFREE COALGEBRAS

In order to give the reader some impression of universal coalgebra at work, we discuss one result, or better, one cluster of results, in some detail. The topic that we have chosen concerns the coalgebraic version of Birkhoff's variety theorem; recall that this result in universal algebra states that a class C of algebras is a *variety*, (that is, closed under the

class operations H, S and P), if and only if it is equationally definable. Thus in essence, Birkhoff established a link between two different ways of characterizing algebraic classes: a logical one, in terms of the validity of certain formulas, and a structural one, in terms of certain class operations.

If we are after a co-Birkhoff result, two roads seem open to us. Since we have already developed the concept of a covariety, the most obvious thing to do would be to try and find out what corresponds to it, logically. An alternative approach would be to investigate the structural counterpart of the logical languages developed in the previous section. Here we follow the first road, but interestingly, it leads us to (very natural generalizations of) modal languages! This provides justification for our earlier claim that modal logic is dual to equational logic.

In the proof of Birkhoff's theorem, *free* algebras play a key role; thus it will come as no surprise that we will be looking at *cofree* coalgebras here. However, these structures do not serve as proof tools only, they have a quite intuitive meaning as well. To explain this, first note that many set functors provide coalgebraic structures that come with a notion of *output*. For instance, the black box machines of Example 141 may be prompted to display some value, the states of the automata of Example 142 output 0 or 1 depending on whether they are final or not, and the states of a Kripke model satisfy some set of propositional variables. For a general functor $\Omega : \mathsf{Set} \to \mathsf{Set}$, such a notion of output may not be available. However, nothing prevents us from *adding* an extra output feature to the functor.

DEFINITION 202. Let Ω be some set functor, and C a set of objects that we will call *colors*. A *C-coloring* of an Ω-coalgebra $\mathbb{A} = \langle A, \alpha \rangle$ is a map $\gamma : A \to C$; the structure $\langle A, \alpha, \gamma \rangle$ will be called the coalgebra $\mathbb{A}$ *colored* by γ.

As a prime example, Kripke models can be seen as $\mathcal{P}\mathsf{Prop}$-colored Kripke frames. In general, C-colored Ω-coalgebras may be identified with Ω_C-coalgebras, where Ω_C is the functor $C \times \Omega$; this provides us with a category of C-colored Ω-coalgebras. Spelling it out, $f : S \to S'$ is a morphism from $\langle S, \sigma, \gamma \rangle$ to $\langle S', \sigma', \gamma' \rangle$ if f is an Ω-coalgebra homomorphism from $\langle S, \sigma \rangle$ to $\langle S', \sigma' \rangle$ such that $\gamma(s) = \gamma'(fs)$ for all $s \in S$.

Colors can be seen as the coalgebraic duals of variables, colorings as the duals of assignments. This brings us to the definition of a cofree coalgebra, which is the formal dual of the notion of a free algebra. We recall the latter notion, for the purposes of the present context, as follows. Let $\Omega : \mathsf{Set} \to \mathsf{Set}$ be some set functor, X a set of variables, and $T = \langle T, \tau : \Omega T \to T \rangle$ some Ω-algebra such that $e : X \to T$ is some kind of injection. (Here we deviate from the more standard presentation, where e is taken to be an inclusion map.) Then T, with e, is called *free over* X if for every Ω-algebra $\mathbb{A} = \langle A, \alpha \rangle$ and every assignment $f : X \to A$, there is a unique homomorphism $\widetilde{f} : \mathbb{T} \to \mathbb{A}$ such that $f = \widetilde{f} \circ e$.

DEFINITION 203. Let Ω be a set functor, C a set of colors, and $\mathbb{Z}$ some Ω-coalgebra with a coloring $\gamma : Z \to C$. Then $\mathbb{Z}$ (with γ) is called *(absolutely) cofree over* C if for every Ω-coalgebra $\mathbb{A} = \langle A, \alpha \rangle$ and every coloring $g : A \to C$ of $\mathbb{A}$, there is a unique homomorphism $\widetilde{g} : \mathbb{A} \to \mathbb{Z}$ such that $g = \gamma \circ \widetilde{g}$.

$$\begin{tikzcd} & Z \arrow[d, "\gamma"] \\ A \arrow[ur, dotted, "\widetilde{g}"] \arrow[r, "g"'] & C \end{tikzcd}$$

Observe that the diagram above is not properly typed (it mixes arrows from different categories). A more proper formulation of the notion of cofreeness would involve the right adjoint to the forgetful functor from $\mathsf{Coalg}(\Omega)$ to Set.

It is immediate from the definitions that an Ω-coalgebra with coloring $\gamma : T \to C$ is

cofree over C iff the structure $\langle T, \tau, \gamma\rangle$ is a *final* coalgebra for the functor $\Omega_C = C \times \Omega$. This explains that we may view the carrier Z of such a cofree coalgebra as the collection of all *behavior patterns* expressible in the output set C. And this perspective paves the way for a dual version of Birkhoff's variety theorem, by providing a natural means for characterizing classes of coalgebras in terms of permitted, or forbidden, behaviors.

DEFINITION 204. Let Ω be some set functor, and let $\mathbb{Z}$, with coloring $\gamma : Z \to C$, be the cofree coalgebra over some set C of colors. Given a set Q in $\mathbb{Z}$, let $\mathsf{Cov}(Q)$ be the class of Ω-coalgebras $\mathbb{A}$ such that $\eta[A] \subseteq Q$ for all homomorphisms $\eta : \mathbb{A} \to \mathbb{Z}$.

And conversely, given a class K of Ω-coalgebras, define $Bhv(\mathsf{K}) \subseteq Z$ to be the union of all images $\widetilde{g}[A]$ in which $\widetilde{g}$ arises from some C-coloring g of some coalgebra $\mathbb{A}$ in K.

There are all kinds of interesting facts concerning these two maps. For instance, it is fairly obvious from the definitions that Bhv and Cov form a (dual) Galois connection: For any class K of Ω-coalgebras, and any set Q of behavior patterns, we have

$$Bhv(\mathsf{K}) \subseteq Q \text{ iff } \mathsf{K} \subseteq \mathsf{Cov}(Q). \tag{48}$$

We will have use for this fact in the proof of a first co-Birkhoff result, which is basically due to Rutten [97]. In the remainder of this section we restrict our attention to *small* functors, in order to ensure the existence of final and cofree coalgebras.

THEOREM 205. *Let Ω be some endofunctor on* Set *which is κ-small for some cardinal κ. Then for any set C of size κ, the cofree coalgebra over C exists, and a class* K *of Ω-coalgebras is a covariety iff* $\mathsf{K} = \mathsf{Cov}(Q)$ *for some set Q of behavior patterns.*

Proof. It follows from the assumption on Ω that the functor $\Omega_C = C \times \Omega$ has a final coalgebra. However, we already observed that this structure may be represented as a triple $\langle Z, \zeta, \gamma\rangle$ such that $\mathbb{Z} = \langle Z, \zeta\rangle$, with coloring γ, is the cofree Ω-coalgebra over C. We fix this $\mathbb{Z}$ and γ for the remainder of the proof.

In order to show that $\mathsf{Cov}(Q)$ is a covariety, one needs to subsequently prove closure under taking homomorphic images, subcoalgebras, and sums. Here we restrict our attention to the proof for subcoalgebras, because that is the only part where the cofreeness of $\mathbb{Z}$ is used.

Suppose that $\mathbb{A}$ is a subcoalgebra of $\mathbb{B}$, with inclusion ι, while $\mathbb{B}$ belongs to $\mathsf{Cov}(Q)$; we need to show that $\mathbb{A}$ also belongs to this class. For that purpose, consider a homomorphism $\eta : \mathbb{A} \to \mathbb{Z}$, and observe that $\gamma \circ \eta : A \to C$ is a coloring of $\mathbb{A}$. Clearly this coloring can be extended to a coloring $g : B \to C$ of $\mathbb{B}$. Let $\widetilde{g} : \mathbb{B} \to \mathbb{Z}$ be the unique homomorphism such that $g = \gamma \circ \widetilde{g}$ — such a map exists by the cofreeness of $\mathbb{Z}$.

$$\begin{tikzcd}
A \arrow[r, "\eta"] \arrow[d, "\iota"'] & Z \arrow[d, "\gamma"] \\
B \arrow[ur, "\widetilde{g}"] \arrow[r, "g"] & C
\end{tikzcd}$$

Now $g = \gamma \circ \widetilde{g}$, so that $\gamma \circ \widetilde{g} \circ \iota = g \circ \iota$. But g was chosen so that $g \circ \iota = \gamma \circ \eta$. Hence we find that $\gamma \circ \widetilde{g} \circ \iota = \gamma \circ \eta$, so by the cofreeness of $\mathbb{Z}$ with respect to colorings of $\mathbb{A}$, we find that $\widetilde{g} \circ \iota = \eta$, that is, $\widetilde{g}$ extends η. From this it is immediate that $\eta[A] = \widetilde{g}{\restriction_A}[A] \subseteq \widetilde{g}[B]$, so that $\eta[A] \subseteq Q$ by the assumption that $\mathbb{B}$ belongs to $\mathsf{Cov}(Q)$.

For the other direction of the theorem, suppose that K is a covariety; we claim that

$$\mathsf{K} = \mathsf{Cov}(Bhv(\mathsf{K})). \tag{49}$$

The inclusion $\subseteq$ is immediate from (48). For the opposite inclusion, it easily follows from the definitions that $Bhv(\mathsf{K})$ is $\mathbb{Z}$-open. Let $\mathbb{B}_{\mathsf{K}}$ be the (unique) subcoalgebra of $\mathbb{Z}$ with

carrier set $Bhv(\mathsf{K})$. It is not hard to prove that $\mathbb{B}_{\mathsf{K}}$ is a conjunct sum of algebras in K, which implies that $\mathbb{B}_{\mathsf{K}}$ actually belongs to K since covarieties are closed under taking conjunct sums. Hence, in order to prove the remaining inclusion $\supseteq$ of (49), it suffices to show that

$$\text{every coalgebra in } \mathsf{Cov}(Bhv(\mathsf{K})) \text{ is a conjunct sum of subcoalgebras of } \mathbb{B}_{\mathsf{K}}. \tag{50}$$

Take an arbitrary coalgebra $\mathbb{A}$ in $\mathsf{Cov}(Bhv(\mathsf{K}))$. From the κ-smallness of Ω it may be derived that $\mathbb{A}$ is the conjunct sum of coalgebras $\mathbb{A}_i$, each of size at most κ. Clearly then it suffices to prove that each $\mathbb{A}_i$ belongs to K, since covarieties are closed under taking conjunct sums.

Fix some $i \in I$; clearly $\mathsf{Cov}(Bhv(\mathsf{K}))$, being closed under taking subcoalgebras, contains $\mathbb{A}_i$. Since $|A_i| \leq \kappa = |C|$, there is an injective coloring $e_i : A_i \to C$. Hence by cofreeness of $\mathbb{Z}$ there is a unique homomorphism $\widetilde{e}_i : \mathbb{A}_i \to \mathbb{Z}$ such that $e_i = \gamma \circ \widetilde{e}_i$. This $\widetilde{e}_i$ must also be injective, which implies that $\mathbb{A}_i$ is isomorphic to its image $\widetilde{e}_i[\mathbb{A}_i]$. But, since $\mathbb{A}_i$ belongs to $\mathsf{Cov}(Bhv(\mathsf{K}))$, the structure $\widetilde{e}_i[\mathbb{A}_i]$ is a subcoalgebra of $\mathbb{B}_{\mathsf{K}}$, and thus, belongs to K. From this it is immediate that each $\mathbb{A}_i$ belongs to K, and thus, so does the conjunct sum $\mathbb{A}$. ❑

Clearly, not only the statement, but also the proof of Theorem 205 is dual to that of Birkhoff's variety theorem. For instance, the coalgebra $\mathbb{B}_{\mathsf{K}}$ clearly fulfills the role of the *cofree* coalgebra *for the class* K over the color set C. What seems to be missing from Theorem 205, however, is some notion of logic, involving *syntax*. (It should be noted that also in the algebraic case, the straightforward characterization of varieties in terms of equations only obtains in the case of relatively simple functors.) Since we are discussing a dual of Birkhoff's theorem, the question this raises is: what are *co-equations*?

Given the nature of systems as state-based models of dynamics, it seems natural to require that formulas describe *behavior*. This would provide natural constraints on possible coequational languages, namely, that formulas are evaluated at states, in such a way that truth is invariant under behavioral equivalence. Furthermore, we allow the use of colors in order to obtain sufficient expressive power. It was an insight of Kurz [76] that these requirements may also be read as a natural *definition* of coalgebraic modal logic.

DEFINITION 206. Let Ω be some set functor. A *coalgebraic modal language* for Ω consists of a set C of colors, a class $\mathcal{L}_C$ of formulas, and, for each C-colored Ω-coalgebra $\langle \mathbb{S}, g\rangle$, a truth or satisfaction relation $\Vdash^{\mathbb{S},g} \subseteq S \times \mathcal{L}_C$ such that $\Vdash$ is invariant under behavioral equivalence. That is, if $\langle \mathbb{S}, g\rangle, s \equiv_{\Omega_C} \langle \mathbb{T}, h\rangle, t$, then $\mathbb{S}, s \equiv_{\mathcal{L}_C} \mathbb{T}, t$, where the latter notation indicates that s in $\langle \mathbb{S}, g\rangle$ and t in $\langle \mathbb{T}, h\rangle$ satisfy exactly the same $\mathcal{L}_C$-formulas φ.

In the sequel we will use notation and terminology from modal logic. For instance, we write $\langle \mathbb{S}, g\rangle, s \Vdash \varphi$ instead of $s \Vdash^{\mathbb{S},g} \varphi$, and we define $\mathbb{S}, g \Vdash \varphi$ and $\mathbb{S} \Vdash \varphi$ by quantifying over all elements and all valuations, respectively.

How can we link such modal languages to the cofree coalgebra? The idea here is that modal formulas correspond to subcoalgebras: if $\mathbb{Z}$, with C-coloring γ is a cofree coalgebra over C, then define

$$[\![\varphi]\!]^{\mathbb{Z},\gamma} := \{z \in Z \mid \mathbb{Z}, \gamma, z \Vdash \varphi\}.$$

Using the behavioral invariance of the logic, it is not hard to see that $[\![\varphi]\!]$ (we usually omit superscripts) is always $\mathbb{Z}$-open. Now one way to obtain nice co-Birkhoff results is to require the modal language to be expressive enough for the converse to hold as well.

DEFINITION 207. Let Ω be some κ-small set functor, and let $\langle C, \mathcal{L}_C, \Vdash\rangle$, with $|C| = \kappa$ constitute a coalgebraic modal logic for Ω. This modal logic is called *expressive* if every open set of the C-cofree coalgebra $\mathbb{Z}$ is of the form $[\![\varphi]\!]$ for some formula φ.

This may seem a strong requirement on a language, but expressive languages are not hard to come by.

EXAMPLE 208. Under some mild additional assumptions on Ω, one may show that Moss' logic of Definition 190 and 191, extended with infinite *disjunctions*, is expressive. For a proof sketch: strengthen Theorem 194 by proving that for any pointed Ω_C-system $(\mathbb{S}, s)$, there is a formula $\varphi^{\mathbb{S},s}$ such that for all pointed Ω_C-system $(\mathbb{S}', s')$ one has that $\mathbb{S}', s' \Vdash \varphi^{\mathbb{S},s}$ iff $\mathbb{S}', s' \equiv_{\Omega_C} \mathbb{S}, s$. Then, given an open set U of the cofree Ω_C-coalgebra $\mathbb{Z}$, one may define $\varphi^U := \bigvee\{\varphi^{\mathbb{Z},u} \mid u \in U\}$.

Now the next theorem bears witness to the tight link between modal logic and coalgebras. It is due to Kurz [76], while a very similar result was proved in Gumm & Schröder [53].

THEOREM 209. *Let Ω be some C-small set functor, and let $\langle C, \mathcal{L}_C, \Vdash\rangle$ constitute an expressive coalgebraic modal logic for Ω. Then a class K of Ω-coalgebras is a covariety iff for some formula φ, K is the class of all Ω-coalgebras $\mathbb{S}$ such that $\mathbb{S} \Vdash \varphi$.*

Proof. Let $\mathbb{Z}$, with coloring $\gamma : Z \to C$, be the cofree Ω-coalgebra over C. Given a formula φ, it is a direct consequence of cofreeness and truth invariance, that for any Ω-coalgebra $\mathbb{S}$ with C-coloring g, and for any state s in $\mathbb{S}$, we have

$$\mathbb{S}, g, s \Vdash \varphi \text{ iff } \widetilde{g}(s) \in [\![\varphi]\!], \tag{51}$$

from which one easily derives that for any $\mathcal{L}_C$-formula φ:

$$\mathsf{Cov}([\![\varphi]\!]) \text{ is the class of all } \Omega\text{-coalgebras } \mathbb{S} \text{ such that } \mathbb{S} \Vdash \varphi. \tag{52}$$

From (52) the direction '$\Leftarrow$' of the Theorem is immediate. For the other direction, suppose that K is a covariety. Then by expressiveness, $Bhv(\mathsf{K}) = [\![\varphi]\!]$ for some formula φ, so by (49) and (52) it follows that $\mathsf{K} = \mathsf{Cov}(Bhv(\mathsf{K})) = \mathsf{Cov}([\![\varphi]\!])$, as required. ❑

Although this theorem, being formulated in terms of a fairly general notion of modal logic, may still seem to be rather abstract, it does provide a useful tool to provide more concrete results. For instance, given Example 208, as a corollary to Theorem 209 one may obtain very general modal co-Birkhoff results for Moss' coalgebraic logic. Or, to give an even more concrete corollary of Theorem 209, call an (ordinary) modal frame *κ-bounded* for some cardinal κ if every point has less than κ successors.

COROLLARY 210. *A class K of κ-bounded frame is (within the class of all κ-bounded frames) definable by means of infinitary modal formulas, if and only if K is closed under taking generated subframes, homomorphic images and disjoint unions.*

The reader who compares the above two result to the Goldblatt-Thomasson Theorem 79, may be puzzled by the absence of ultrafilter extensions here. The explanation

for this absence is of course that such Stone-type completions are not relevant in the presence of infinite disjunctions and conjunctions. If one takes the alternative road to co-Birkhoff theorems and starts, not from the notion of a covariety, but from a *finitary* coalgebraic logical formalism, one will find that notions like ultrafilter extensions or ultraproducts are needed in the characterization of definable classes of coalgebras. Results in this direction can be found in for instance Goldblatt [42, 43] or Roşu [94].

Finally, the search for coalgebraic versions of Birkhoff's variety theorem has received considerable attention in the coalgebraic literature, as is witnessed by many contributions in [66, 93, 20, 52, 4]. Perhaps Gumm [51] should get some special mentioning for developing an alternative coequational syntax based on equivalence classes of infinite labeled trees.

15 DUALITY OF ALGEBRA AND COALGEBRA

Various other coalgebraic topics may be of interest to modal logicians, but here we confine ourselves to a brief discussion of the duality between algebra and coalgebra.

In remark 152 we already observed that some of the similarities between algebra and coalgebra are based on the fact that a coalgebra $\mathbb{C} = \langle C, \gamma : C \to \Omega C \rangle$ over an endofunctor $\Omega : \mathsf{C} \to \mathsf{C}$ can also be seen as an algebra in the *opposite* category C^{op}. In fact, it is a trivial exercise to show that

$$\mathsf{Coalg}(\Omega) = (\mathsf{Alg}(\Omega^{op}))^{op}. \tag{53}$$

That is, the category of Ω-coalgebras is dually isomorphic to the category of algebras over the functor Ω^{op} (which acts on objects and arrows just like Ω does, the difference being that Ω^{op} is an endofunctor on C^{op}).

This duality between algebras and coalgebras has been a major guideline in the development of universal coalgebra, see Rutten [97]. To mention just one example (many more can be found in the text): whereas *initial* algebras play an important role in universal algebra, it is the *final* objects that are relevant in coalgebra. For instance, whereas the principle of induction is based on the fact that initial algebras have no proper subalgebras, the dual *coinduction* principle boils down to the fact that final coalgebras have no proper quotients. However, it is important to realize that in (53) the *base* category has been dualized. This means, for instance, that systems, or Set-coalgebras, correspond, not so much to algebras over Set, as to algebras over the opposite category Set^{op} (which happens to be equivalent to the category of complete and atomic Boolean algebras with complete homomorphisms). As a consequence, a general theory of systems cannot be obtained by a straightforward dualization of universal (Set-based) algebra. On the other hand, the fact that systems are, just like standard algebras, 'sets with structure', indicates that many universal algebraic concepts may apply to coalgebra by *analogy* rather than by duality — see for instance Proposition 179. Thus, the universal coalgebraic theory of systems is an interesting mix of dualized and non-dualized universal algebra, with, of course, some characteristics of its own.

In case that there is an informative *duality* for the base category C, more can be said of (53). This applies for instance to the just mentioned duality of the category Set, but for the present purpose we prefer to focus on the category Stone of Stone spaces. The point is, that since Stone is dually equivalent to the well-known category BA of Boolean

algebras, every endofunctor Ω on Stone induces an endofunctor $\Omega^* := (\cdot)_* \circ \Omega \circ (\cdot)^*$ on BA. It is then an immediate consequence of (53) that the categories $\mathsf{Coalg}(\Omega)$ and $\mathsf{Alg}(\Omega^*)$ are dually equivalent:

$$\mathsf{Coalg}(\Omega) \rightleftharpoons \mathsf{Alg}(\Omega^*). \tag{54}$$

For an example of this, consider the Vietoris functor $\mathcal{V}$ of Example 147. Concretely, the behavior of its dual functor $\mathcal{V}^* : \mathsf{BA} \to \mathsf{BA}$ on objects is as follows. To a Boolean algebra $\mathbb{B}$ it assigns the Boolean algebra $\mathcal{V}^*(\mathbb{B})$ freely generated by the set $\{\Diamond b \mid b \in B\}$, subject to the axioms $\Diamond\bot = \bot$ and $\Diamond a \vee \Diamond b = \Diamond(a \vee b)$. Since the category $\mathsf{Coalg}(\mathcal{V})$ is dually equivalent to that of modal algebras, we thus see that the latter category, MA, may be represented as an algebraic category $\mathsf{Alg}(\mathcal{V}^*)$. This insight in fact provided the very first connection between modal logic and coalgebra, see Abramsky [1]. Recently, the duality that (54) provides between algebra and coalgebra has been used to prove results on coalgebraic modal *logics*, where we now use the word 'logic' in the technical sense. For instance, Jacobs [62] and Kupke, Kurz & Venema [74] use dualities in the style of (54) to prove completeness results for the multi-sorted modal logic of Definition 195 and 196. Kupke, Kurz & Pattinson [73] apply the above framework in order to characterize properties of arbitrary coalgebraic modal logics.

Let us finish the chapter with the observation that *both* of the fundamental dualities underlying the mathematical theory of modal logic are nontrivial instances of an algebra/coalgebra duality. This means that the algebraic and the coalgebraic approach towards modal logic may be fruitfully operated in tandem. We believe that a thorough study of the interaction of algebra and coalgebra will provide a better understanding, not only of modal logic itself, but also of its mathematical surroundings.

ACKNOWLEDGEMENTS

Many people have contributed to this chapter by commenting on earlier versions of it. I am grateful to Nick Bezhanishvili, Mai Gehrke, Çiğdem Gencer, Rob Goldblatt, H. Peter Gumm, Gaelle Fontaine, Helle Hansen, Ian Hodkinson, Ramon Jansana, Clemens Kupke, Alessandra Palmigiano, Jan Rutten, and Mark Theunissen for their help. Great is my gratitude to Alexander Kurz, who provided a large number of suggestions to improve the chapter.

A BASICS OF UNIVERSAL ALGEBRA AND CATEGORY THEORY

This section provides some technical preliminaries to this Chapter; we briefly review notation and terminology on universal algebra and category theory.

If we equip a set with a collection of finitary operations, we call the resulting structure an *algebra*; two such structures are called *similar* if their operations correspond in number and rank. In order to formalize this notion we introduce the notion of a *similarity type* as a set Σ of function symbols each of which comes with a nonnegative integer to be called its *rank* or *arity*. The arity of a function symbol f is denoted as $ar(f)$. Function symbols of rank zero are called *constants*.

The similarity type of (bounded) lattices is the set $Latt = \{\top, \bot, \wedge, \vee\}$ where $\top$ ('top') and $\bot$ ('bottom') are constants, and $\wedge$ ('meet') and $\vee$ ('join') are binary symbols. As

the similarity type for Boolean algebras we take the set $Bool = \{\top, \bot, \neg, \wedge, \vee\}$ where $\top$, $\bot$, $\wedge$ and $\vee$ are as before, and $\neg$ ('complementation') is a unary symbol.

A Σ-algebra is then a pair $\mathbb{A} = (A, I)$, in which the *interpretation* I assigns to each function symbol $f \in \Sigma$ an operation of arity $ar(f)$ on the *carrier* A of the algebra. Usually we write $f^{\mathbb{A}}$ rather than $I(f)$, and denote the algebra $\mathbb{A} = \langle A, I\rangle$ by $\mathbb{A} = \langle A, \{f^{\mathbb{A}} \mid f \in \Sigma\}\rangle$. As an example, let, for a set S, $\mathbb{P}(S) = \langle \mathcal{P}(S), S, \varnothing, \sim_S, \cap, \cup\rangle$ be the power set algebra, where $\sim_S$ denotes the unary operation of complementation with respect to S. An algebra is called *trivial* if it has just one element; this completely determines the behavior of the operations.

A *homomorphism* from a Σ-algebra $\mathbb{A}$ to a similar algebra $\mathbb{B}$ is a map $\theta : A \to B$ that preserves Σ-structure, in the sense that, for all $f \in \Sigma$, and all $a_1, \ldots, a_n$ in A (where $n = ar(f)$):

$$\theta(f^{\mathbb{A}}(a_1, \ldots, a_n)) = f^{\mathbb{B}}(\theta a_1, \ldots, \theta a_n). \tag{55}$$

An injective homomorphism is called an *embedding* and a surjective one, an *epimorphism*; an *isomorphism* is a bijective homomorphism. A homomorphism with the same source as target algebra is called an *endomorphism* in general, and an *automorphisms* if it is bijective.

Homomorphisms are closely related to special equivalence relations: a *congruence* on $\mathbb{A}$ is an equivalence relation $\sim$ satisfying, for all $f \in \Sigma$:

$$\text{if } a_1 \sim b_1 \;\&\; \ldots \;\&\; a_n \sim b_n, \text{ then } f^{\mathbb{A}}(a_1, \ldots, a_n) \sim f^{\mathbb{A}}(b_1, \ldots, b_n), \tag{56}$$

where n is the rank of f. Given a congruence $\sim$ on $\mathbb{A}$, the *quotient algebra of* $\mathbb{A}$ *by* $\sim$ is the algebra $\mathbb{A}/{\sim}$ whose carrier is the set $A/{\sim} := \{[a] \mid a \in A\}$ of equivalence classes of A under $\sim$, and whose operations are defined by

$$f_{\mathbb{A}/\sim}([a_1], \ldots, [a_n]) = [f_{\mathbb{A}}(a_1, \ldots, a_n)].$$

(This is well-defined by (56).) The close connection between homomorphisms and congruences is formed by the fact that if $\theta : \mathbb{A} \to \mathbb{B}$ is a homomorphism, its *kernel* $\ker(\theta) := \{(a, b) \in A \times A \mid \theta(a) = \theta(b)\}$ is a congruence on $\mathbb{A}$, while, on the other hand, for any congruence $\sim$ on $\mathbb{A}$, the associated *natural map* $\nu_\sim$ taking an element $a \in A$ to its equivalence class $[a]$ is a surjective homomorphism from $\mathbb{A}$ onto $\mathbb{A}/{\sim}$.

The set of congruences $Cg\mathbb{A}$ of an algebra $\mathbb{A}$ forms in fact a complete lattice under the subset ordering; this lattice is denoted as $\mathbb{C}\mathsf{g}(\mathbb{A})$; the meet operation of this lattice is simply their intersection, while the join of two congruences is given by $\Theta_1 \vee \Theta_2 = \Theta_1 \cup (\Theta_1 \circ \Theta_2) \cup (\Theta_1 \circ \Theta_2 \circ \Theta_1) \cup \cdots$.

A Σ-algebra $\mathbb{A}$ is a *subalgebra* of a Σ-algebra $\mathbb{B}$ if $A \subseteq B$ and for all $f \in \Sigma$, the operation $f^{\mathbb{A}}$ coincides with the restriction of $f^{\mathbb{B}}$ to A. The *direct product* $\mathbb{A} = \prod_{i \in I} \mathbb{A}_i$ of a family of Σ-algebras is an algebra with carrier $\prod_{i \in I} A_i$ and such that for $f \in \Sigma$ and $a_1, \ldots, a_n \in \prod_{i \in I} A_i$:

$$f^{\mathbb{A}}(a_1, \ldots, a_n)(i) := f^{\mathbb{A}_i}(a_1(i), \ldots, a_n(i))$$

We assume familiarity with the notions of ultraproduct and ultrapower.

Given a class K of algebras, we let $\mathsf{H}(\mathsf{K})$ denote the class of homomorphic images of algebras in K; $\mathsf{S}(\mathsf{K})$ is the class of isomorphic copies of subalgebras of algebras in K, and likewise definitions applies for the class operations P (products), Pu (ultraproducts) and Pw (ultrapowers).

A class of algebras is called a *variety* if it is closed under taking subalgebras, homomorphisms, and products; the smallest variety containing a class K is called the variety *generated by* K, notation: $\mathsf{Var}(\mathsf{K})$. Using inequalities like $\mathsf{SH} \leq \mathsf{HS}$ (meaning that, for any class of algebras K, $\mathsf{SH}(\mathsf{K})$ is a subclass of $\mathsf{HS}(\mathsf{K})$), together with the idempotence of the class operations S, H and P, one can prove Tarski's Theorem stating that

$$\mathsf{Var}(\mathsf{K}) = \mathsf{HSP}(\mathsf{K}) \tag{57}$$

for any class of algebras K.

Given a similarity type Σ and a set of variables X, we define the set $Ter_\Sigma(X)$ of Σ-*terms over* X by a straightforward induction: it is the smallest including X which contains $f(t_1, \ldots, t_n)$ whenever it contains $t_1, \ldots, t_n$ and $f \in \Sigma$ is a function symbol of rank n. (In particular, $Ter_\Sigma(X)$ contains all constants in Σ.) In this chapter we adopt the convention that unless explicitly indicated otherwise, X denotes a countably infinite set of variables; we often omit explicit reference to X, writing for instance Ter_Σ rather than $Ter_\Sigma(X)$, etc. Also, writing $s(x_1, \ldots, x_n)$ for a term s, we indicate that the variables occurring in s are among $x_1, \ldots, x_n$.

Given an assignment α of a set X of variables to (the carrier A of) an algebra $\mathbb{A}$, we inductively define the *meaning* $\widetilde{\alpha}(s)$ of a term s as follows:

$$\begin{array}{lcl} \widetilde{\alpha}(x) & = & \alpha(x) \\ \widetilde{\alpha}(f(t_1, \ldots, t_n)) & = & f^{\mathbb{A}}(\widetilde{\alpha}(t_1), \ldots, \widetilde{\alpha}(t_n)). \end{array} \tag{58}$$

Thus any term $s(x_1, \ldots, x_n)$ induces an n-ary *term function* $s^{\mathbb{A}}$ on $\mathbb{A}$, given by

$$s^{\mathbb{A}}(a_1, \ldots, a_n) = \widetilde{\alpha}(s),$$

where α is any assignment mapping each x_i to a_i. (Of course, $s^{\mathbb{A}}$ can also be given an inductive definition.)

Using the close resemblance between the second clause of (58) and (55), we can turn the meaning function into a real homomorphism by imposing Σ-algebra structure on the set $Ter_\Sigma(X)$, obtaining the *term algebra* $\mathbb{T}\mathsf{er}_\Sigma(X)$. The idea is to interpret the function symbol $f \in \Sigma$ as follows:

$$f^{\mathbb{T}\mathsf{er}_\Sigma(X)} : (t_1, \ldots, t_n) \mapsto f(t_1, \ldots, t_n).$$

Elaborating on this perspective, let K be a class of Σ-algebras, and $\mathbb{F}$ a Σ-algebra generated by a set $X \subseteq F$. Suppose that for every $\mathbb{A}$ in K and every map $\alpha : X \to A$ there is a homomorphism $\widetilde{\alpha} : \mathbb{F} \to \mathbb{A}$ extending α. Then we say that $\mathbb{F}$ has the *universal mapping property for* K *over* X, or that $\mathbb{F}$ is *free for* K *over* X. The identities of (58) thus reveal that $\mathbb{T}\mathsf{er}_\Sigma(X)$ is free over X for the class of *all* Σ-algebras; for this reason it is often referred to as the *absolutely free algebra over* X.

Free algebras have a number of important properties of which we mention the following:

- every algebra in K is a homomorphic image of a free algebra over an appropriately large set of generators;
- all free algebras for K belongs to the class $\mathsf{SP}(\mathsf{K})$;
- if $\mathbb{F}$ and $\mathbb{F}'$ are free for K over the generator sets X and X', respectively, and X and X' have the same cardinality, then $\mathbb{F}$ and $\mathbb{F}'$ are isomorphic.

Universal algebra may on the one hand be seen as generalizing the study of individual classes of algebras such as groups, fields, or lattices. On the other hand we may consider it as a rather special branch of model theory in which one is interested in structures for a language without relation symbols. The standard language for talking about such structures is *equational*.

An *equation* is nothing but a pair (s,t) of terms, always denoted as $s \approx t$. The equation $s \approx t$ (with $s,t \in Ter_\Sigma(X)$) *is true* or *holds* in the algebra $\mathbb{A}$ *under the assignment* $\alpha : X \to A$, notation: $\mathbb{A} \models_\alpha s \approx t$ if s and t obtain the same meaning in $\mathbb{A}$ under α, that is, if $\widetilde{\alpha}(s) = \widetilde{\alpha}(t)$. An equation $s \approx t$ *holds in* the algebra $\mathbb{A}$, or, equivalently, the algebra $\mathbb{A}$ *satisfies* the equation $s \approx t$, notation: $\mathbb{A} \models s \approx t$, if $\mathbb{A} \models_\alpha s \approx t$ for every assignment α.

The relation $\models$ induces a Galois connection between sets of formulas and classes of algebras; the polarities of this connection are given as the maps Equ and Mod, where $Equ(\mathsf{K})$ is the set of all equations that hold in K, and $\mathsf{Mod}(E)$ denotes the class of algebras that satisfy every equation in E. The classes of algebras that are stable under this connection, that is, the classes K of the form $\mathsf{Mod}(E)$ for some set E of equations, are called *equational classes*. An important result by Birkhoff states that this notion coincides with that of a variety, and that for any class K of algebras it holds that

$$\mathsf{Mod}(Equ(\mathsf{K})) = \mathsf{Var}(\mathsf{K}). \tag{59}$$

The relation

$$s \equiv_{\mathsf{K}} t \;:\Longleftrightarrow\; \mathsf{K} \models s \approx t$$

corresponding to the set $Equ(\mathsf{K})$ is in fact a *congruence* on the term algebra $\mathbb{T}\mathsf{er}_\Sigma$. The algebra $\mathbb{T}\mathsf{er}_\Sigma(X)/\equiv_{\mathsf{K}}$ has the universal mapping property for K over $[X]$ (the set of equivalence classes of X under $\equiv_{\mathsf{K}}$), which, together with the third fact on free algebras listed above, explains why we call it the *free algebra for* K over $[X]$.

A *category* C consists of a class $\mathsf{Ob}(\mathsf{C})$ of *objects*, and for each pair of objects A, B, a family $\mathsf{C}(A,B)$ of *arrows*. If f belongs to the latter set, we write $f : A \to B$, and call A the *domain* and B the *codomain* of the arrow. The collection of arrows is endowed with some algebraic structure: for every object A of C there is an arrow $id_A : A \to A$, and every pair $f : A \to B$, $g : B \to C$ can be uniquely *composed* to an arrow $g \circ f : A \to C$. These operations are supposed to satisfy the associative law for composition, while the appropriate identity arrows are left- and right neutral elements. An arrow $f : A \to B$ is an *iso* if it has an *inverse*, that is, an arrow $g : B \to A$ such that $f \circ g = id_B$ and $g \circ f = id_A$. Examples of categories are Set, the class of sets with functions, and, for every similarity type Σ, the class $\mathsf{Alg}(\Sigma)$ of Σ-algebras, with homomorphisms as arrows. The *opposite* category C^{op} of a given category C has the same objects as C, while $\mathsf{C}^{op}(A,B) = \mathsf{C}(B,A)$ for all objects A, B from C, and the operations on arrows are defined in the obvious way.

An object X is *initial* in a category C if for every object A in C there is a unique arrow $\alpha : X \to A$, and *final* if for all A there is a unique $\alpha : A \to X$. In Set, the empty set is initial, and the final objects are precisely the singletons. A *product* of two objects A_0 and A_1 in a category C consists of a triple $(A, \alpha_0 : A \to A_0, \alpha_1 : A \to A_1)$, such that for every triple $(A', \alpha_0' : A' \to A_0, \alpha_1' : A' \to A_1)$ there is a unique arrow $f : A' \to A$ such that $\alpha_i \circ f = \alpha_i'$ for both i. *Coproducts* of A_0 and A_1 are defined dually as triples $(A, \alpha_0 : A_0 \to A, \alpha_1 : A_1 \to A)$, such that for every triple $(A', \alpha_0' : A_0 \to A', \alpha_1' : A_1 \to A')$ there

is a unique arrow $f : A \to A'$ such that $f \circ \alpha_i = \alpha'_i$ for each i. The category Set *has* both products and coproducts — that is, every pair (S_0, S_1) of sets has both a product (for which we may take the cartesian product $S_0 \times S_1$ together with the two projection functions $\pi_i : S_0 \times S_1 \to S_i$), and a coproduct (for which we may take the disjoint union $S_0 \uplus S_1 = S_0 \times \{0\} \cup S_1 \times \{1\}$ together with the coproduct maps κ_0 and κ_1 given by $\kappa_i(s) = (s, i)$).

A *functor* $\Omega : \mathsf{C} \to \mathsf{D}$ from a category C to a category D consists of an operation mapping objects and arrows of C to objects and arrows of D, respectively, in such a way that $\Omega f : \Omega A \to \Omega B$ if $f : A \to B$, $\Omega(id_A) = id_{\Omega A}$ and $\Omega(g \circ f) = (\Omega g) \circ (\Omega f)$ for all objects and arrows involved. A functor $\Omega : \mathsf{C} \to \mathsf{D}^{op}$ is sometimes called a *contravariant* functor from C to D. An *endofunctor* on C is a functor $\Omega : \mathsf{C} \to \mathsf{C}$.

As examples we consider the following *set functors* (that is, endofunctors on Set): (i) for a fixed set C, the *constant* functor mapping all sets to C and all arrows to id_C; this functor is denoted as C, (ii) the *power set functor* $\mathcal{P}$, which maps any set S to its power set $\mathcal{P}S$, and any map $f : S \to S'$ to the map $\mathcal{P}f : \mathcal{P}S \to \mathcal{P}S'$ given by $\mathcal{P}f : X \mapsto \{fx \mid x \in X\}$, and (iii) for every cardinal κ, the variant $\mathcal{P}_\kappa$ of the power set functor, which maps any set S to the the collection $\mathcal{P}_\kappa S := \{X \subseteq S \mid \kappa > |X|\}$, and agrees with $\mathcal{P}$ on the arrows for which is defined. Furthermore, given two functors Ω_0 and Ω_1, their *product functor* $\Omega_0 \times \Omega_1$ is given (on objects) by $(\Omega_0 \times \Omega_1)S := \Omega_0 S \times \Omega_1 S$, while for $f : S \to S'$, the map $(\Omega_0 \times \Omega_1)f$ is given as $((\Omega_0 \times \Omega_1)f)(\sigma_0, \sigma_1) := ((\Omega_0 f)(\sigma_0), (\Omega_1 f)(\sigma_1))$. The *coproduct functor* is defined similarly. Finally, every category C admits the *identity functor* $\mathcal{I}_\mathsf{C} : \mathsf{C} \to \mathsf{C}$ which is the identity on both objects and arrows of C.

Let C and D be two categories, and let Ω and Ψ be two functors from C to D. A *natural transformation* τ from Ω to Ψ, notation $\tau : \Omega \Rightarrow \Psi$, consists of D-arrows $\tau_A : \Omega A \to \Psi A$ such that $\tau_B \circ \Omega f = \Psi f \circ \tau_A$ for each $f : A \to B$ in C.

Finally, let $\Omega : \mathsf{C} \to \mathsf{D}$ and $\Psi : \mathsf{D} \to \mathsf{C}$ be two functors linking the categories C and D. Ω and Ψ constitute an *equivalence* between C and D if their compositions are naturally isomorphic to the identity functors, that is, if there are natural transformations $\sigma : \mathcal{I}_\mathsf{C} \Rightarrow \Psi\Omega$ and $\tau : \mathcal{I}_D \Rightarrow \Omega\Psi$ such that all arrows $\sigma_A : A \to \Psi\Omega A$ and $\tau_B : B \to \Omega\Psi B$ are isos. If such Ω and Ψ exist, then the categories C and D are called *equivalent*; if Ω and Ψ are in fact each other's inverse (both on maps and on arrows) then C and D are *isomorphic*. If Ω and Ψ form a *dual equivalence* between the categories C and D, that is, an equivalence between the categories C and D^{op}, then we say that the categories are *dual* or *dually equivalent* to each other.

1 MODAL LOGIC AS 'DIE KLASSENTHEORIE'

There are different views on the subject of Modal Logic. For the purpose of this chapter it is important to distinguish between two of them.

According to the *local* view, Modal Logic deals with a number of *concrete modal logics*. Since the beginning of the 20th century developers and users of Modal Logic from philosophy, mathematics, computer science, artificial intelligence, linguistics and other fields have introduced and investigated dozens of particular modal logics suitable for their

needs: *epistemic*, *provability*, *temporal*, *dynamic*, *description*, *spatial*, to mention just a few.

With the number of concrete modal logics introduced in the literature growing, there came an understanding that it may be interesting and important to formulate general abstract notions of modal logics and to investigate the landscape of the resulting classes of logics and their properties. The pioneers of this *global* approach were Scroggs [127] who considered all extensions of **S5**, Dummett and Lemmon [33] who studied all logics between **S4** and **S5**, Bull [14] and Fine [40] who investigated the logics containing **S4.3**, and Lemmon [86, 87, 88] and Segerberg [129] who launched a systematical investigation of various classes of modal logics. Two other influential figures that should also be mentioned here are Kuznetsov [81, 84, 85] and Jankov [67, 66, 68, 69] who investigated the class of all extensions of intuitionistic propositional logic which is closely related to the class of modal logics containing **S4**; see Section 9.

Although not formulated explicitly, the 'globalist's' dream research programme was to develop a mathematical machinery that could provide general solutions to the following major problems:[1]

1. given a class of models/structures, axiomatise the modal logic it determines, decide in an effective way whether it has certain important properties, say, decidability, compactness, interpolation, etc., and determine its computational complexity.

2. given a modal logic in the form of a finite set of axioms and inference rules, characterise the (simplest, smallest, largest, etc.) class of models/structures with respect to which this logic is sound and complete, decide in an effective way whether it has important properties as above, and determine its computational complexity.

This research programme is formulated in quite general terms and therefore can be interpreted in various ways. For example, it is not specified what kind of classes of frames/models we consider and what kind of axiomatic systems we take into account. Of course, different interpretations may lead to different solutions, but anyway first results within this ambitious programme looked very promising indeed! For example, Bull [14] proved that all extensions of **S4.3** have the finite model property and Fine [40] showed that all of them are finitely axiomatisable, and so decidable. (Actually, Dummett and Lemmon [33] claimed that all logics between **S4** and **S5** have the finite model property, but their proof was wrong: ten years later Jankov [68] constructed a counterexample.) In view of Makinson's theorem [94], one can effectively decide whether a given logic above **K** is consistent. Maksimova [95, 97] proved that two properties of logics containing **S4**—tabularity and interpolation—are decidable as well. It seems that many modal logicians did believe in an eventual success of this Big Programme.

In this chapter we analyse the development of Modal Logic within the research framework formulated above, starting from the beginning of the 1970s, although not necessarily in chronological order; for a historical analysis of mathematical modal logic the reader is referred to the recent paper of Goldblatt [57] and notes in [24]. Because of space limitations, we mainly concentrate on normal (multi-) modal logics and their decidability and completeness (in particular, with respect to Kripke or finite frames).

[1]Kuznetsov did formulate such problems *explicitly* in the context of superintuitionistic logics; e.g., given an axiomatisation of a superintuitionistic logic, can we decide in an effective way whether the logic is characterised by a finite algebra?

Roughly, our plan is as follows. We start in Section 2 with Thomason's explication (i′) of the *semantical* part (i) of the research programme above. Then, in Section 3, we lay the foundation for the most important *syntactical* notion of Modal Logic, namely, that of a *normal modal logic*. Having introduced an adequate semantics for normal modal logics in terms of *general frames*, we discuss in detail Blok's dichotomy in order to clarify the difference between Thomason's semantical definition of modal logics and the syntactically defined normal modal logics. Based on this discussion, we then come to the appropriate refinement (ii′) of the *syntactical* part (ii) of the research programme for normal modal logics and solutions to it given by Chagrov and Thomason.

Although beautiful from a mathematical point of view, the results of Thomason and Chagrov are 'negative' in the sense that almost all general algorithmic problems formulated in the Big Research Programme turn out to be undecidable. In the same way as the negative solution to the *classical decision problem* of Hilbert transformed the original problem into a *classification* problem, the 'negative' solution to the modal decision problems brings us down to a more 'modest' and realistic 'relativisation' of the programme to various syntactically or semantically defined classes of modal logics.

In Section 4, we consider logics axiomatised by formulas satisfying certain syntactical constraints, in particular, Sahlqvist formulas, uniform formulas, modal reduction principles, etc., and see whether such constraints allow us to prove general decidability/completeness results. In Section 5, we survey the literature on general decidability/completeness results for logics with some 'strong' axioms, say, extensions of tabular and pretabular logics, logics of finite depth and width, extensions of **S4.3**, **K5**, etc.

Then, in Section 6, we discuss an attempt to attack the Big Research Programme for normal extensions of **K4** (that is, unimodal logics with transitive general frames) and the tense logic **Lin** (of linear flows of time) by means of finite representations of modally definable classes of frames via frame and subframe formulas of Jankov and Fine [69, 41, 45] and more general 'canonical' formulas of [172, 174, 163]. This technique will be also used to draw and discuss connections between extensions of **S4** and superintuitionistic logics in Section 9.

In Section 7 we provide a 'positive' solution to the Big Research Programme for the class of all tense logics of linear flows of time. In fact, it turns out that for this class of logics all the questions posed in the programme are decidable (sometimes even in nondeterministic polynomial time).

In Section 8, we consider the class of subframe logics—i.e., logics determined by classes of (general) frames closed under the formation of substructures in the standard model-theoretic sense—and explore to what extent the research programme can be realised for this semantically defined class of modal logics.

A number of important open problems are formulated throughout the chapter.

2 THOMASON'S ANALYSIS

As we saw in Chapter 1, the standard propositional modal language with a countably infinite set of propositional variables (say, $p_0, p_1, \dots$), the Boolean connectives $\wedge$, $\neg$ (and their derivatives $\rightarrow$, $\vee$, etc.) and unary modal operators $\Box_1, \dots, \Box_n$ can be regarded as a basic tool for talking about relational structures $\mathfrak{F} = \langle W, R_1, \dots, R_n \rangle$, where the R_i are binary relations on $W \neq \emptyset$. We denote this *n-modal language* by $\mathcal{ML}_n$ and call $\mathfrak{F}$ an *n-frame* or simply a (*Kripke*) *frame*, if n is understood.

$\mathcal{ML}_n$ is interpreted in n-frames by means of *valuations* $\mathfrak{V}$ which associate with every propositional variable p_i a subset $\mathfrak{V}(p_i)$ of W. The pair $\mathfrak{M} = (\mathfrak{F}, \mathfrak{V})$ is called a (*Kripke*) *model* based on $\mathfrak{F}$. Given an $\mathcal{ML}_n$-formula φ, the *truth-relation* $(\mathfrak{M}, x) \models \varphi$, read as '*$\varphi$ is true at x in $\mathfrak{M}$*' (for $x \in W$), is defined by induction on the construction of φ as follows:

$$
\begin{array}{lll}
(\mathfrak{M}, x) \models p_i & \text{iff} & x \in \mathfrak{V}(p_i), \\
(\mathfrak{M}, x) \models \psi \wedge \chi & \text{iff} & (\mathfrak{M}, x) \models \psi \text{ and } (\mathfrak{M}, x) \models \chi, \\
(\mathfrak{M}, x) \models \neg\psi & \text{iff} & \text{not } (\mathfrak{M}, x) \models \psi, \\
(\mathfrak{M}, x) \models \Box_j\psi & \text{iff} & (\mathfrak{M}, y) \models \psi \text{ for all } y \in W \text{ such that } xR_jy.
\end{array}
$$

If $(\mathfrak{M}, x) \models \varphi$ does not hold then we write $(\mathfrak{M}, x) \not\models \varphi$ and say that $\mathfrak{M}$ *refutes* φ at x. Instead of $(\mathfrak{M}, x) \models \varphi$ and $(\mathfrak{M}, x) \not\models \varphi$ we write simply $x \models \varphi$ and $x \not\models \varphi$, if $\mathfrak{M}$ is understood. A formula φ is said to be *true in* $\mathfrak{M}$ ($\mathfrak{M} \models \varphi$, in symbols) if $x \models \varphi$ for all $x \in W$; φ is *satisfied in* $\mathfrak{M}$ if $x \models \varphi$ for some $x \in W$. We say that φ is *valid* in the frame $\mathfrak{F}$ (or $\mathfrak{F}$ *validates* φ) and write $\mathfrak{F} \models \varphi$ if φ is true in all models based on $\mathfrak{F}$; φ is *satisfiable in* $\mathfrak{F}$ if it is satisfied in some model based on $\mathfrak{F}$. For a set Γ of $\mathcal{ML}_n$-formulas, we say that $\mathfrak{F}$ is a *frame for* Γ if all formulas from Γ are valid in $\mathfrak{F}$. In this case we write $\mathfrak{F} \models \Gamma$. A formula φ is Γ-*satisfiable* if it is satisfiable in a frame for Γ. Finally, we write $\Gamma \models\!\!\!\!\!\!\;\approx \varphi$ if φ is valid in every frame for Γ (that is, if φ is a *semantic consequence of* Γ *over Kripke frames*).

As in classical first-order logic, given a class $\mathcal{K}$ of structures for our language—that is, a class of n-frames—we define the *theory* $\mathsf{Th}\,\mathcal{K}$ of $\mathcal{K}$ by the equation

$$\mathsf{Th}\,\mathcal{K} \quad = \quad \{\varphi \in \mathcal{ML}_n \mid \varphi \text{ is valid in every frame from } \mathcal{K}\}.$$

For example, as we know from Chapters 1 and 2, $\mathbf{K}_n$ is the theory of the class of all n-frames and **S4** is the theory of the class of all partial orders (or all quasi-orders).

Conversely, given a set Γ of $\mathcal{ML}_n$-formulas, denote by $\mathsf{Fr}\,\Gamma$ the class of frames for Γ. For example, $\mathsf{Fr}\,\{\Box p \to \Box\Box p\}$ is the class of all transitive frames $\mathfrak{F} = \langle W, R\rangle$. This and other similar results were in fact obtained by Kripke in his seminal paper [79].

Being equipped with these notions and notations, let us take a closer look at the research programme from Section 1. Clearly, problem (i) depends on *how exactly* the class of models/frames we are interested in is presented. For example, it can be given as the class of structures satisfying certain first- or second-order sentences. This understanding of (i) would lead us to the branch of Modal Logic known as *correspondence theory* (which is partially considered in Chapters 1 and 5; see also [153]). In the pure modal perspective, it makes sense to describe frame classes by means of modal formulas, namely as $\mathsf{Fr}\,\{\varphi\}$, for $\varphi \in \mathcal{ML}_n$. Thus, we arrive to our first precise approximation of (i):

(i′) given an arbitrary $\mathcal{ML}_n$-formula φ, axiomatise $\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\} = \{\psi \in \mathcal{ML}_n \mid \varphi \models\!\!\!\!\!\!\;\approx \psi\}$, decide in an effective way whether $\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\}$ has certain important properties, say, consistency, decidability, interpolation, etc., and determine its computational complexity.

Note that this problem is not as trivial as it might look from first sight. Of course, for numerous formulas φ the theory $\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\}$ was axiomatised and thoroughly investigated a long time ago. Well-known examples are, for instance, $\mathbf{T} = \mathsf{Th}\,\mathsf{Fr}\,\{\Box p \to p\}$, the theory of the reflexive frames, and $\mathbf{K4} = \mathsf{Th}\,\mathsf{Fr}\,\{\Box p \to \Box\Box p\}$, the theory of the transitive

frames; see Chapters 1 and 2. Our concern here, however, is not some particular formulas, but effective axiomatisation procedures which could work for *all* modal formulas. Such a procedure is available, for example, for first-order logic: by Gödel's completeness theorem, given a first-order sentence φ, we can axiomatise the theory of structures validating φ by adding φ as an extra axiom to any standard Hilbert-style first-order system. But do we have a Gödel-type completeness theorem for $\mathcal{ML}_n$ with respect to Kripke frames?

A comprehensive analysis of problem (i′) was launched by S. Thomason in his series of papers [140, 141, 143, 145, 144].

THEOREM 1 (Thomason). (a) *There is an $\mathcal{ML}_1$-formula φ such that the set*

$$\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\} \quad = \quad \{\psi \in \mathcal{ML}_1 \mid \varphi \models \psi\}$$

is Π^1_1-complete (in particular, it is not recursively enumerable).

(b) *There is no algorithm which is capable of deciding, given an $\mathcal{ML}_2$-formula φ, whether the theory $\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\}$ is consistent, or, equivalently, whether there exists a 2-frame validating φ.*

(c) *There is a set Γ of $\mathcal{ML}_1$-formulas and an $\mathcal{ML}_1$-formula φ such that $\Gamma \models \varphi$, but $\Delta \not\models \varphi$ for any finite $\Delta \subset \Gamma$.*

(d) *For every $n < \omega + \omega$, there is an $\mathcal{ML}_2$-formula γ_n such that every rooted frame validating γ_n is of cardinality $\beth_n$ and, moreover, all such frames are isomorphic.*[2] *(Here $\beth_0 = \aleph_0$, $\beth_{m+1} = 2^{\beth_m}$, and $\beth_\omega = \lim\{\beth_m \mid m < \omega\}$.)*

Theorem 1 (a) shows that the first part of research problem (i′) cannot be solved, while both (a) and (b) indicate that the second part is also hopeless. In fact, this theorem clearly shows that modal theories behave similarly to second-order logic: we do not have any of the classical properties of first-order logic such as compactness, recursive enumerability of valid formulas or the Löwenheim–Skolem theorem. Interestingly, rather simple $\mathcal{ML}_1$-formulas φ such that $\mathsf{Fr}\,\{\varphi\}$ is not first-order definable had already been constructed by Segerberg [129]. Perhaps, the best known example is the *Löb formula*

$$\boldsymbol{la} = \Box(\Box p \to p) \to \Box p$$

which is valid in a frame $\mathfrak{F} = \langle W, R\rangle$ iff $\mathfrak{F}$ is transitive and contains no infinite ascending chain $x_1 R x_2 R x_3 \dots$. The latter condition is not definable in first-order logic.

Thomason proved his results by constructing (rather complex and 'artificial') multi-modal formulas with the required properties. To obtain (a) and (c) he showed that multi-modal logics can be reduced to unimodal logics with similar properties. (For a discussion of this kind of reductions see Chapter 8.) Now (in 2005) we know more simple and natural bimodal formulas with the properties of φ in (a) of Theorem 1. Take, for example, the conjunction φ of the following formulas:

$$\Box_1(\Box_1 p \to p) \to \Box_1 p, \qquad \Box_2(\Box_2 p \to p) \to \Box_2 p, \tag{1}$$

$$\Box_1(\Box_1 p \to q) \vee \Box_1(\Box_1 q \to p), \qquad \Box_2(\Box_2 p \to q) \vee \Box_2(\Box_2 q \to p), \tag{2}$$

$$\Diamond_2\Diamond_1 p \leftrightarrow \Diamond_1\Diamond_2 p, \qquad \Diamond_1\Box_2 p \to \Box_2\Diamond_1 p. \tag{3}$$

(1) says that both boxes satisfy the Löb axiom above, (2) ensures that frames for $\Box_1$ and $\Box_2$ satisfy the connectedness condition

$$\forall x, y, z\ (xR_i y \wedge xR_i z \wedge y \neq z \to yR_i z \vee zR_i y),$$

[2] See also [16] and [75].

while (3) says that R_1 and R_2 commute and satisfy the Church–Rosser property, i.e.,

$$\forall x, z\,\big(\exists y\,(xR_2y \land yR_1z) \leftrightarrow \exists y\,(xR_1y \land yR_2z)\big),$$
$$\forall x\forall y\forall z\,\big(xR_2y \land xR_1z \to \exists u\,(yR_1u \land zR_2u)\big).$$

Typical frames validating φ are products of finite strict linear orders or infinite reverse well-founded linear orders like $\langle\{0,1,\dots,n\},<\rangle$ or $\langle\omega+1,>\rangle$, where

$$\begin{array}{lcl} \langle W_h, R_h\rangle \times \langle W_v, R_v\rangle & = & \langle W_h \times W_v, R_1, R_2\rangle, \\ (u,v)R_1(u',v') & \text{iff} & uR_hu' \text{ and } v = v', \\ (u,v)R_2(u',v') & \text{iff} & vR_vv' \text{ and } u = u'. \end{array}$$

(For more details about product frames and logics see Chapter 15). To show that validity in frames for φ is Π^1_1-hard, one can reduce the following Σ^1_1-complete *recurrent tiling problem* [62] to the satisfiability problem for $\mathcal{ML}_2$-formulas in frames for φ: 'given a finite set T of tile types (1×1-squares with colours along their edges) and a $t_0 \in T$, can T tile the $\mathbb{N}\times\mathbb{N}$-grid in such a way that colours on adjacent edges of adjacent tiles match and t_0 appears infinitely often in the first column?' For details the reader is referred to [49, 120].

Of course, the notion of validity in Kripke frames is of a second-order nature. Indeed, we can easily define a translation $\cdot^s$ of $\mathcal{ML}_n$ into monadic second-order logic with n extra binary relations $R_1,\dots,R_n$ by taking inductively

$$\begin{array}{lcl} p_i^s & = & P_i(x) \\ (\varphi\land\psi)^s & = & \varphi^s \land \psi^s \\ (\neg\varphi)^s & = & \neg\varphi^s \\ (\Box_i\varphi)^s & = & \forall y\ (xR_iy \to \varphi^s[y/x]), \end{array}$$

where y is a fresh variable. And then, for every frame $\mathfrak{F} = \langle W, R_1,\dots,R_n\rangle$ and every $\mathcal{ML}_n$-formula $\varphi(p_1,\dots,p_k)$, we have $\mathfrak{F}\models\varphi$ iff $\forall P_1\dots\forall P_k\forall x\ \varphi^s$ is true in $\mathfrak{F}$. This means that for every set $\Gamma\cup\{\varphi\}$ of $\mathcal{ML}_n$-formulas, $\Gamma \mathrel{|\!\!\!\asymp} \varphi$ iff φ^s is a logical consequence of $\{\gamma^s \mid \gamma\in\Gamma\}$ in second-order logic.

What is more surprising is that the full monadic second-order theory of a binary predicate can be reduced to propositional modal logic:

THEOREM 2 (Thomason). *There is an effective translation $\cdot^\sharp$ of the language $\mathcal{MSO}$ of monadic second-order logic with one extra binary relation into $\mathcal{ML}_1$, and there is an $\mathcal{ML}_1$-formula τ such that, for every set $\Xi\cup\{\zeta\}$ of $\mathcal{MSO}$-formulas,*

$$\zeta \text{ is a logical consequence of } \Xi \quad \text{iff} \quad \{\tau\}\cup\{\xi^\sharp \mid \xi\in\Xi\} \mathrel{|\!\!\!\asymp} \zeta^\sharp.$$

Thus, Thomason's [145] conclusion was that $\mathcal{ML}_n$ or even $\mathcal{ML}_1$ can be regarded as a rather strong fragment of second-order predicate logic and that the modal consequence relation $\mathrel{|\!\!\!\asymp}$ is as complex as it could be. In particular, there is an $\mathcal{ML}_1$-formula φ such that the set $\{\psi\in\mathcal{ML}_1 \mid \varphi \mathrel{|\!\!\!\asymp} \psi\}$ is not definable in number theory of any finite order.

3 NORMAL MODAL LOGICS

The analogy with second-order logic discussed above also indicated a way of 'regaining' nice properties of first-order logic (compactness, recursive enumerability and Löwenheim–Skolem). Recall (see, e.g., [34]) that following Henkin's idea of introducing a special

universe over which the predicates can be interpreted, one can obtain an essentially first-order semantics—known as *general structures*—for second-order logic. Actually, this appears to be Thomason's [141] motivation for introducing *general frames* (which he called *first-order semantics* for modal logic).[3] The idea is very simple: restrict the range of the valuation function $\mathfrak{V}$ in the definition of Kripke models to some subset of 2^W that is closed under the available operations. This leads us to the following definition.

A *general n-frame* is a structure of the form

$$\mathfrak{G} \quad = \quad \langle W, R_1, \ldots, R_n, P \rangle ,$$

where $\langle W, R_1, \ldots, R_n \rangle$ is an ordinary Kripke frame and P is a subset of 2^W containing W and closed under set-theoretic intersection and complementation as well as under the operations

$$\Box_i X \quad = \quad \{x \in W \mid \forall y\ (xR_i y \to y \in X)\},$$

for all $i = 1, \ldots, n$. As before, the language $\mathcal{ML}_n$ is interpreted in general frames by means of *valuations* $\mathfrak{V}$ which associate with every propositional variable p_i a set $\mathfrak{V}(p_i)$. The only difference is that now $\mathfrak{V}(p_i)$ *must belong to* P. The pair $\mathfrak{M} = \langle \mathfrak{G}, \mathfrak{V} \rangle$ is called then a *model* based on the general frame $\mathfrak{G}$. The remaining semantical notions are defined in precisely the same way as for Kripke models, e.g., $\mathsf{Th}\,\mathcal{K}$, a general frame for a logic, etc. To simplify notation, we denote general frames of the form $\mathfrak{F} = \left\langle W, R_1, \ldots, R_n, 2^W \right\rangle$ by $\mathfrak{F} = \langle W, R_1, \ldots, R_n \rangle$ (because the theories of these frames are the same).

The first radical difference between Kripke and general frames is that the set of theories of classes of general frames can be characterised *syntactically*. Say that a subset L of $\mathcal{ML}_n$ is a *normal n-modal logic* if it contains the tautologies of classical propositional logic, the formulas

$$\Box_i (p \to q) \to (\Box_i p \to \Box_i q)$$

for all $i = 1, \ldots, n$, and is closed under the rules of uniform substitution, modus ponens and *necessitation* $\varphi / \Box_i \varphi$. The smallest normal n-modal logic is known to be $\mathbf{K}_n$; it clearly coincides with the theory of the class GFr of all general n-frames.

Now, given a set Γ of $\mathcal{ML}_n$-formulas, denote by $\mathbf{K}_n \oplus \Gamma$ the minimal normal n-modal logic containing Γ, and by $\mathsf{GFr}\,\Gamma$ the class of general frames for Γ.

THEOREM 3. (a) *For every class $\mathcal{K}$ of general n-frames,* $\mathsf{Th}\,\mathcal{K}$ *is a normal n-modal logic. More precisely,*

$$\mathsf{Th}\,\mathcal{K} \quad = \quad \mathbf{K}_n \ \oplus\ \{\varphi \in \mathcal{ML}_n \mid \varphi \textit{ is valid in every general frame from } \mathcal{K}\}.$$

(b) *For every set Γ of $\mathcal{ML}_n$-formulas,*

$$\mathbf{K}_n \ \oplus\ \Gamma \quad = \quad \mathsf{Th}\,\mathsf{GFr}\,\Gamma.$$

(Some comments on the proof of this theorem will be given later on in this section; see also Chapter 5.)

From now on, instead of $\mathsf{Th}\,\mathcal{K}$ we will write $\mathsf{Log}\,\mathcal{K}$ and call it the (*normal n-modal*) *logic characterised* (or *determined*) *by* $\mathcal{K}$. The set of all normal n-modal logics containing

[3] In fact, general frames were also introduced in 1951 by Jónsson and Tarski [71] as Stone-like representations of Boolean algebras with operators; see [57] for more references, details and discussion.

a logic L will be denoted by $\mathrm{NExt}\, L$. In particular, $\mathrm{NExt}\, \mathbf{K}_n$ is the set of all normal n-modal logics. Thus,

$$\mathrm{NExt}\, \mathbf{K}_n \quad = \quad \{\mathbf{K}_n \oplus \Gamma \mid \Gamma \subseteq \mathcal{ML}_n\} \quad = \quad \{\mathsf{Log}\, \mathcal{K} \mid \mathcal{K} \subseteq \mathsf{GFr}\,\}.$$

Let Kripke_n be the set of all *Kripke complete* normal n-modal logics, that is

$$\mathsf{Kripke}_n \quad = \quad \{\mathsf{Log}\, \mathcal{K} \mid \mathcal{K} \text{ a class of Kripke } n\text{-frames}\}.$$

As follows from Theorem 1 (a), Kripke_n is a *proper* subset of $\mathrm{NExt}\, \mathbf{K}_n$. Indeed, take a formula φ such that $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$ is not recursively enumerable and consider the normal modal logic $\mathbf{K}_n \oplus \varphi$. Then

$$\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\} \quad \supsetneqq \quad \mathsf{Log}\,\mathsf{GFr}\,\{\varphi\} \quad = \quad \mathbf{K}_n \ \oplus \ \varphi$$

simply because $\mathbf{K}_n \oplus \varphi$ is recursively enumerable. On the other hand, $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$ and $\mathsf{Log}\,\mathsf{GFr}\,\{\varphi\}$ have precisely the same Kripke frames, and so the latter cannot be Kripke complete. The logic $\mathbf{K}_2 \oplus (1) \oplus (2) \oplus (3)$ is probably the 'simplest natural' Kripke incomplete normal modal logic.

So what is the relation between the classes Kripke_n and $\mathrm{NExt}\, \mathbf{K}_n$? What can be said about the class $\mathrm{NExt}\, \mathbf{K}_n - \mathsf{Kripke}_n$?

3.1 Blok's dichotomy

The first examples of Kripke incomplete logics were discovered by Thomason [141, 142] and Fine [42]. In order to understand the phenomenon of Kripke incompleteness more deeply, Fine proposed to investigate how many logics may share the same Kripke frames with a given normal (uni)modal logic L. The cardinality of the set

$$\{L' \in \mathrm{NExt}\, \mathbf{K} \mid \mathsf{Fr}\, L \ = \ \mathsf{Fr}\, L'\}$$

was called by Fine the *degree of Kripke incompleteness* of L. A very interesting complete solution to this problem was found by Blok [8]. The key player in his solution was the concept of splitting originating in lattice theory [106] (for details see Chapter 8).

To explain the idea behind Blok's result informally, let us observe first that a Kripke complete logic L is always the maximal logic in the set $\{L' \mid \mathsf{Fr}\, L' = \mathsf{Fr}\, L\}$. Now suppose that L is a Kripke complete logic with the following property: there exists a Kripke frame $\mathfrak{F}$ such that L is the smallest logic in the class $\{L' \in \mathrm{NExt}\, \mathbf{K} \mid \mathfrak{F} \notin \mathsf{Fr}\, L'\}$. Then the degree of Kripke incompleteness of L is 1. Indeed, assume that L' is a normal modal logic with $\mathsf{Fr}\, L = \mathsf{Fr}\, L'$. Then $\mathfrak{F} \notin \mathsf{Fr}\, L'$, and so $L \subseteq L'$. To prove $L' \subseteq L$, assume $\varphi \notin L$. As L is Kripke complete, there exists a Kripke frame $\mathfrak{F}' \in \mathsf{Fr}\, L$ such that $\mathfrak{F}' \not\models \varphi$. And since $\mathfrak{F}' \in \mathsf{Fr}\, L'$, we then have $\varphi \notin L'$. Of course, the same argument goes through if instead of just one frame $\mathfrak{F}$ we take some set of frames.

Thus, we can try to generate modal logics with degree of Kripke incompleteness 1 by taking sets $\mathcal{F}$ of frames, proving that the smallest normal logic $L_{\mathcal{F}}$ in the class $\{L' \in \mathrm{NExt}\, \mathbf{K} \mid \exists \mathfrak{F} \in \mathcal{F}\, \mathfrak{F} \notin \mathsf{Fr}\, L'\}$ *exists* and showing its Kripke completeness. Blok's achievement was that he (a) characterised sets $\mathcal{F}$ of frames for which the logics $L_{\mathcal{F}}$ exist, (b) proved that all these $L_{\mathcal{F}}$ are Kripke complete (actually, have the finite model property), and (c) showed that any normal modal logic different from such $L_{\mathcal{F}}$ has degree of Kripke incompleteness $2^{\aleph_0}$.

We now introduce the notions required to explain Blok's result in more detail. Given a logic $L_0 \in \mathrm{NExt}\,\mathbf{K}$, we say that a (finite rooted) frame $\mathfrak{F}$ *splits* $\mathrm{NExt}\,L_0$ if $\mathfrak{F}$ is not a frame for the normal modal logic

$$L_1 \quad = \quad \bigcap\{L \in \mathrm{NExt}\,L_0 \mid \mathfrak{F} \not\models L\}.$$

In this case we denote L_1 by $L_0/\mathfrak{F}$ and call it the *splitting* of $\mathrm{NExt}\,L_0$ *by* $\mathfrak{F}$. This notation reflects the fact that $L_0/\mathfrak{F}$ is the *smallest* logic in $\mathrm{NExt}\,L_0$ which does not have $\mathfrak{F}$ as its frame. If all frames in a set $\mathcal{F}$ split $\mathrm{NExt}\,L_0$, we call $\bigoplus\{L_0/\mathfrak{F} \mid \mathfrak{F} \in \mathcal{F}\}$—i.e., the smallest normal modal logic containing $\bigcup\{L_0/\mathfrak{F} \mid \mathfrak{F} \in \mathcal{F}\}$—the *union-splitting of* $\mathrm{NExt}\,L_0$ *by* $\mathcal{F}$ and denote it by $L_0/\mathcal{F}$.

EXAMPLE 4. Denote by $\bullet$ the Kripke frame which consists of a single irreflexive point. A frame comprised of a single reflexive point is denoted by $\circ$.

(a) $\bullet$ splits $\mathrm{NExt}\,\mathbf{K}$ and $\mathbf{D} = \mathbf{K}/\bullet$ (we remind the reader that $\mathbf{D} = \mathbf{K} \oplus \Diamond\top$ is characterised by the class of *serial* Kripke frames in which every point has a successor). To see this, set

$$L_1 \quad = \quad \bigcap\{L \in \mathrm{NExt}\,\mathbf{K} \mid \bullet \not\models L\}.$$

Since, for every $L \in \mathrm{NExt}\,\mathbf{K}$, $\bullet \not\models L$ iff $\Diamond\top \in L$, L_1 is the intersection of all normal modal logics containing $\Diamond\top$. But $\mathbf{D}$ is the smallest such logic and therefore $L_1 = \mathbf{D}$.

(b) $\circ$ does not split $\mathrm{NExt}\,\mathbf{K}$. To see this recall that $\mathbf{K}$ is determined by the class of finite frames $\mathfrak{F} = \langle W, R\rangle$ without cycles (i.e., R-paths from a point to itself); see, e.g., Chapter 1. For every such $\mathfrak{F}$, we have $\circ \not\models \mathsf{Log}\,\{\mathfrak{F}\}$ because there exists $n < \omega$ such that $\Box^n\bot \in \mathsf{Log}\,\{\mathfrak{F}\}$, but $\circ \not\models \Box^n\bot$. Therefore,

$$\bigcap\{L \in \mathrm{NExt}\,\mathbf{K} \mid \circ \not\models L\} \quad \subseteq \quad \bigcap\{\mathsf{Th}\,\mathfrak{F} \in \mathrm{NExt}\,\mathbf{K} \mid \mathfrak{F} \text{ finite and cycle free }\} \quad = \quad \mathbf{K}$$

which means that there does *not* exist a smallest normal modal logic without $\circ$ among its frames.

(c) No frame with cycles splits $\mathrm{NExt}\,\mathbf{K}$. The argument is similar to that in (b): just use the fact that no $\Box^n\bot$ is valid in a frame with cycles.

(d) Every finite cycle-free rooted frame splits $\mathrm{NExt}\,\mathbf{K}$. To prove this, we associate with every finite rooted frame $\mathfrak{F} = \langle W, R\rangle$ the formula

$$\delta_{\mathfrak{F}} \quad = \quad \bigwedge_{xRy}(p_x \to \Diamond p_y) \wedge \bigwedge_{\neg xRy}(p_x \to \neg\Diamond p_y) \wedge \bigwedge_{x \neq y}(p_x \to \neg p_y) \wedge \bigvee_{x \in W} p_x.$$

Suppose now that $\mathfrak{F}$ is cycle free, r is a root of $\mathfrak{F}$, $d(\mathfrak{F})$ is the *depth* of $\mathfrak{F}$ (i.e., the length of the longest R-path in $\mathfrak{F}$), and $\Box^{\leq n}\varphi = \varphi \wedge \Box\varphi \wedge \cdots \wedge \Box^n\varphi$. It is not hard to see then that a (general) frame $\mathfrak{G}$ satisfies $\Box^{\leq d(\mathfrak{F})}\delta_{\mathfrak{F}} \wedge p_r$ iff there is a generated subframe $\mathfrak{H}$ of $\mathfrak{G}$ which can be p-morphically mapped onto $\mathfrak{F}$. It follows that the smallest normal logic without $\mathfrak{F}$ among its frames exists and can be axiomatised as

$$\mathbf{K}/\mathfrak{F} \quad = \quad \mathbf{K} \oplus \Box^{\leq d(\mathfrak{F})}\delta_{\mathfrak{F}} \to \neg p_r. \tag{4}$$

(e) The *inconsistent logic*—i.e., $\mathcal{ML}_1$—can be represented as $\mathbf{D}/\circ = (\mathbf{K}/\bullet)/\circ$ (actually this is a variant of Makinson's theorem [94]).

(f) Note by the way that if $L_0 \in \mathrm{NExt}\,\mathbf{K4}$ then *every* finite rooted transitive frame $\mathfrak{F}$ for L_0 splits $\mathrm{NExt}\,L_0$ and $L_0/\mathfrak{F} = L_0 \oplus \Box^{\leq 1}\delta_{\mathfrak{F}} \to \neg p_r$ (a (general) transitive frame $\mathfrak{G}$

satisfies $\Box^{\leq 1}\delta_{\mathfrak{F}} \wedge p_r$ iff there is a generated subframe $\mathfrak{H}$ of $\mathfrak{G}$ which can be p-morphically mapped onto $\mathfrak{F}$).

Now, returning back to the degree of Kripke incompleteness, we obtain the first part of Blok's dichotomy:

THEOREM 5 (Blok). (i) *A finite rooted frame $\mathfrak{F}$ splits* NExt **K** *iff it is cycle free. In this case we have $\mathbf{K}/\mathfrak{F} = \mathbf{K} \oplus \Box^{\leq n}\delta_{\mathfrak{F}} \to \neg p_r$, where $n = d(\mathfrak{F})$.*

(ii) *Every union-splitting of* NExt **K** *has the finite model property, and so its degree of Kripke incompleteness is* 1.

The proof of (ii) is by a variant of standard filtration (see Chapter 1). By (e) from the example above, the inconsistent logic $\mathcal{ML}_1$ also has degree of Kripke incompleteness 1 (it may be of interest to note that the degree of Kripke incompleteness of $\mathcal{ML}_2$ in NExt $\mathbf{K}_2$ is $2^{\aleph_0}$). The second part of Blok's dichotomy states that all normal modal logics not covered by Theorem 5 have degree of Kripke incompleteness $2^{\aleph_0}$:

THEOREM 6 (Blok). *If a logic L is inconsistent or a union-splitting of* NExt **K**, *then L has degree of Kripke incompleteness* 1. *Otherwise L has degree of Kripke incompleteness* $2^{\aleph_0}$ *in* NExt **K**.

Before we sketch a proof of this result it is worth spending some time on its interpretation. First, it means that **D** is the only 'standard' normal modal logic with degree of Kripke incompleteness 1. Logics like **S5**, **T**, **K4**, and **S4** have degree of incompleteness $2^{\aleph_0}$. In fact, every consistent normal logic containing **K4** or containing **D** properly as well as every consistent tabular normal modal logic (a logic is *tabular* if it is determined by a single finite frame; see Section 5), has degree of Kripke incompleteness $2^{\aleph_0}$. Second, in frame-theoretic terms it means that for every modally definable class $\mathcal{F}$ of, say, transitive frames (that is, $\mathcal{F} = \mathsf{Fr}\,\Gamma$ for some set Γ of modal formulas containing $\Box p \to \Box\Box p$) there exist uncountably many different $L \in$ NExt **K** such that

$$\mathcal{F} \quad = \quad \mathsf{Fr}\,L.$$

This applies, for example, to the class of all frames based on equivalence relations, quasi-orders, linear orders, and so on.

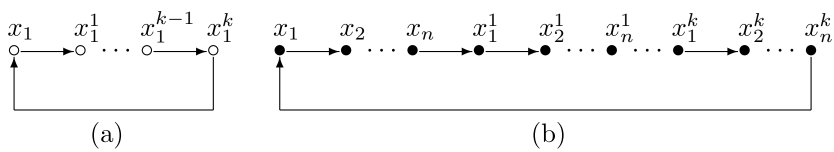

Figure 1.

Proof. Suppose that a consistent L is not a union-splitting and L' is the greatest union-splitting contained in L. Since L' has the finite model property, there is a finite rooted frame $\mathfrak{F} = \langle W, R\rangle$ for L' refuting some $\varphi \in L$ and such that every proper generated subframe of $\mathfrak{F}$ validates L. Clearly, $\mathfrak{F}$ is not cycle free. Let $x_1 R x_2 R \ldots R x_n R x_1$ be the shortest cycle in $\mathfrak{F}$ and $k = md(\varphi)+1$. We construct a new frame $\mathfrak{F}'$ by extending the cycle $x_1, \ldots, x_n, x_1$ as shown in Fig. 1 ((a) for $n = 1$ and (b) for $n > 1$). More precisely, we add to $\mathfrak{F}$ copies $x_i^1, \ldots, x_i^k$ of x_i for each $i \in \{1, \ldots, n\}$, organise them into the nontransitive cycle shown in Fig. 1 and draw an arrow from x_i^j to $y \in W - \{x_1, \ldots, x_n\}$ iff $x_i R y$.

Denote the resulting frame by $\mathfrak{F}' = \langle W', R' \rangle$ and let $x' = x_n^k$. By the construction, $\mathfrak{F}$ is a p-morphic image of $\mathfrak{F}'$. Therefore, for all models $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ and $\mathfrak{M}' = \langle \mathfrak{F}', \mathfrak{V}' \rangle$ such that

$$\mathfrak{V}'(p) \quad = \quad \mathfrak{V}(p) \cup \{x_i^j \mid x_i \in \mathfrak{V}(p),\ j < k\}$$

and for every $x \in W$ and every subformula ψ of φ, we have $(\mathfrak{M}, x) \models \psi$ iff $(\mathfrak{M}', x) \models \psi$. So we can hook some other model on x', and points in W will not feel its presence by means of φ's subformulas. The frame to be hooked on x' depends on whether $\bullet \models L$ or $\circ \models L$. We consider only the former alternative.

Fix some $m > |W'|$. For each $I \subseteq \omega - \{0\}$, let $\mathfrak{F}_I = \langle W_I, R_I, P_I \rangle$ be the frame whose diagram is shown in Fig. 2 (d_0 sees the root of $\mathfrak{F}'$, all points e_i and e'_j and is seen from x'; the subframes in dashed boxes are transitive, $e'_i \in W_I$ iff $i \in I$, and P_I consists of sets of the form $X \cup Y$ such that X is a finite or cofinite subset of $W_I - \{b, a_i \mid i < \omega\}$ and Y is either a finite subset of $\{a_i \mid i < \omega\}$ or is of the form $\{b\} \cup Y'$, where Y' is a cofinite subset of $\{a_i \mid i < \omega\}$. It is not hard to see that the points a_i, c, e_i and e'_i are

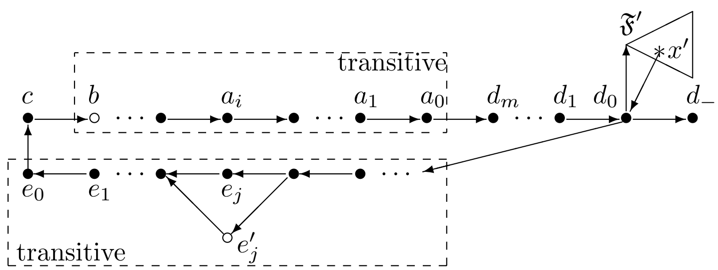

Figure 2.

characterised by the variable free formulas

$$\alpha_0 \;=\; \Diamond(\delta_m \wedge \Diamond(\delta_{m-1} \wedge \cdots \wedge \Diamond\delta_0)\cdots) \wedge \neg\Diamond^2(\delta_m \wedge \Diamond(\delta_{m-1} \wedge \cdots \wedge \Diamond\delta_0)\cdots),$$

$$\alpha_{i+1} \;=\; \Diamond\alpha_i \wedge \neg\Diamond^2\alpha_i, \qquad \gamma \;=\; \Diamond^2\alpha_0 \wedge \neg\Diamond\alpha_0,$$

$$\epsilon_0 \;=\; \Diamond\gamma, \qquad \epsilon_{i+1} \;=\; \Diamond\epsilon_i \wedge \neg\Diamond^2\epsilon_i, \qquad \epsilon'_{i+1} \;=\; \Diamond\epsilon_i \wedge \neg\Diamond^+\epsilon_{i+1},$$

(in the sense that $x \models \alpha_i$ iff $x = a_i$, etc.), where

$$\delta_0 \;=\; \Diamond\Box\bot, \qquad \delta_1 \;=\; \Diamond\delta_0 \wedge \neg\delta_0, \qquad \delta_2 \;=\; \Diamond\delta_1 \wedge \neg\delta_1 \wedge \neg\Diamond^+\delta_0,$$

$$\delta_{k+1} \;=\; \Diamond\delta_k \wedge \neg\delta_k \wedge \neg\Diamond^+\delta_{k-1} \wedge \cdots \wedge \neg\Diamond^+\delta_0.$$

Define L_I to be the logic determined by the class of frames for L and $\mathfrak{F}_I$, that is, $L_I = L \cap \mathsf{Log}\,\mathfrak{F}_I$. Since $\neg(\epsilon'_i \wedge \Diamond^{m+6}\neg\varphi) \in L_J - L_I$ for $i \in I - J$ (φ is refuted at the root of $\mathfrak{F}'$), $\left|\{L_I \mid I \subseteq \omega - \{0\}\}\right| = 2^{\aleph_0}$.

Let us show now that L_I has the same Kripke frames as L. Since $L_I \subseteq L$, we must prove that every Kripke frame for L_I validates L. Suppose there is a rooted Kripke frame $\mathfrak{G}$ such that $\mathfrak{G} \models L_I$ but $\mathfrak{G} \not\models \psi$, for some $\psi \in L$. Since ψ is in L, it is valid in all frames for L, in particular, $\bullet \models \psi$. And since $\psi \notin L_I$, ψ is refuted in $\mathfrak{F}_I$. Moreover, by the construction of $\mathfrak{F}_I$, it is refuted at a point from which the root of $\mathfrak{F}'$ can be reached by

a finite number of steps. Therefore, the following formulas are valid in $\mathfrak{F}_I$ and so belong to L_I and are valid in $\mathfrak{G}$:

$$\neg\psi \to \bigvee_{i=0}^{l} \Diamond^i \gamma, \tag{5}$$

$$\neg\psi \to \bigwedge_{i=0}^{l} \Box^i \big(\gamma \to \Box(\Box_0(\Box_0 p \to p) \to p)\big), \tag{6}$$

where p does not occur in ψ and l is a sufficiently big number so that any point in $\mathfrak{F}_I$ is accessible by $\leq l$ steps from every point in the selected cycle and every point at which ψ may be false, and $\Box_0\chi = \Box(\Diamond\alpha_0 \to \chi)$. According to (5), $\mathfrak{G}$ contains a point where γ is true. By the construction of γ, this point has a successor y where, by (6), $\Box_0(\Box_0 p \to p) \to p$ is true *under any valuation* in $\mathfrak{G}$ and $y \models \Diamond\alpha_0$. Define a valuation $\mathfrak{U}$ in $\mathfrak{G}$ by taking $\mathfrak{U}(p) = y\!\uparrow$, where $y\!\uparrow$ is the set of all points accessible from y. Then $y \models \Box_0(\Box_0 p \to p)$, from which $y \models p$ and so $y \in y\!\uparrow$. Now define another valuation $\mathfrak{U}'$ so that $\mathfrak{U}'(p) = y\!\uparrow - \{y\}$. Since y is reflexive, we again have $y \models \Box_0(\Box_0 p \to p)$, whence $y \models p$, which is a contradiction. ❑

Blok's dichotomy can be generalised in various directions. First, it holds for the languages $\mathcal{ML}_n$ and the corresponding classes NExt $\mathbf{K}_n$ as well; see [92]. And second, it can be extended to completeness with respect to the neighbourhood semantics [27] as well as some other, algebraically motivated, semantics for normal modal logics [92]. On the other hand, the following major problem remains open:

PROBLEM 1. Characterise the degree of Kripke incompleteness of 'transitive' logics in the classes NExt $\mathbf{K4}$, NExt $\mathbf{S4}$, etc., where Theorem 5 does not hold.

One conclusion to be drawn from these results is that Kripke complete logics are rather exceptional, that Kripke completeness of syntactically defined 'standard' modal logics is a kind of good luck. Another conclusion is that instead of considering logics in the class Kripke_n it may be worthwhile to move to the larger class NExt $\mathbf{K}_n$. First, as we know from other disciplines, more general settings can be very useful (for example, various problems about natural or rational numbers can only be analysed in the framework of real numbers). The second reason is that NExt $\mathbf{K}_n$ is quite natural not only from the syntactical point of view. In fact, as follows from Chapters 6 and 8, the lattice $\langle \text{NExt}\,\mathbf{K}_n, \subseteq\rangle$ is dually isomorphic to the lattice of varieties (alias equational theories) of Boolean algebras with operators. This means, in particular, that ideas and techniques from universal algebra are more suitable for investigating NExt $\mathbf{K}_n$ rather than Kripke_n.

Thus, it makes sense to extend the research programme above to the class of all normal n-modal logics.

Research programme for normal modal logics

Within the framework of normal modal logics, the original research programme can be interpreted as follows. By Thomason's Theorem 1, we know that (i′) is not realisable. The reformulation of (i′) for general frames has a trivial solution—just remember that $\mathsf{Log}\,\mathsf{GFr}\,\{\varphi\}$ is axiomatised as $\mathbf{K}_n \oplus \varphi$. Instead, we suggest the following reformulation a solution to which would clearly show how complex it is to axiomatise logics determined by classes of (general) frames:

(i″) Characterise those modal formulas φ for which we can effectively recognise whether $\mathbf{K} \oplus \psi$ axiomatises $\mathsf{Log\,GFr}\,\{\varphi\}$. Characterise those formulas φ for which we can effectively recognise whether $\mathbf{K} \oplus \psi$ axiomatises $\mathsf{Log\,Fr}\,\{\varphi\}$. For example, is there an algorithm which decides, for a formula ψ, whether $\mathbf{K} \oplus \psi$ axiomatises the logic of all transitive frames (i.e., $\mathsf{Log\,Fr}\,\{\Box p \to \Box\Box p\}$), reflexive frames (i.e., $\mathsf{Log\,Fr}\,\{\Box p \to p\}$), etc.?

The first part of (i″) can be reformulated as an axiomatisation problem. Given a modal formula φ and a logic $L_0 \in \mathrm{NExt}\,\mathbf{K}$, we say that the *axiomatisation problem* for $L_0 \oplus \varphi$ is *decidable above* L_0 if the set $\{\psi \in \mathcal{ML}_1 \mid L_0 \oplus \psi = L_0 \oplus \varphi\}$ is recursive. Then the first part of (i″) asks for a characterisation of those modal formulas φ for which the axiomatisation problem for $\mathbf{K} \oplus \varphi$ is decidable.

Being equipped with the notion of a normal modal logic, we can give a precise interpretation of the syntactically formulated problem (ii) from Section 1:

(ii″) Given a modal formula φ, characterise the (simplest, smallest, largest, etc.) class of frames with respect to which $\mathbf{K} \oplus \varphi$ is sound and complete. In particular, is it decidable whether the logic $\mathbf{K}\oplus\varphi$ is Kripke complete, has the finite model property, is determined by a finite frame? Furthermore, can we effectively recognise, given a modal formula φ, whether $\mathbf{K} \oplus \varphi$ is decidable, compact, has interpolation, etc.?

3.2 Chagrov's classification

Rather surprisingly, the *partition* of NExt $\mathbf{K}$ into union-splittings and non-union-splittings not only gives a concise solution to the problem of locating Kripke_n within NExt $\mathbf{K}_n$, but also provides means to attack (i″). A comprehensive solution was found by A. Chagrov.

To explain the intuition behind Chagrov's classification result for the axiomatisation problem, consider the logic $\mathbf{D} = \mathbf{K}/\bullet$ and suppose that we want to decide, for a given formula ψ, whether $\mathbf{K}/\bullet = \mathbf{K} \oplus \psi$ or, equivalently, whether

(a) $\mathbf{K} \oplus \psi \quad \subseteq \quad \mathbf{K}/\bullet$ and

(b) $\mathbf{K}/\bullet \quad \subseteq \quad \mathbf{K} \oplus \psi$.

Now, (a) is equivalent to the problem '$\psi \in \mathbf{K}/\bullet$?' which is decidable because the modal logic $\mathbf{D}$ is decidable. And (b) can be checked effectively because, by the definition of splittings, it is equivalent to the problem '$\bullet \not\models \psi$?'. Thus we have proved the decidability of the axiomatisation problem for $\mathbf{D}$ using the fact that $\mathbf{D}$ is decidable and is a union-splitting of NExt $\mathbf{K}$. By Theorem 5, all union-splittings have the finite model property and, therefore, are decidable if finitely axiomatisable. So this proof shows the decidability of the axiomatisation problem for every union-splitting $\mathbf{K}/\mathcal{F}$, where $\mathcal{F}$ is a finite set of finite rooted cycle free frames. Chagrov's achievement was to show that for no other logic is the axiomatisation problem decidable:

THEOREM 7 (Chagrov). *The axiomatisation problem for a consistent logic* $\mathbf{K} \oplus \varphi \supsetneq \mathbf{K}$ *is decidable iff* $\mathbf{K} \oplus \varphi$ *is a union-splitting.*

Hence, the axiomatisation problem is undecidable for such intuitively simple logics as $\mathbf{S4}$ or $\mathbf{K4}$. Again, $\mathbf{D}$ is the only 'standard' modal logic for which the problem is decidable. Before explaining the proof in some detail, we draw conclusions regarding the second part of (i″) and formulate and discuss solutions for (ii″).

COROLLARY 8. *If* $\mathsf{Fr}\{\varphi\}$ *is nonempty, then the problem '*$\mathbf{K} \oplus \psi = \mathsf{Log}\,\mathsf{Fr}\{\varphi\}$*?' is decidable iff*

- $\mathsf{Log}\,\mathsf{Fr}\{\varphi\}$ *is a union-splitting of* $\mathrm{NExt}\,\mathbf{K}$ *or*
- $\mathsf{Log}\,\mathsf{Fr}\{\varphi\}$ *is not finitely axiomatisable.*

Similarly to Blok's dichotomy, this means, for example, that for any nonempty modally definable class $\mathcal{F}$ of transitive frames such that $\mathsf{Log}\,\mathcal{F}$ is finitely axiomatisable, no algorithm can recognise whether a given formula axiomatises $\mathsf{Log}\,\mathcal{F}$.

The following result due to Thomason [146] and Chagrov [18, 19, 22] (for more details see [24] and references therein) gives 'negative' solutions to (ii$''$):

THEOREM 9 (Thomason & Chagrov). *The following sets are undecidable:*

(a) $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi$ *is Kripke complete*$\}$,

(b) $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi$ *is decidable*$\}$,

(c) $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi$ *has the fmp*$\}$,

(d) $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi$ *is tabular*$\}$,

(e) $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi = L\}$, *where L is an arbitrarily fixed consistent tabular logic.*

Proof. We begin by showing how to prove Theorem 7. The implication ($\Leftarrow$) should be clear from the example $\mathbf{D} = \mathbf{K}/\bullet$ discussed above.

($\Rightarrow$) We show that if $L = \mathbf{K} \oplus \varphi \neq \mathbf{K}$ is a consistent logic that is not a union-splitting then the axiomatisation problem for L is undecidable. The proof is by reduction of the undecidable configuration problem for Minsky (alias register) machines with two tapes (registers).

We remind the reader that a *Minsky machine* (with two tapes) is a finite set of instructions for transforming triples $\langle s, m, n\rangle$ of natural numbers, called *configurations.* The intended meaning of the current configuration $\langle s, m, n\rangle$ is as follows: s is the number (label) of the current machine state and m, n represent the current state of information. Each instruction has one of the four possible forms:

$$s \to \langle t, 1, 0\rangle\,, \quad s \to \langle t, 0, 1\rangle\,, \quad s \to \langle t, -1, 0\rangle\,(\langle t', 0, 0\rangle), \quad s \to \langle t, 0, -1\rangle\,(\langle t', 0, 0\rangle).$$

The last of them, for instance, means: transform $\langle s, m, n\rangle$ into $\langle t, m, n-1\rangle$ if $n > 0$ and into $\langle t', m, n\rangle$ if $n = 0$. For a Minsky machine $\boldsymbol{P}$, we write $\boldsymbol{P} : \langle s, m, n\rangle \to \langle t, k, l\rangle$ if starting with $\langle s, m, n\rangle$ and applying the instructions in $\boldsymbol{P}$, in finitely many steps (possibly, in 0 steps) we can reach $\langle t, k, l\rangle$.

We use the well known fact (see, e.g., [102]) that the following *configuration problem* is undecidable: given a program $\boldsymbol{P}$ and configurations $\langle s, m, n\rangle$, $\langle t, k, l\rangle$, determine whether $\boldsymbol{P} : \langle s, m, n\rangle \to \langle t, k, l\rangle$.

Now let $L = \mathbf{K} \oplus \varphi$. Similarly to the proof of Blok's Theorem 6, we analyse two cases: $\bullet \models \varphi$ and $\circ \models \varphi$. Here we only show that the axiomatisability problem for $L = \mathbf{K} \oplus \varphi$ with $\bullet \models \varphi$ is undecidable and leave the remaining case to the reader.

We will use a modification of the (general) frame $\mathfrak{F}_I$ constructed in the proof of Blok's theorem. Let us take another look at this frame. The root of $\mathfrak{F}'$ refutes some formula

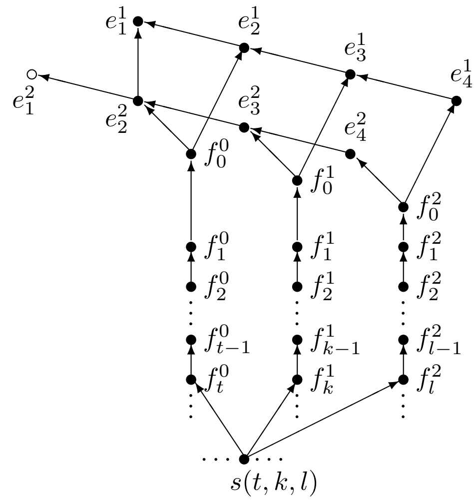

Figure 3.

in L; without loss of generality we may assume that this formula is φ. The part of $\mathfrak{F}_I$ comprising points a_i, b, c was used to ensure that the logic of $\mathfrak{F}_I$ is Kripke incomplete, while the points e_0, e_j, e'_j $(j > 0)$ were used to produce a continuum of frames of the form $\mathfrak{F}_I$, i.e., to make sure that $\mathsf{Log}\,\{\mathfrak{F}_I\} \neq \mathsf{Log}\,\{\mathfrak{F}_J\}$ whenever $I \neq J$. Finally, the points d_k $(-1 \leq k \leq m)$ ensured, in particular, that a_i, b, c, e_0, e_j, e'_j have no impact on $\mathfrak{F}'$ and the other way round.

For our present aims the subframe consisting of points a_i, b, c, e_0, e_j, e'_j is not required and we can modify it. Namely, we remove from $\mathfrak{F}_I$ the points e_j, e'_j $(j \geq 1)$ and replace them with the frame shown in Fig. 3. More precisely, the frame in Fig. 3 is transitive, e_1^2 is its only reflexive point, all points are accessible from d_0 and 'see' e_0; the points of the form $s(t,k,l)$ to not see each other and occur in the frame iff $\boldsymbol{P} : \langle s, m, n\rangle \to \langle t, k, l\rangle$, where $\boldsymbol{P}$, $\langle s, m, n\rangle$ are some fixed Minsky machine and configuration. Denote the resulting frame by $\mathfrak{F}(\boldsymbol{P}, \langle s, m, n\rangle)$.

Now, starting with the formula ϵ_0 from the proof of Blok's theorem, we define the following formulas

$$
\begin{array}{rclcrcl}
\epsilon_1^1 & = & \Diamond\epsilon_0 \wedge \neg\Diamond\Diamond\epsilon_0, & & \epsilon_1^2 & = & \Diamond\Diamond\epsilon_0 \wedge \neg\Diamond\epsilon_1^1,\\
\epsilon_2^1 & = & \Diamond\epsilon_1^1 \wedge \neg\Diamond\Diamond\epsilon_1^1 \wedge \neg\Diamond\epsilon_1^2, & & \epsilon_2^2 & = & \Diamond\epsilon_1^1 \wedge \Diamond\Diamond\epsilon_1^2 \wedge \neg\Diamond\Diamond\epsilon_1^1,\\
\epsilon_3^1 & = & \Diamond\epsilon_2^1 \wedge \neg\Diamond\Diamond\epsilon_2^1 \wedge \neg\Diamond\epsilon_2^2, & & \epsilon_4^1 & = & \Diamond\epsilon_3^1 \wedge \neg\Diamond\Diamond\epsilon_3^1 \wedge \neg\Diamond\epsilon_2^2,\\
\epsilon_3^2 & = & \Diamond\epsilon_2^2 \wedge \neg\Diamond\Diamond\epsilon_2^2 \wedge \neg\Diamond\epsilon_2^1, & & \epsilon_4^2 & = & \Diamond\epsilon_3^2 \wedge \neg\Diamond\Diamond\epsilon_3^2 \wedge \neg\Diamond\epsilon_2^1.
\end{array}
$$

These variable free formulas characterise points e_j^i in $\mathfrak{F}(\boldsymbol{P}, \langle s, m, n\rangle)$ in the sense that ϵ_j^i is true in $\mathfrak{F}(\boldsymbol{P}, \langle s, m, n\rangle)$ only at the point denoted by e_j^i. Further, let

$$
\begin{array}{rclcrcl}
\phi_0^0 & = & \Diamond\epsilon_2^1 \wedge \Diamond\epsilon_2^2 \wedge \neg\Diamond\Diamond\epsilon_2^1 \wedge \neg\Diamond\Diamond\epsilon_2^2, & & \phi_0^1 & = & \Diamond\epsilon_3^1 \wedge \Diamond\epsilon_3^2 \wedge \neg\Diamond\Diamond\epsilon_3^1 \wedge \neg\Diamond\Diamond\epsilon_3^2,\\
\phi_0^2 & = & \Diamond\epsilon_4^1 \wedge \Diamond\epsilon_4^2 \wedge \neg\Diamond\Diamond\epsilon_4^1 \wedge \neg\Diamond\Diamond\epsilon_4^2, & & \phi_{j+1}^i & = & \Diamond\phi_j^i \wedge \neg\Diamond\Diamond\phi_j^i \wedge \displaystyle\bigwedge_{i\neq k=0}^{2} \neg\Diamond\phi_0^k,
\end{array}
$$

for $i \in \{0, 1, 2\}$, $j \geq 0$. The formula ϕ^i_j is true only at f^i_j. The formulas characterising $s(t, k, l)$ are denoted by $\sigma(t, \phi^1_k, \phi^2_l)$, where

$$\sigma(t, \psi, \chi) \quad = \quad \bigwedge_{i=0}^{t} \Diamond\phi^0_i \wedge \neg\Diamond\phi^0_{t+1} \wedge \Diamond\psi \wedge \neg\Diamond^2\psi \wedge \Diamond\chi \wedge \neg\Diamond^2\chi.$$

We also require formulas characterising not only fixed but arbitrary configurations:

$$\begin{array}{lcl}
\kappa_1 & = & (\Diamond\phi^1_0 \vee \phi^1_0) \wedge \neg\Diamond\phi^0_0 \wedge \neg\Diamond\phi^2_0 \wedge p_1 \wedge \neg\Diamond p_1, \\
\kappa_2 & = & \Diamond\phi^1_0 \wedge \neg\Diamond\phi^0_0 \wedge \neg\Diamond\phi^2_0 \wedge \Diamond p_1 \wedge \neg\Diamond^2 p_1, \\
\pi_1 & = & (\Diamond\phi^2_0 \vee \phi^2_0) \wedge \neg\Diamond\phi^0_0 \wedge \neg\Diamond\phi^1_0 \wedge p_2 \wedge \neg\Diamond p_2, \\
\pi_2 & = & \Diamond\phi^2_0 \wedge \neg\Diamond\phi^0_0 \wedge \neg\Diamond\phi^1_0 \wedge \Diamond p_2 \wedge \neg\Diamond^2 p_2,
\end{array}$$

where p_1 and p_2 are fresh variables.

Now we are fully equipped to simulate the behaviour of Minsky machines by means of modal formulas. Let

$$\blacklozenge\psi \quad = \quad \psi \vee \Diamond\psi \vee \cdots \vee \Diamond^n\psi,$$

where n is a sufficiently large number such that if xR^*y in $\mathfrak{F}(\boldsymbol{P}, \langle s, m, n\rangle)$ then $xR^k y$ for some $k \leq n$. (Note that in the proof of Blok's theorem we took $n = m + 6$.)

With each instruction I in $\boldsymbol{P}$ we associate a formula AxI by taking:

$$AxI \quad = \quad \neg\varphi \wedge \blacklozenge\sigma(t, \pi_1, \kappa_1) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t', \pi_2, \kappa_1)$$

if I has the form $t \rightarrow \langle t', 1, 0\rangle$,

$$AxI \quad = \quad \neg\varphi \wedge \blacklozenge\sigma(t, \pi_1, \kappa_1) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t', \pi_1, \kappa_2)$$

if I is $t \rightarrow \langle t', 0, 1\rangle$,

$$\begin{array}{lcl}
AxI & = & (\neg\varphi \wedge \blacklozenge\sigma(t, \pi_2, \kappa_1) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t', \pi_1, \kappa_1)) \wedge \\
& & \qquad (\neg\varphi \wedge \blacklozenge\sigma(t, \phi^1_0, \kappa_1) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t'', \phi^1_0, \kappa_1))
\end{array}$$

if I is $t \rightarrow \langle t', -1, 0\rangle\,(\langle t'', 0, 0\rangle)$,

$$\begin{array}{lcl}
AxI & = & (\neg\varphi \wedge \blacklozenge\sigma(t, \pi_1, \kappa_2) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t', \pi_1, \kappa_1)) \wedge \\
& & \qquad (\neg\varphi \wedge \blacklozenge\sigma(t, \pi_1, \phi^2_0) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t'', \pi_1, \phi^2_0))
\end{array}$$

if I is $t \rightarrow \langle t', 0, -1\rangle\,(\langle t'', 0, 0\rangle)$. The formula simulating $\boldsymbol{P}$ as a whole is

$$Ax\boldsymbol{P} \quad = \quad \bigwedge_{I \in \boldsymbol{P}} AxI.$$

Now, by induction on the length of computations one can show that, for every program $\boldsymbol{P}$ and all configurations $\langle s, m, n\rangle$, $\langle t, k, l\rangle$, we have the following property ($\Downarrow$):

$$\begin{array}{c}
\boldsymbol{P} : \langle s, m, n\rangle \rightarrow \langle t, k, l\rangle \\
\Downarrow \\
\neg\varphi \wedge \blacklozenge\sigma(s, \phi^1_m, \phi^2_n) \rightarrow \neg\varphi \wedge \blacklozenge\sigma(t, \phi^1_k, \phi^2_l) \quad \in \quad \mathbf{K} \oplus Ax\boldsymbol{P}.
\end{array}$$

Finally, define a logic $L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle)$ by taking

$$L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle) \;=\; \mathbf{K} \oplus Ax\boldsymbol{P} \oplus (\neg\varphi \wedge \blacklozenge\sigma(s,\phi^1_m,\phi^2_n) \to \neg\varphi \wedge \blacklozenge\sigma(t,\phi^1_k,\phi^2_l)) \to \varphi.$$

Clearly, for given $\boldsymbol{P}$ and configurations $\langle s,m,n\rangle$ and $\langle t,k,l\rangle$, the logic $L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle)$ is constructed effectively. We claim that

$$\boldsymbol{P} : \langle s,m,n\rangle \to \langle t,k,l\rangle \qquad \text{iff} \qquad L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle) = \mathbf{K} \oplus \varphi.$$

The implication ($\Rightarrow$) is proved using the property ($\Downarrow$) above and the obvious inclusion $L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle) \subseteq \mathbf{K} \oplus \varphi$. To show the converse direction, it suffices to observe that if $\boldsymbol{P} : \langle s,m,n\rangle \not\to \langle t,k,l\rangle$ then $\mathfrak{F}(\boldsymbol{P}, \langle s,m,n\rangle)$ validates all the axioms of $L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle)$ and refutes φ.

To prove Theorem 9, we modify the definition of the logic $L(\boldsymbol{P}, \langle s,m,n\rangle, \langle t,k,l\rangle)$ above. First we take a formula φ such that $\mathbf{K} \oplus \varphi$ is a consistent tabular logic. One can show that every such logic is not a union-splitting.

Now observe that there exist a program $\boldsymbol{P}$ and a configuration $\langle s,m,n\rangle$ such that no algorithm can decide, given a configuration $\langle t,k,l\rangle$, whether $\boldsymbol{P} : \langle s,m,n\rangle \to \langle t,k,l\rangle$ (for details see [24]). Fix some $\boldsymbol{P}$ and $\langle s,m,n\rangle$ satisfying this condition, and let

$$\begin{aligned} L'(\langle t,k,l\rangle) \quad = \quad & \mathbf{K} \oplus Ax\boldsymbol{P} \oplus \big(\neg\varphi \wedge \blacklozenge\sigma(s,\phi^1_m,\phi^2_n) \to \neg\varphi \wedge \blacklozenge\sigma(t,\phi^1_k,\phi^2_l)\big) \to \varphi \oplus \\ & \neg\varphi \to \bigvee_{i=0}^{l} \Diamond^i\gamma \quad \oplus \quad \neg\varphi \to \bigwedge_{i=0}^{l} \Box^i\big(\gamma \to \Box(\Box_0(\Box_0 p \to p) \to p)\big), \end{aligned}$$

where p is a fresh variable.

If $\boldsymbol{P} : \langle s,m,n\rangle \to \langle t,k,l\rangle$ then, as in the proof of Theorem 7, it is easy to see that we have $L'(\langle t,k,l\rangle) = \mathbf{K} \oplus \varphi$. Thus, this logic is tabular (coincides with the chosen tabular logic, to be more precise), and so it is decidable, Kripke complete and has the fmp.

If $\boldsymbol{P} : \langle s,m,n\rangle \not\to \langle t,k,l\rangle$ then $L'(\langle t,k,l\rangle) \neq \mathbf{K} \oplus \varphi$, which can be shown with the help of the frame $\mathfrak{F}(\boldsymbol{P}, \langle s,m,n\rangle)$. Thus, our logic is different from the chosen tabular logic $\mathbf{K} \oplus \varphi$. Moreover, using the last two axioms (cf. formulas (5), (6) in the proof of Blok's theorem) one can show that although $\varphi \notin L'(\langle t,k,l\rangle)$, no Kripke frame for $L'(\langle t,k,l\rangle)$ can refute φ. It follows that $L'(\langle t,k,l\rangle)$ is Kripke incomplete and does not have the finite model property. Next we use the properties of $\boldsymbol{P}$ and $\langle s,m,n\rangle$ to show that

$$\boldsymbol{P} : \langle s,m,n\rangle \not\to \langle t',k',l'\rangle \quad \text{iff} \quad L'(\langle t,k,l\rangle) \vdash \neg\varphi \wedge \blacklozenge\sigma(s,\phi^1_m,\phi^2_n) \to \neg\varphi \wedge \blacklozenge\sigma(t',\phi^1_{k'},\phi^2_{l'}).$$

The implication ($\Rightarrow$) is proved by induction on the length of computation and ($\Leftarrow$) is shown using the frame $\mathfrak{F}(\boldsymbol{P}, \langle s,m,n\rangle)$. It follows that $L'(\langle t,k,l\rangle)$ is undecidable. ❑

In fact, using the technique above one can prove undecidability of many other important properties of modal logics such as first-order definability (i.e., whether $\mathsf{Fr}\,\{\varphi\}$ is definable by first-order formulas, for an arbitrarily given φ), canonicity, the interpolation and the disjunction properties, etc.; see [24] and references therein. Actually, we know only two interesting decidable properties of finitely axiomatisable logics in NExt $\mathbf{K}$: consistency and coincidence with $\mathbf{K}$. However, even consistency becomes undecidable in NExt $\mathbf{K}_2$ [146].

Theorems 7 and 9 give rise to further interesting questions. First, we still do not know a solution to the following open problem:

PROBLEM 2. Is the set $\{\varphi \in \mathcal{ML}_1 \mid \mathbf{K} \oplus \varphi \text{ is a union-splitting}\}$ decidable?

Second, some of the undecidable problems formulated above may turn out to be *recursively enumerable*, so that we can at least effectively enumerate finitely axiomatisable logics with this or that property. For example, it is easy to show recursive enumerability of the set $\{\varphi \in \mathcal{ML}_n \mid \mathbf{K}_n \oplus \varphi = L\}$, where L is fixed consistent tabular logic (just use the fact that L is finitely axiomatisable, say, by a formula ψ and enumerate those φ from which ψ is derivable in $\mathbf{K}_n$ and vice versa). However, for the majority of important properties of modal logics this problem remains open:

PROBLEM 3. Is it possible to effectively enumerate $\mathcal{ML}_n$-formulas φ for which $\mathbf{K}_n \oplus \varphi$ is decidable (Kripke complete, has the finite model property, interpolation, etc.)?

Finally, one may wonder what happens if we consider the decision problems above for *recursively axiomatisable* modal logics, i.e., those that are given by programs generating their formulas. In this case we have the following analogue of the Rice theorem from general recursion theory:

THEOREM 10 (Kuznetsov). *No nontrivial property of recursively axiomatisable logics is decidable in any of the classes of logics considered above.*

In particular, this result applies even to NExt **S5** (where all logics are finitely axiomatisable)—provided that its logics are represented as programs computing their formulas. Of course, we can recognise, say, consistency in NExt **S5** if all logics in the class are given by finite sets of axioms. The situation is different in, e.g., NExt **S4** where there exist recursively enumerable logics that are not finitely axiomatisable. The proof of this theorem (Kuznetsov left it unpublished) is very simple. In fact, it has nothing to do with modal logics; it is rather about effective computations. The reader can find it in [24].

3.3 Postmortem

So, was the Big Research Programme a failure or a success? Or simply lost illusions?

Dealing with individual systems like $\mathbf{K}_n$, **S4** or even **PDL**, one might think that Modal Logic is 'harmless,' that it is a reasonable compromise between expressiveness and effectiveness, especially in various application areas in computer science and artificial intelligence. Looking at modal logics from a more general perspective, we see, however, that the propositional modal language is extremely expressive, even if we have a single box operator. Modal Logic has been praised by 'users' for being *robustly decidable.* The analysis above shows that, when put in a more general setting, Modal Logic is rather *robustly **un**decidable.* (However, we can take comfort in the mathematical beauty of the splitting-based dichotomy between Kripke completeness and Kripke incompleteness and its transparent repercussions for modal decision problems.)

The outcomes of the Big Research Programme discussed above appear to be similar to the negative solution to the Classical Decision Problem, *das Entscheidungsproblem*, of Hilbert; see [11] and references therein. According to [11], 'the reaction of logicians to the discoveries of Church and Turing was that the classical decision problem was wider than the yes/no version of it . . . The logicians started to think about the classical decision problem as a classification problem. Which fragments are decidable for satisfiability and

which are undecidable? Which fragments are decidable for finite satisfiability and which are undecidable? Which fragments have the finite model property and which contain axioms of infinity (that is satisfiable formulae without finite models)?'

Similar questions make sense in Modal Logic as well. The modal decision problems considered above can be transformed into *modal classification problems*:

(iii) determine (in some sense) maximal classes of modal logics with the desirable properties.

Of course, particularly interesting are natural classes like

- extensions of certain logics, e.g., $\mathbf{K4}$, $\mathbf{S5} \times \mathbf{S5}$, $\mathbf{K4}_t$;
- logics axiomatised by certain 'normal' formulas (e.g., reductions of modalities, Sahlqvist or uniform formulas);
- logics whose classes of frames are closed under certain natural operations (e.g., taking subframes).

To understand the landscape of modal logics in this respect, a variety of different methodologies are required. One established path is to look 'outside' and, e.g., employ modal logics' relation to finite variable/guarded fragments of first-order logic (see Chapter 5), or their relation to languages recognised by tree automata (see Chapter 17). In this chapter we follow the 'internal' approach and analyse how different 'modal' syntactic or semantic restrictions can guarantee this or that desirable property.

4 SYNTACTICAL CLASSES OF MODAL LOGICS

To understand a modal logic is, to a large extent, to understand the structure of its frames, in particular, Kripke frames. An obvious way of doing this is to try to characterise frames by means of first-order formulas in some suitable signature. Classical observations going back to Kripke [79] are as follows, where $\mathfrak{F} = \langle W, R\rangle$ is treated as a Kripke frame in the left-hand column and as a first-order structure in the right-hand one:

$$
\begin{array}{lll}
\mathfrak{F} \models \Box p \to p & \text{iff} & \mathfrak{F} \models \forall x\ R(x,x),\\
\mathfrak{F} \models \Box p \to \Box\Box p & \text{iff} & \mathfrak{F} \models \forall x,y,z\ \big(R(x,y) \land R(y,z) \to R(x,z)\big),\\
\text{etc.} & &
\end{array}
$$

A nice first-order characterisation not only helps in understanding the structure of frames. First, using the standard translation $\cdot^s$ of modal formulas into the first-order language from Section 2 (see also Chapters 1 and 5) and Gödel's completeness theorem, it is readily seen that if $\mathsf{Fr}\,\{\varphi\}$ is definable by a first-order formula as above, then $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$ is recursively enumerable, while in general, by Theorem 1 (a), $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$ might be Π^1_1-hard and even more complex. Second, as was proved by Fine [44] (see also [156, 152]), we have the following:

THEOREM 11 (Fine). *If a logic $L \in \mathrm{NExt}\,\mathbf{K}$ is determined by a first-order definable class of frames then L is $\mathcal{D}$-persistent.*[4]

[4] L is called *$\mathcal{D}$-persistent* if the underlying Kripke frame of any descriptive frame for L validates L as well. A general frame is *descriptive* if it satisfies certain closure conditions which can be found in Chapter 5. If a logic L is $\mathcal{D}$-persistent, then the underlying Kripke frame of its canonical model validates L. In particular, every $\mathcal{D}$-persistent logic is Kripke complete.

This means that to investigate a first-order definable $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$, we can use the well-known methods of canonical models and filtration developed in the 1960–1970s (see, e.g., [24] and references therein). Although the converse of Fine's theorem does not hold, as has been recently shown in [58], it is nevertheless a kind of empirical rule that logics not determined by first-order definable classes are *not* $\mathcal{D}$-persistent, and therefore, the standard way of proving completeness or the finite model property is blocked for them.

By Chagrova's theorem [29], there is no effective way of deciding, given a formula φ, whether $\mathsf{Fr}\,\{\varphi\}$ is first-order definable. However, one can try to find and describe *syntactically* some classes of formulas φ for which $\mathsf{Fr}\,\{\varphi\}$ is first-order definable. In fact, this approach has been the driving force behind much research in Modal Logic since the 1960s (see, e.g., [88]). The (so far) most general syntactically defined class of formulas for which this holds true was discovered by H. Sahlqvist [125].

4.1 Sahlqvist logics

Sahlqvist's theorem [125] (see also [53])—perhaps the most celebrated general result in Modal Logic—gives a sufficient condition for first-order definability and Kripke completeness of logics in $\mathrm{NExt}\,\mathbf{K}_n$. To formulate it we require the following definitions.

Say that a formula is *positive* if it is constructed from variables and the constants $\top$, $\bot$ using $\wedge$, $\vee$, $\Diamond_i$ and $\Box_i$. An arbitrary finite sequence of boxes $\Box_i$, $i = 1, \dots, n$ will be denoted by $\Box^*$.

A formula $\varphi \in \mathcal{ML}_n$ is called a *Sahlqvist formula* if it is equivalent in $\mathbf{K}_n$ to a formula of the form $\Box^*(\psi \to \chi)$, where χ is positive and ψ is constructed from variables and their negations, $\bot$ and $\top$ with the help of $\wedge$, $\vee$, $\Box_i$ and $\Diamond_i$ in such a way that no subformula of ψ of the form $\psi_1 \vee \psi_2$ or $\Diamond_i \psi_1$, containing an occurrence of a variable without $\neg$, is in the scope of some $\Box_j$. For example, formulas (2)–(3) from Section 2 are Sahlqvist, while the Löb axiom (1) and the McKinsey axiom

$$\boldsymbol{ma} \quad = \quad \Box\Diamond p \to \Diamond\Box p \tag{7}$$

are not.

THEOREM 12 (Sahlqvist). (a) *Given a Sahlqvist formula $\varphi \in \mathcal{ML}_n$, one can effectively construct a first-order formula $\phi(x)$ in $R_1, \dots, R_n$ and $=$ having x as its only free variable and such that, for every descriptive or Kripke frame $\mathfrak{F}$ and every point a in $\mathfrak{F}$,*

$$(\mathfrak{F}, a) \models \varphi \qquad \textit{iff} \qquad \mathfrak{F} \models \phi(x)[a].$$

(*Here $(\mathfrak{F}, a) \models \varphi$ means that φ is true at a in $\mathfrak{F}$ under any valuation.*)

(b) *If Γ is a set of Sahlqvist $\mathcal{ML}_n$-formulas and $L \in \mathrm{NExt}\,\mathbf{K}_n$ is a $\mathcal{D}$-persistent logic then the logic $L \oplus \Gamma$ (in particular, $\mathbf{K}_n \oplus \Gamma$) is $\mathcal{D}$-persistent as well. Moreover, $L \oplus \Gamma$ is elementary (in the sense that the class of Kripke frames for it coincides with the class of all models for some set of first-order formulas in R_i and $=$) whenever L is so.*

Various detailed proofs of this result can be found in [126, 70, 7] (for some generalisations see, e.g., [30, 60, 72, 50]). So, instead of going into technical details, we will concentrate on the meaning of Sahlqvist's theorem.

First, it gives much more than just first-order definability of $\mathsf{Fr}\,\{\varphi\}$, for a Sahlqvist formula φ, and, therefore, recursive enumerability of $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$. In fact, we also obtain an axiomatisation, namely, that $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\} = \mathbf{K} \oplus \varphi$. As we know from Blok's theorem,

this is much stronger than just first-order definability. (For example, there are a lot of formulas φ such that $\mathsf{Fr}\{\varphi\}$ is the class of transitive frames, but $\mathbf{K} \oplus \varphi \neq \mathbf{K4}$.) Thus, Sahlqvist's theorem has two aspects: the correspondence part (stating first-order definability of $\mathsf{Fr}\{\varphi\}$) and the completeness part (stating that $\mathsf{Log}\,\mathsf{Fr}\{\varphi\} = \mathbf{K} \oplus \varphi$).

However, Sahlqvist axioms do not guarantee good computational properties of modal logics. For example, there are finitely axiomatisable Sahlqvist logics without the finite model property in NExt $\mathbf{S4}$ [26] (see also [65]). There are undecidable finitely axiomatisable Sahlqvist logics in NExt $\mathbf{K}$. Such a logic can easily be constructed if we have more than one box [23]. For instance, consider the undecidable associative calculus T of [148] with the axioms

$$ac = ca, \quad ad = da, \quad bc = cb, \quad bd = db, \quad edb = be, \quad eca = ae, \quad abac = abacc.$$

The reader will notice immediately an analogy between these axioms and the axioms of the following modal logic with five necessity operators:

$$\begin{aligned} L \quad = \quad \mathbf{K}_5 \quad \oplus \quad & \Box_1\Box_3 p \leftrightarrow \Box_3\Box_1 p \ \oplus \ \Box_1\Box_4 p \leftrightarrow \Box_4\Box_1 p \ \oplus \ \Box_2\Box_3 p \leftrightarrow \Box_3\Box_2 p \ \oplus \\ & \Box_2\Box_4 p \leftrightarrow \Box_4\Box_2 p \ \oplus \Box_5\Box_4\Box_2 p \leftrightarrow \Box_2\Box_5 p \ \oplus \ \Box_5\Box_3\Box_1 p \leftrightarrow \Box_1\Box_5 p \ \oplus \\ & \Box_1\Box_2\Box_1\Box_3 p \leftrightarrow \Box_1\Box_2\Box_1\Box_3\Box_3 p. \end{aligned}$$

Moreover, it is not hard to see that words x, y in the alphabet $\{a, b, c, d, e\}$ are equivalent in T iff $f(x)p \leftrightarrow f(y)p \in \mathbf{K}_5$, where f is the natural one-to-one correspondence between such words and modalities in language $\{\Box_1, \dots, \Box_5\}$ under which, for instance, $f(cadedb) = \Box_3\Box_1\Box_4\Box_5\Box_4\Box_2$. It follows immediately that the Sahlqvist 5-modal logic L is undecidable. An even simpler example of an undecidable finitely axiomatisable Sahlqvist logic is the bimodal product $\mathbf{K4} \times \mathbf{K4}$; for details see Chapter 15. Now, using the reduction of multi-modal logics to those in NExt $\mathbf{K}$ [77] one can construct an undecidable finitely axiomatisable Sahlqvist logic from NExt $\mathbf{K}$.

PROBLEM 4. Are finitely axiomatisable Sahlqvist logics in NExt $\mathbf{K4}$ decidable?

It is also worth noting that there is no effective way of recognising whether a given modal formula is (deductively equivalent to) a Sahlqvist formula; in particular, the set

$$\{\varphi \in \mathcal{ML}_1 \mid \mathbf{S4} \oplus \varphi \text{ is a Sahlqvist logic}\}$$

is not recursive [26].

The simplest formula not covered by Sahlqvist's theorem is the Mckinsey axiom $\boldsymbol{ma}$ (see (7) above). It is neither first-order definable [56, 154][5], nor canonical [55]. The problem whether the following equality holds

$$\mathbf{K} \quad \oplus \quad \Box\Diamond p \to \Diamond\Box p \quad = \quad \mathsf{Log}\,\mathsf{Fr}\{\Box\Diamond p \to \Diamond\Box p\}$$

and whether the logic $\mathbf{K} \oplus \boldsymbol{ma}$ is decidable had resisted all attempts based on the standard methods of canonical models and filtration until Fine [44] introduced a new proof technique based on certain normal forms to be considered in the next section.

Another logic not covered by Sahlqvist's theorem is $\mathbf{KM}^\infty = \mathbf{K} \oplus \{\boldsymbol{ma}_k \mid k \geq 1\}$ defined in [88], where

$$\boldsymbol{ma}_k \quad = \quad \Diamond \bigwedge_{1 \leq i \leq k} (\Diamond p_i \to \Box p_i).$$

[5]This result was first proved by R. Goldblatt in his PhD thesis in 1974.

$\boldsymbol{ma}_1$ is $\mathbf{K}$-equivalent to $\boldsymbol{ma}$, so $\mathbf{KM}^\infty \supseteq \mathbf{K} \oplus \boldsymbol{ma}$. In fact, $\mathbf{KM}^\infty$ is the logic of the class of frames satisfying

$$\forall x \exists y \ \big(R(x,y) \wedge \forall z, z' \ (R(y,z) \wedge R(y,z') \to z = z')\big), \tag{8}$$

so by Theorem 11 it is canonical.

In [64], the proof of Sahlqvist's theorem is extended to $\mathbf{KM}^\infty$ and other logics. The method uses *'quasipositive' hybrid sentences*; see Chapter 14 for full details of hybrid logic. In these formulas, existential and relativised universal quantifiers over nominals are allowed, negation can only occur in the latter, and there are no free nominals or propositional variables. From any quasipositive sentence φ, an infinite set of *modal* axioms can be obtained effectively. The modal axioms approximate φ, by treating nominals as propositional variables ranging over the partition sets of finite partitions of the worlds of a model. Each partition is defined by the truth values of an arbitrary finite set of modal formulas. Existential and universal quantification are simulated by disjunctions and conjunctions over partition sets. The axioms obtained in this way axiomatise a modal logic L_φ, which is shown to be the logic of the class of frames validating φ: i.e., $L_\varphi = \mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$.

For example, let $\varphi = \Diamond \exists i \Box i$, where i is a nominal. Then φ is valid in precisely the frames satisfying (8). The axioms obtained from φ are equivalent to substitution instances of the $\boldsymbol{ma}_k$ above, and so $L_\varphi = \mathbf{KM}^\infty$. For instance, the axiom obtained by approximating φ with respect to the finite set $X = \{p_1, \dots, p_k\}$ is

$$\Diamond \bigvee_{Y \subseteq X} \Box \Big(\bigwedge_{p \in Y} p \wedge \bigwedge_{p \in X - Y} \neg p \Big),$$

and this is $\mathbf{K}$-equivalent to $\boldsymbol{ma}_k$.

The method extends to sets Φ of quasipositive sentences. Every L_Φ is the logic of an elementary class of frames, namely, $\mathsf{Fr}\,\Phi$. [64] shows that the modal logics of elementary classes of frames are *precisely* those of the form Λ_Φ. The result applies to multi-modal logics and to logics with polyadic modalities.

This result gives an interesting link between modal and hybrid logic. It is analogous to Sahlqvist's completeness theorem, since $\mathsf{Log}\,\mathsf{Fr}\,\Phi = L_\Phi$. An analogue of Sahlqvist's correspondence theorem would state that $\mathsf{Fr}\,L_\Phi$ is first-order definable (by Φ), but this cannot be achieved in general, since in many cases, $\mathsf{Fr}\,L_\Phi$ is non-elementary.

4.2 Uniform logics

Fine [44] used a modal analogue of the full disjunctive normal form for constructing finite models and proving the fmp of a family of logics in NExt $\mathbf{D}$ (containing, in particular, $\mathbf{K} \oplus \boldsymbol{ma}$).

Observe first that every modal formula $\varphi(p_1, \dots, p_m)$ is equivalent in $\mathbf{K}$ either to $\bot$ or to a disjunction of normal forms (in the variables $p_1, \dots, p_m$) of degree $md(\varphi)$ (the modal depth of φ), which are defined inductively in the following way. $\mathbf{NF}_0$, the set of *normal forms of degree* 0, contains all formulas of the form $\neg_1 p_1 \wedge \cdots \wedge \neg_m p_m$, where each $\neg_i$ is either blank or $\neg$. $\mathbf{NF}_{n+1}$, the set of *normal forms of degree* $n+1$, consists of formulas of the form

$$\theta \wedge \neg_1 \Diamond \theta_1 \wedge \cdots \wedge \neg_k \Diamond \theta_k,$$

where $\theta \in \mathbf{NF}_0$ and $\theta_1, \ldots, \theta_k$ are all distinct normal forms in $\mathbf{NF}_n$. Put $\mathbf{NF} = \bigcup_{n<\omega} \mathbf{NF}_n$. Using the fact that $\bigvee\{\Diamond\theta \mid \theta \in \mathbf{NF}_n\} \in \mathbf{D}$, it is not hard to see also that in $\mathbf{D}$ every formula φ with $md(\varphi) \leq n$ is equivalent either to $\bot$ or to a disjunction of normal forms of degree n such that at least one of $\neg_1, \ldots, \neg_k$ in the inductive step of the definition above is blank. Such normal forms are called $\mathbf{D}$-*suitable*. It should be clear that, for any distinct $\theta', \theta'' \in \mathbf{NF}_n$, $\neg(\theta' \wedge \theta'') \in \mathbf{K}$. Consequently, for every $\theta \in \mathbf{NF}_n$ and every $\varphi(p_1, \ldots, p_m)$ with $md(\varphi) \leq n$, we have either $\theta \to \varphi \in \mathbf{K}$ or $\theta \to \neg\varphi \in \mathbf{K}$.

With each $\mathbf{D}$-suitable normal form θ we associate a model $\mathfrak{M}_\theta = \langle \mathfrak{F}_\theta, \mathfrak{V}_\theta \rangle$ based on $\mathfrak{F}_\theta = \langle W_\theta, R_\theta \rangle$ by taking

$$\begin{array}{lll} W_\theta & = & \{\top\} \cup \{\theta' \in \mathbf{NF} \mid \theta' <^n \theta, \text{ for some } n \geq 0\}, \\ \theta' < \theta'' & \text{iff} & \Diamond\theta' \text{ is a conjunct of } \theta'', \\ \theta' R_\theta \theta'' & \text{iff} & \text{either } \theta' > \theta'' \text{ or } md(\theta') = 0 \text{ and } \theta'' = \top, \\ \mathfrak{V}_\theta(p) & = & \{\theta' \in W_\theta \mid p \text{ is a conjunct of } \theta'\}. \end{array}$$

According to the definition, $\top$ is the reflexive end-point in $\mathfrak{F}_\theta$, and so $\mathfrak{F}_\theta$ is serial. By a straightforward induction on the degree of $\theta' \in W_\theta$ one can show that $(\mathfrak{M}_\theta, \theta') \models \theta'$. It follows immediately that $\mathbf{D}$ has the finite model property (fmp, for short). Indeed, given $\varphi \notin \mathbf{D}$, we reduce $\neg\varphi$ to a disjunction of $\mathbf{D}$-suitable normal forms with at least one disjunct θ, and then $(\mathfrak{M}_\theta, \theta) \models \theta$.

It turns out that in the same way we can prove the fmp of all logics in NExt $\mathbf{D}$ that are axiomatisable by *uniform formulas* which are defined as follows. Every φ without modal operators is a *uniform formula of degree* 0; and if $\varphi = \psi(\blacklozenge_1\chi_1, \ldots, \blacklozenge_m\chi_m)$, where $\blacklozenge_i \in \{\Box, \Diamond\}$, $md(\psi(p_1, \ldots, p_m)) = 0$ and $\chi_1, \ldots, \chi_m$ are uniform formulas of degree n, then φ is a *uniform formula of degree* $n+1$. A remarkable property of uniform formulas is the following. Suppose that φ is a uniform formula of degree n and $\mathfrak{M}$, $\mathfrak{N}$ are models based on the same frame $\mathfrak{F} = \langle W, R \rangle$ and such that, for some point x, $(\mathfrak{M}, y) \models p$ iff $(\mathfrak{N}, y) \models p$ for every $y \in x{\uparrow}^n$ and every variable p in φ, where

$$X{\uparrow} \;=\; X{\uparrow}^1 \;=\; \{y \in W \mid \exists x \in X\; xRy\}, \qquad X{\uparrow}^{n+1} \;=\; (X{\uparrow}^n){\uparrow}\,.$$

Then $(\mathfrak{M}, x) \models \varphi$ iff $(\mathfrak{N}, x) \models \varphi$.

Given a logic L, we call a normal form θ L-*suitable* if $\mathfrak{F}_\theta \models L$.

THEOREM 13 (Fine). *Every logic $L \in$ NExt$\mathbf{D}$ axiomatisable by uniform formulas has the fmp.*

Proof. It suffices to prove that each formula φ with $md(\varphi) \leq n$ is equivalent in L either to $\bot$ or to a disjunction of L-suitable normal forms of degree n. And this fact will be established if we show that every $\mathbf{D}$-suitable normal form θ such that $\theta \to \bot \notin L$ is L-suitable. Suppose otherwise. Let θ be an L-consistent and $\mathbf{D}$-suitable normal form of the least possible degree under which it is not L-suitable. Then there are a uniform formula $\psi \in L$ of some degree m and a model $\mathfrak{M} = \langle \mathfrak{F}_\theta, \mathfrak{V} \rangle$ such that $(\mathfrak{M}, \theta) \not\models \psi$.

For every variable p in ψ, let $\Gamma_p = \{\theta' \in \theta{\uparrow}^m \mid (\mathfrak{M}, \theta') \models p\}$ and let $\delta_p = \bigvee \Gamma_p$ (if $\Gamma_p = \emptyset$ then $\delta_p = \bot$). Observe that for every $\theta' \in \theta{\uparrow}^m$ we have $(\mathfrak{M}_\theta, \theta') \models \delta_p$ iff $\theta' \in \Gamma_p$ iff $(\mathfrak{M}, \theta') \models p$. Therefore, the formula ψ' that results from ψ by replacing each p with δ_p is false at θ in $\mathfrak{M}_\theta$. Now, if $md(\psi') > n$ then $m > n$, and so $\delta_p = \bot$ for every p in ψ, i.e., ψ' is variable free. But then ψ' is equivalent in $\mathbf{D}$ to $\top$ or $\bot$, contrary to $\mathfrak{F}_\theta \not\models \psi'$ and L being consistent. And if $md(\psi') \leq n$ then either $\theta \to \psi' \in \mathbf{K}$, which is impossible,

since $(\mathfrak{M}_\theta, \theta) \not\models \theta \to \psi'$, or $\theta \to \neg\psi' \in \mathbf{K}$, from which $\psi' \to \neg\theta \in \mathbf{K}$ and so $\neg\theta \in L$, contrary to θ being L-consistent. ❑

It is not hard to extend Fine's theorem to the multi-modal case, namely, to those logics that contain $\Diamond_i \top$, for all $i = 1, \dots, n$, and are axiomatisable by formulas φ in which all maximal sequences of nested modal operators coincide with respect to the distribution of the indices i of $\Box_i$ and $\Diamond_i$.

As a consequence of Theorem 13 we obtain that $\mathbf{KM} = \mathbf{K} \oplus \boldsymbol{ma}$ enjoys the fmp and so is decidable. Strange as it may seem, the following problem is still open:

PROBLEM 5. What is the computational complexity of **KM**?

4.3 Logics with $\Box\Diamond$-axioms

Another result, connecting the fmp of logics with the distribution of $\Box$ and $\Diamond$ over their axioms, is based on the following observation which can be regarded as the modal analogue of Glivenko's theorem for intuitionistic logic (see, e.g., [24]): for all formulas $\varphi, \psi \in \mathcal{ML}_1$, we have $\Diamond\varphi \leftrightarrow \Diamond\psi \in \mathbf{S5}$ iff $\Box\Diamond\varphi \leftrightarrow \Box\Diamond\psi \in \mathbf{K4}$. The proof of this observation is almost trivial. Suppose $\Box\Diamond\varphi \to \Box\Diamond\psi \notin \mathbf{K4}$. Then there exist a finite model $\mathfrak{M}$, based on a transitive frame, and a point x in it such that $x \models \Box\Diamond\varphi$ and $x \not\models \Box\Diamond\psi$. It follows from the former that every final cluster accessible from x, if any, is non-degenerate and contains a point where φ is true. The latter means that x 'sees' a final cluster C at all points of which ψ is false. Now, by taking the generated submodel of $\mathfrak{M}$ based on C, we obtain a model for **S5** refuting $\Diamond\varphi \to \Diamond\psi$. The rest is obvious, since $\Diamond p \leftrightarrow \Box\Diamond p$ is in **S5** and $\mathbf{K4} \subseteq \mathbf{S5}$.

$\mathcal{ML}_1$-formulas in which every occurrence of a variable is in the scope of a modality $\Box\Diamond$ will be called *$\Box\Diamond$-formulas*. The next theorem is due to Rybakov [124].

THEOREM 14 (Rybakov). *If a logic $L \in \mathrm{NExt}\,\mathbf{K4}$ is decidable* (*or has the fmp*) *and ψ is a $\Box\Diamond$-formula then $L \oplus \psi$ is also decidable* (*has the fmp*).

Proof. Suppose that $\psi = \psi'(\Box\Diamond\chi_1, \dots, \Box\Diamond\chi_n)$, for some formula $\psi'(q_1, \dots, q_n)$. If $\varphi(p_1, \dots, p_m) \in L \oplus \psi$ then there exists a derivation of φ in $L \oplus \psi$ in which substitution instances of ψ contain no variables different from $p_1, \dots, p_m$. Each of these instances has the form $\psi'(\Box\Diamond\chi'_1, \dots, \Box\Diamond\chi'_n)$, where every χ'_i is some substitution instance of χ_i containing only $p_1, \dots, p_m$. Now, it is not hard to see that, similarly to classical propositional logic, there are finitely many pairwise nonequivalent formulas in **S5** built from $p_1, \dots, p_m$ (for more details see, e.g., [129] or [24]). In view of the observation above, there are finitely many pairwise nonequivalent in **K4** substitution instances of $\Box\Diamond\chi_i$ of that sort (the reader can easily estimate the number of them). So there exist only finitely many pairwise nonequivalent in **K4** substitution instances of ψ containing $p_1, \dots, p_m$, say, $\psi_1, \dots, \psi_k$, and we can effectively construct them. Then, by the deduction theorem,

$$\varphi \in L \oplus \psi \qquad \text{iff} \qquad \Box^+(\psi_1 \wedge \dots \wedge \psi_k) \to \varphi \in L,$$

where $\Box^+\chi = \chi \wedge \Box\chi$. Thus, $L \oplus \psi$ is decidable (or has the fmp) whenever L is decidable (has the fmp). ❑

It should be noted that by adding infinitely many $\Box\Diamond$-formulas to a logic L with the fmp one can construct a Kripke incomplete logic; for a concrete example see [123].

4.4 Logics with noniterative axioms

Lewis [91] considered those logics in NExt $\mathbf{K}_n$ that can be axiomatised by $\mathcal{ML}_n$-formulas without nested modal operators. We call such logics *noniterative.* Examples of noniterative logics are

$$\mathbf{T} \;=\; \mathbf{K} \oplus \Box p \to p \qquad \text{or} \qquad \mathbf{K}_2 \oplus \Box_2 p \to \Box_1 p.$$

THEOREM 15 (Lewis). *All noniterative logics in* NExt $\mathbf{K}_n$ *have the fmp.*

Proof. Suppose that the axioms of $L = \mathbf{K}_n \oplus \Gamma$ have no nested modal operators and $\varphi \notin L$. Let $\mathsf{sub}\,\varphi$ be the set of all subformulas of φ. By a *φ-description* we mean any set of subformulas of φ together with the negations of the remaining formulas in $\mathsf{sub}\,\varphi$. For each L-consistent φ-description Θ, take a maximal L-consistent set Δ_Θ containing Θ. Denote by W the (finite) set of the selected Δ_Θ and define $\mathfrak{F} = \langle W, (R_i \mid i \in I)\rangle$ and $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V}\rangle$ by taking

$$\Delta_\Theta R_i \Delta_\Psi \qquad \text{iff} \qquad \Diamond_i \bigwedge \Psi \in \Delta_\Theta$$

and $\mathfrak{V}(p) = \{\Delta_\Theta \in W \mid p \in \Delta_\Theta\}$. It is easily proved that $(\mathfrak{M}, \Delta_\Theta) \models \psi$ iff $\psi \in \Delta_\Theta$, for all subformulas ψ of φ and $\Delta_\Theta \in W$. Hence $\mathfrak{F} \not\models \varphi$. It is also easy to see that for all truth-functional compounds ψ of subformulas of φ,

(9) $\quad (\mathfrak{M}, \Delta_\Theta) \models \Diamond_i \psi \qquad \text{iff} \qquad \Diamond_i \psi \in \Delta_\Theta.$

Consider now a model $\mathfrak{M}' = \langle \mathfrak{F}, \mathfrak{V}'\rangle$ and $\chi \in \Gamma$. For each variable p put

$$\psi_p \quad = \quad \bigvee \left\{ \bigwedge \Theta \mid \Delta_\Theta \in \mathfrak{V}'(p) \right\}$$

and denote by χ' the result of substituting ψ_p for p, for each p in χ. Then $\mathfrak{M}' \models \chi$ iff $\mathfrak{M} \models \chi'$. In view of (9), we have $\mathfrak{M} \models \chi'$ because χ' has no nested modalities. Thus, $\mathfrak{F} \models \chi$ and so $\mathfrak{F} \models L$. ❑

4.5 Modal reduction principles

Modal reduction principles—that is, formulas of the form $\boldsymbol{M}p \to \boldsymbol{N}p$, where $\boldsymbol{M}$ and $\boldsymbol{N}$ are strings of $\Box_i$ and $\Diamond_j$—have always attracted the attention of modal logicians, with the aim being to reduce the number of nested modal operators. (For example, both $\Box\Diamond p \leftrightarrow \Diamond p$ and $\Diamond\Box p \leftrightarrow \Box p$ are in $\mathbf{S5}$.) In the context of this chapter, we are interested in completeness and decidability of normal modal logics axiomatised by modal reduction principles.

As we know from Section 4.1, there are undecidable logics in NExt $\mathbf{K}_2$ with finitely many modal reduction principles as their axioms. But it seems that nearly nothing is known about the behaviour of logics with such axioms in NExt $\mathbf{K}$. Perhaps one of the most intriguing open problems in Modal Logic is the following:

PROBLEM 6. Do the logics of the form $\mathbf{K} \oplus \Box^n p \to \Box^m p$ have the finite model property?

Note, however, that by Sahlqvist theorem all logics of the form $\mathbf{K} \oplus \Box^n p \to \Box^m p$ are characterised by their Kripke frames that are definable by first-order formulas (which are

similar to transitivity: if y is accessible from x in m steps, then y is accessible from x in n steps as well).

Van Benthem [155] showed that modal reduction principles in $\mathcal{ML}_1$ are all first-order definable over *transitive* frames (this is not the case in general: e.g., the McKinsey axiom $\Box\Diamond p \to \Diamond\Box p$ is not first-order definable over arbitrary frames; see [155] for a complete characterisation).

The following result was proved in [175] using the method of canonical formulas to be discussed in Section 6:

THEOREM 16. *All logics in* NExt **K4** *axiomatisable by modal reduction principles have the fmp and are decidable.*

PROBLEM 7. Are extensions of $\mathbf{K}_n$ with modal reduction principles Kripke complete?

PROBLEM 8. Are extensions of **K** with modal reduction principles decidable?

4.6 Logics with n-variable axioms

A very natural syntactical parameter of a modal logic $L \oplus \Gamma$ is the number of variables in its extra axioms Γ over L. For example, $\mathbf{D} = \mathbf{K} \oplus \Diamond\top$ is axiomatised by a *variable-free* formula over **K** and almost all standard modal logics—e.g., **K4**, **S4**, **S5**, **Grz**, **GL**—can be axiomatised by adding axioms with only one variable to **K**. (A notable exception is **K4.3** whose axiomatisation requires two variables; see [119]).

We start our discussion of variable-free axioms with a simple observation that the truth of a variable-free formula φ does not depend on the valuation, i.e., for every model $\mathfrak{M}$ based on a frame $\mathfrak{F}$, we have $\mathfrak{M} \models \varphi$ iff $\mathfrak{F} \models \varphi$. Therefore, we can reduce deduction in $L \oplus \varphi$ to 'global' deduction in L. More precisely, we say that a formula ψ *follows globally* from a set Γ of formulas in a logic L if $\mathfrak{M} \models \Gamma$ implies $\mathfrak{M} \models \psi$ for every model $\mathfrak{M}$ based on a frame for L. Now, if global deduction is decidable for L, then $L \oplus \varphi$ is decidable: indeed, $\psi \in L \oplus \varphi$ iff ψ follows globally from φ in L.

To make use of this observation we need to know how to prove decidability of 'global deducibility' for modal logics L. For $L \in$ NExt **K4** this is simple because ψ follows globally from φ in L iff $\varphi \wedge \Box\varphi \to \psi \in L$.

THEOREM 17. *If φ is variable-free and $L \in$ NExt* **K4** *is decidable, then $L \oplus \varphi$ is decidable.*

Note that there are extensions of **K4** with *infinitely many* variable free axioms which are undecidable and do not have the fmp; for a concrete example and further details see [24]. This cannot happen in NExt **GL**, however, because each variable-free formula is deductively equivalent in **GL** to one of the formulas $\top$, $\Box^n\bot$, where $n < \omega$. Since $\Box^i\bot \to \Box^j\bot \in \mathbf{K4} \subseteq \mathbf{GL}$, for $i \leq j$, all extensions of **GL** with variable-free formulas are finitely axiomatisable and decidable.

The simple reduction of global deducibility above does not apparently work for 'non-transitive' logics in NExt **K**. In fact, there are decidable normal modal logics L such that global deducibility is undecidable for L. (The first example of such a logic was constructed by Spaan [139]. Another natural example is $\mathbf{K} \times \mathbf{K}$; for details see Chapter 15 or [48].) It should be clear that global deducibility in a finitely axiomatisable modal logic L is decidable if L enjoys the so-called *global finite model property* (global fmp, for short): for every finite set $\Gamma \cup \{\psi\}$ of formulas, ψ does not follow globally from Γ iff there exists a finite model $\mathfrak{M}$ based on a frame for L such that $\mathfrak{M} \models \Gamma$ and $\mathfrak{M} \not\models \varphi$. The global

fmp of many standard modal logics like $\mathbf{K}_n$, $\mathbf{K4}_n$, $\mathbf{S5}_n$ can be proved by filtration: just start with a possibly infinite model $\mathfrak{M}$ such that $\mathfrak{M} \models \Gamma$ and $\mathfrak{M} \not\models \psi$, and then filtrate it through the subformulas of $\Gamma \cup \{\psi\}$; see [59] for details. For example, we have the following:

THEOREM 18. *If φ is variable-free, then $\mathbf{K}_n \oplus \varphi$ is decidable.*

The undecidable Sahlqvist logic on page 447 shows that this result does not hold for axioms with one variable. Chagrov [21] constructed a one-variable formula φ such that $\mathbf{GL} \oplus \varphi$ is undecidable. It turns out, however, that we have the following theorem which was proved in [175] using the method of canonical formulas (to be discussed in Section 6):

THEOREM 19. *For every one-variable formula φ, $\mathbf{S4} \oplus \varphi$ has the fmp and is decidable.*

On the other hand, an infinite number of one-variable axioms can yield an extension of **S4** without the fmp [133]. A Kripke incomplete extension of **S4** with a two-variable axiom was constructed by Shehtman [132] and an undecidable logic above **S4** with a three-variable axiom by Chagrov [21].

PROBLEM 9. Are extensions of **S4** with a two-variable axiom decidable?

5 SEMANTICALLY CONSTRAINED CLASSES OF MODAL LOGICS

In the previous section we considered 'nice' classes of modal logics defined in terms of the form of the logics' axioms. Here we give a brief overview of well-behaved classes of modal logics determined by imposing some natural constraints on the form of their frames.

Tabular logics

A normal modal logic L is said to be *tabular* if it is determined by a *finite* set of *finite* frames . Since the class of frames for a normal modal logic is closed under disjoint unions, L is tabular iff there exists a single finite frame that determines L. In many respects tabular logics are easy to deal with. For instance, the problem of deciding whether a formula φ belongs to a tabular logic is trivially decided in NP by considering all possible valuations in the finite frame characterising L. Moreover, it is not difficult to provide a finite axiomatisation for a tabular logic; for details see, e.g., [177]. Thus, we arrive at the following:

THEOREM 20. *Every tabular logic is coNP-complete and finitely axiomatizable. Moreover, a normal modal logic is tabular if, and only if, it contains one of the formulas*

$$\boldsymbol{tab}_n \;=\; \neg(\varphi_1 \wedge \Diamond(\varphi_2 \wedge \Diamond(\varphi_3 \wedge \cdots \wedge \Diamond\varphi_n)\dots)) \wedge \bigwedge_{m=0}^{n-1} \neg\Diamond^m(\Diamond\varphi_1 \wedge \dots \wedge \Diamond\varphi_n)$$

where $\varphi_i = p_1 \wedge \cdots \wedge p_{i-1} \wedge \neg p_i \wedge p_{i+1} \wedge \cdots \wedge p_n$.

What is the position of tabular logics within the lattices NExt $\mathbf{K}_n$? First, it is easy to see that every normal modal logic containing a tabular modal logic L is tabular as well and is determined by frames that are p-morphic images of generated subframes of any frame which determines L. Therefore, we have:

THEOREM 21. *If L is tabular then* NExt L *is finite and contains only tabular logics.* NExt L *can be effectively computed.*

On the other hand, according to Theorem 9, the axiomatisation problem for tabular modal logics is always undecidable in NExt $\mathbf{K}_n$. The situation is not so hopeless if we consider the following relativised version of the axiomatisation problem for tabular logics above some sufficiently 'strong' logic $L_0 \supset \mathbf{K}_n$: given a tabular logic $L \supset L_0$ and an arbitrary formula φ, decide whether $L_0 \oplus \varphi = L$. For example, one can easily show (see, e.g., [24, 177] and references therein) that every tabular logic containing **K4** is a union-splitting of **K4** and that a logic is tabular in NExt **K4** iff it has finitely many normal extensions. Moreover, the following holds:

THEOREM 22. *If $L \in$ NExt* **K4** *is tabular then $\{\varphi \mid \mathbf{K4} \oplus \varphi = L\}$ is decidable.*

How to determine whether a given logic is tabular? The key idea suggested by Kuznetsov [82] is to consider the so-called pretabular logics.

A logic $L \in \text{NExt}\, L_0$ is said to be *pretabular* if L is not tabular but every proper extension of L in NExt L_0 is tabular. In other words, a pretabular logic is a maximal nontabular logic in NExt L_0. Using Zorn's lemma it is easily seen that, in NExt $\mathbf{K}_n$, every non-tabular logic is contained in a pretabular one. It is also known that every pretabular logic in NExt **K4** has the fmp (for proofs and references consult [24]). Moreover, Maksimova [96] and Esakia and Meskhi [38] showed that there are only five (pretty simple) pretabular logics in NExt **S4**. Using this result one can show the following:

THEOREM 23. *The set $\{\varphi \mid \mathbf{S4} \oplus \varphi$ is tabular$\}$ is decidable.*

Indeed, we launch two parallel processes: one of them generates all derivations in $\mathbf{S4} \oplus \varphi$ and stops after finding a derivation of $\boldsymbol{tab}_n$, for some $n < \omega$; another process checks if φ belongs to a pretabular logic in NExt **S4** and stops if this is the case. The termination of the first process means that $\mathbf{S4} \oplus \varphi$ is tabular, and if the second one comes to a stop then this logic is not tabular.

Note that there are a continuum of pretabular logics in NExt **K4**, while NExt **GL** contains countably many of them [10, 17], and the set $\{\varphi \mid \mathbf{GL} \oplus \varphi$ is tabular$\}$ is decidable.

PROBLEM 10. Is the set $\{\varphi \mid \mathbf{K4} \oplus \varphi$ is tabular$\}$ decidable?

Transitive logics of finite depth and width

A very natural semantical constraint on logics from NExt **K4** is the length of maximal chains and antichains in their rooted frames. Say that a logic $L \in$ NExt **K4** is of *depth* $n < \omega$ if L has a frame $\langle W, R\rangle$ with a chain $x_1 R x_2 R \dots R x_n$ of points from distinct clusters, but no frame with such chains of greater length validates L. Syntactically, logics of depth n can be defined as those extensions of **K4** that contain the formula $\boldsymbol{bd}_n$ but not $\boldsymbol{bd}_{n+1}$, where

$$\begin{aligned} \boldsymbol{bd}_1 &= \Diamond\Box p_1 \to p_1, \\ \boldsymbol{bd}_{n+1} &= \Diamond(\Box p_{n+1} \wedge \neg \boldsymbol{bd}_n) \to p_{n+1}. \end{aligned}$$

The following theorem was proved in [129]:

THEOREM 24 (Segerberg). *Every logic of finite depth has the finite model property* (*in fact, is locally tabular in the sense that it has only finitely many nonequivalent formulas with variables $p_1, \dots, p_n$*), *and so is decidable if finitely axiomatisable.*

It is to be noted that there are a continuum of logics of depth 3 [84].

Say that a logic $L \in \mathrm{NExt}\,\mathbf{K4}$ is of *width* $n < \omega$ if it has a rooted frame $\langle W, R\rangle$ with an antichain $x_1, \dots, x_n$ (i.e., $x_i R x_j$ does not hold for any distinct $i, j \leq n$) but no rooted frame with an $n+1$-point antichain validates L. Syntactically, logics of width n can be described as those extensions of $\mathbf{K4}$ that contain the formula $\boldsymbol{bw}_n$ but not $\boldsymbol{bw}_{n+1}$, where

$$\boldsymbol{bw}_n \quad = \quad \bigwedge_{i=0}^{n} \Diamond p_i \to \bigvee_{0 \leq i \neq j \leq n} \Diamond\big(p_i \wedge (p_j \vee \Diamond p_j)\big).$$

The logics of width 1 are precisely the extensions of $\mathrm{NExt}\,\mathbf{K4.3}$.

The following theorem was proved in [43]:

THEOREM 25 (Fine). *All logics of finite width are Kripke complete.*

There are a continuum of logics of width 1. However, those of them that are finitely axiomatisable behave quite nicely as was shown in [176, 93]:

THEOREM 26. *All finitely axiomatisable logics in* $\mathrm{NExt}\,\mathbf{K4.3}$ *are decidable* (*in fact coNP-complete*), *though not necessarily have the finite model property.*

Nothing is known about decidability of finitely axiomatisable logics of width $n > 1$ (our conjecture is that all of them are decidable):

PROBLEM 11. Are finitely axiomatisable logics of width $n > 1$ decidable? What is their computational complexity?

For logics above $\mathbf{S4.3}$ we have the following classical result of [14, 40, 139]. Here and in what follows we say that a logic L has the *poly-size model property* if every formula $\varphi \notin L$ is refuted in a model based of a frame for L of polynomial size.

THEOREM 27 (Bull, Fine, Spaan). *All logics in* $\mathrm{NExt}\,\mathbf{S4.3}$ *are finitely axiomatisable, have the poly-size model property, and are coNP-complete.*

PROBLEM 12. Does there exist an algorithm that decides, given a formula φ, whether the logic $\mathbf{K4} \oplus \varphi$ is of finite width/depth?

It is worth noting that if the problem whether $L = \mathbf{K4} \oplus \varphi$ is of depth depth (or, which is equivalent, whether L is locally tabular) is decidable, then the tabularity problem for $\mathbf{K4}$ (that is, Problem 10) is decidable as well. Indeed, suppose that we have an algorithm for deciding, given a formula φ, whether $\mathbf{K4} \oplus \varphi$ is locally tabular. If this hypothetical algorithm says that $L = \mathbf{K4} \oplus \varphi$ is not locally tabular then L is not tabular either. Otherwise, we can effectively find some number n such that $\boldsymbol{bd}_n \in L$. And then we use Blok's [10] result according to which there are only *finitely many* pretabular logics containing $\boldsymbol{bd}_n$. All these pretabular logics have rather simple Kripke frames which can be easily axiomatised, so all of them are decidable. What remains to be done is to run Kuznetsov's algorithm described above.

Logics containing K5

Recall that $\mathbf{K5} = \mathbf{K} \oplus \Diamond\Box p \to \Box p$ is the logic determined by all *Euclidean* frames $\langle W, R\rangle$, where Euclidean means that

$$\forall x \forall y \forall z (xRz \wedge xRy \to yRz).$$

The papers [113, 114] investigate the (possibly non-normal) extensions of **K5**. The following theorem summarises the results for logics in NExt **K5**:

THEOREM 28 (Nagle, Thomason). *All logics in* NExt **K5** *have the finite model property, are finite axiomatisable, and so decidable. The lattice* NExt **K5** *can be computed effectively.*

It is not difficult to see that actually all logics in NExt **K5** have the poly-size model property and are coNP-complete.

Logics containing $\mathbf{S5} \times \mathbf{S5}$

$\mathbf{S5} \times \mathbf{S5}$ is the bimodal logic determined by product frames of the form $\langle W \times W, R_1, R_2 \rangle$, where $(w_1, w_2)R_1(w_1', w_2')$ iff $w_2 = w_2'$, and $(w_1, w_2)R_2(w_1', w_2')$ iff $w_1 = w_1'$. It was introduced and investigated because of its close relation to the two-variable fragment of first-order logic [130, 48]; see also Chapter 15. $\mathbf{S5} \times \mathbf{S5}$ can be axiomatised by adding to the fusion (see Chapter 15) of **S5** with **S5** the modal axiom $\Diamond_1 \Diamond_2 p \leftrightarrow \Diamond_2 \Diamond_1 p$ saying that R_1 and R_2 commute. Logics containing $\mathbf{S5} \times \mathbf{S5}$ are surprisingly well-behaved. Indeed, while $\mathbf{S5} \times \mathbf{S5}$ itself is NEXPTIME-complete [103], it was proved in [6, 5] that we have the following:

THEOREM 29. *Every normal bimodal logic properly containing* $\mathbf{S5} \times \mathbf{S5}$ *has the poly-size model property, is finitely axiomatisable and coNP-complete.*

The axiomatisation result is based on a variant of Kruskal's tree theorem. The picture is different if a constant for the diagonal $\{(w, w) \mid w \in W\}$ (motivated by its interpretation as 'equality' in first-order logic) is added to the bimodal language. In this case there exist uncountably many normal modal logics extending $\mathbf{S5} \times \mathbf{S5}$ with the diagonal, and it is open whether all of them have the finite model property [3, 4].

Logics containing $\mathbf{K} \oplus \mathbf{alt}_n$

A frame $\mathfrak{F} = \langle W, R \rangle$ validates the formula

$$\boldsymbol{alt}_n \quad = \quad \Box p_1 \vee \Box(p_1 \to p_2) \vee \cdots \vee \Box(p_1 \wedge \cdots \wedge p_n \to p_{n+1}),$$

where $n \geq 0$, iff each point in $\mathfrak{F}$ has at most n distinct R-successors. Segerberg [131] proved the following:

THEOREM 30. *All logics in* NExt $(\mathbf{K} \oplus \boldsymbol{alt}_1)$ *have the finite model property, are finitely axiomatisable, and so decidable. The lattice* NExt $(\mathbf{K} \oplus \boldsymbol{alt}_1)$ *can be computed effectively.*

It is not difficult to see that actually all extensions of $\mathbf{K} \oplus \boldsymbol{alt}_1$ have the poly-size model property and are coNP-complete. Extensions of $\mathbf{K} \oplus \boldsymbol{alt}_n$ for $n > 1$ are investigated in [1]:

THEOREM 31. *All logics in* NExt $(\mathbf{K} \oplus \boldsymbol{alt}_n)$ *are Kripke complete and their frames are first-order definable.*

An analysis of polymodal extensions of $\mathbf{K} \oplus \boldsymbol{alt}_n$ is given in [76, 61].

6 FRAME-THEORETIC CHARACTERISATION

Finding characterisations of those classes of structures that can be defined by (sets of) formulas of a given language $\mathcal{L}$ is one of the central research problems in the development of a model theory for the language. This is often achieved by introducing certain truth-preserving operators on classes of structures (e.g., the formation of p-morphic images, generated subframes, disjoint unions, ultraproducts, etc.) and then proving that the $\mathcal{L}$-definable classes are precisely those that are closed under these operators—a kind of Birkhoff-type theorem for varieties of abstract algebras. Such characterisations for modal logics are discussed in Chapters 5 and 6 on modal model theory and algebras. Unfortunately, abstract characterisations of this sort are of limited use when we deal with modal decision problems. In this context, what we need is not characterisations that are 'as abstract as possible,' but rather *explicit finitely presentable* ones.

Of course, modal formulas themselves can be regarded as a 'finitely presented characterisation' of modally definable classes of frames. However, in general, the information contained in formulas is rather *implicit* and non-structural (or 'non-geometric')—one has to work hard to learn how to decipher their meaning.

As a first step towards more informative finite presentations of modally definable classes of general frames, let us find out which of these classes $\mathcal{F}$ cannot be *decomposed* in the sense that whenever $\mathcal{F} = \mathsf{GFr}\,\Gamma$, for some set Γ of modal formulas, then there is a $\psi \in \Gamma$ such that $\mathcal{F} = \mathsf{GFr}\,\{\psi\}$. This means, in particular, that we cannot make the information provided by such a formula ψ 'more explicit' by replacing it with two (or more) formulas ψ_1 and ψ_2 such that $\mathsf{GFr}\,\{\psi\} = \mathsf{GFr}\,\{\psi_1, \psi_2\}$, but $\mathsf{GFr}\,\{\psi\} \subsetneqq \mathsf{GFr}\,\{\psi_i\}$ for $i = 1, 2$.

Again, as in Blok's dichotomy and Chagrov's classification, it is the notion of splittings that provides a proper framework for investigating indecomposability. In fact, one can show that, for every normal modal logic L, the class $\mathsf{GFr}\,L$ is indecomposable iff there exists a finite rooted (cycle free) frame $\mathfrak{F}$ such that $L = \mathbf{K}/\mathfrak{F}$. Indeed, suppose that $L = \mathbf{K}/\mathfrak{F} = \mathbf{K} \oplus \Gamma$ for some set of formulas Γ. Then there is a $\psi \in \Gamma$ such that $\mathfrak{F} \not\models \psi$ (for otherwise $\mathfrak{F} \models \Gamma$ and therefore $\mathfrak{F} \in \mathsf{GFr}\,L$). But then $L \subseteq \mathbf{K} \oplus \psi$, from which (since $\psi \in \Gamma$) $L = \mathbf{K} \oplus \psi$. (For the other direction and further details see Chapter 8.) Thus, we can say that the formula ψ describes $\mathcal{F}$. Moreover, in view of (4), ψ is deductively equivalent to the formula $\Box^{\leq n}\delta_{\mathfrak{F}} \to \neg p_r$, where $n = d(\mathfrak{F})$, which explicitly says: '$\mathfrak{G} \in \mathcal{F}$ *iff there does not exist a generated subframe of* $\mathfrak{G}$ *having* $\mathfrak{F}$ *as its p-morphic image.*' The formula $\Box^{\leq n}\delta_{\mathfrak{F}} \to \neg p_r$ can be regarded as a *modal diagram* of $\mathfrak{F}$.

It follows from these considerations that we would have a kind of optimal explicit and finite presentation of modally definable classes if we could prove that for every formula φ there exists a set $\mathcal{F}$ of finite rooted frames such that

$$\mathsf{GFr}\,\varphi \quad = \quad \mathsf{GFr}\,(\mathbf{K}/\mathcal{F}).$$

Then every modally definable class could be presented by means of a set of indecomposable geometrically explicit formulas as above.

Now, the *bad news* is that we know from the proof of Blok's dichotomy that this is far from being the case: $\mathbf{D}$ is the only standard modal system that can be represented in this way.

But the *good news* is that this situation changes drastically as soon as we confine ourselves to 'transitive' modal logics, in particular, unimodal normal extensions of $\mathbf{K4}$,

linear tense logics, or bimodal provability logics. Although, as we shall see below, it is impossible to represent all normal modal logics extending, say, **K4** in the form $L = \mathbf{K4}/\mathcal{F}$, for some set $\mathcal{F}$ of finite rooted frames, we can still introduce appropriate modifications and extensions of the notion of splitting which allow geometric finite representations of every normal extension of **K4**. In this chapter we will show such representations first for normal extensions of **K4** and then for extensions of linear tense logics. The case of bimodal provability logics is considered in [167].

6.1 Canonical formulas for **K4**

This frame-theoretic or 'geometric' approach to investigating modal logics in NExt **K4** and similar classes was launched by Jankov [66, 69] (in the framework of extensions of intuitionistic logic[6]), Blok [9], Fine [45] and Zakharyaschev [172, 174, 175]. Let us observe first that a number of standard logics in NExt **K4** are indeed union-splittings, and so their frames can be elegantly characterised in frame-theoretic terms. For example,

$\mathbf{S4} = \mathbf{K4} \oplus \Box p \to p = \mathbf{K4}/\{\bullet,$  $\}$,

$\mathbf{S4.1} = \mathbf{S4} \oplus \Box\Diamond p \to \Diamond\Box p = \mathbf{S4}/②$,

$\mathbf{S4.2} = \mathbf{S4} \oplus \Diamond\Box p \to \Box\Diamond p = \mathbf{S4}/$  ,

where ② is a two-point cluster. As we saw above, this means that, e.g., for every (general) frame $\mathfrak{F}$ for **S4**, $\mathfrak{F} \not\models \Box\Diamond p \to \Diamond\Box p$ iff there is a generated subframe of $\mathfrak{F}$ which can be p-morphically mapped onto ②. To appreciate the elegance of this frame-theoretic language, compare the purely geometric characterisation above with the standard first-order description of the Kripke frames for **S4.1**:

$$\langle W, R\rangle \models \Box\Diamond p \to \Diamond\Box p \qquad \text{iff} \qquad \forall x \exists y \; \big(xRy \wedge \forall z \; (yRz \to y = z)\big).$$

This observation leads to the following natural questions:

(A) Is it possible to characterise transitive frames for arbitrary formulas in a similar way?

(B) If this is indeed the case, then perhaps the decision problem (as well as many other problems) could be reduced to 'comparing' some finite frames? (For example, $\mathbf{K4}/\mathfrak{F} \subseteq \mathbf{K4}/\mathfrak{G}$ iff $\mathfrak{G}$ is a p-morphic image of some generated subframe of $\mathfrak{F}$.)

We analyse these questions using a number of simple examples. Consider first the Gödel–Löb provability logic $\mathbf{GL} = \mathbf{K4} \oplus \boldsymbol{la}$, where

$$\boldsymbol{la} \quad = \quad \Box(\Box p \to p) \to \Box p.$$

It is well-known that a Kripke frame $\mathfrak{F}$ validates $\boldsymbol{la}$ iff $\mathfrak{F}$ is transitive, irreflexive (i.e., a strict partial order) and *Noetherian* in the sense that it contains no infinite ascending

[6] Jankov [69] described all 'conjunctively indecomposable' intuitionistic formulas—i.e., splittings of the extensions of intuitionistic logic—and promised to investigate 'decomposable formulas' in his next paper which has never appeared. At the beginning of the 1980s he was arrested by the KGB for his support of the Solidarity movement in Poland.

chain. It is also well-known that the condition of Noetherianness is not a first-order one. But what is more important in the present context, the frame

$$\circ \quad \cdots \rightarrow\bullet\rightarrow\bullet\rightarrow\bullet$$

refutes $\boldsymbol{la}$ and yet contains no generated subframe that can be p-morphically mapped onto a finite frame refuting $\boldsymbol{la}$. This means that **GL** is not a union-splitting of NExt **K4** by means of finite frames. To find an explicit finitely presentable geometric characterisation of frames for **GL** some other frame-theoretic constructions are needed. Let us have another look at the structure of countermodels for $\boldsymbol{la}$.

Suppose that a general frame $\mathfrak{F} = \langle W, R, P\rangle$ refutes $\boldsymbol{la}$ under some valuation. Then the set $V = \{x \in W \mid x \not\models \boldsymbol{la}\}$ is in P and $V \subseteq V{\downarrow} = \{w \in W \mid \exists v \in V\ wRv\}$. It follows from the former that $\mathfrak{G} = \langle V, R{\restriction}V, \{X \cap V \mid X \in P\}\rangle$ is a frame—we call it the *subframe of* $\mathfrak{F}$ *induced by* V. And the latter condition means that there is a p-morphism from $\mathfrak{G}$ onto a single reflexive point $\circ$, which is the simplest refutation frame for $\boldsymbol{la}$. Moreover, one can readily check that the converse also holds: if there is a subframe $\mathfrak{G}$ of $\mathfrak{F}$ which can be p-morphcally mapped onto $\circ$ then $\mathfrak{F} \not\models \boldsymbol{la}$.

This example motivates the following definitions. Given frames $\mathfrak{F} = \langle W, R, P\rangle$ and $\mathfrak{G} = \langle V, S, Q\rangle$, a partial (i.e., not totally defined, in general) map f from W onto V is called a *subreduction* of $\mathfrak{F}$ to $\mathfrak{G}$ if, for all $x, y \in \operatorname{dom} f = f^{-1}(V)$ and all $X \in Q$, it satisfies the following conditions

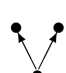
- xRy implies $f(x)Sf(y)$;
- $f(x)Sf(y)$ implies $\exists z \in W\ \big(xRz \wedge f(z) = f(y)\big)$;
- $f^{-1}(X) \in P$.

In other words, an f-*subreduct* of $\mathfrak{F}$ is a p-morphic image—or a *reduct*—of the subframe of $\mathfrak{F}$ induced by $\operatorname{dom} f$. A frame $\mathfrak{G} = \langle V, S, Q\rangle$ is a *subframe* of $\mathfrak{F} = \langle W, R, P\rangle$ if $V \subseteq W$ and the identity map on V is a subreduction of $\mathfrak{F}$ to $\mathfrak{G}$, i.e., if $S = R{\restriction}V$ and $Q \subseteq P$. Note that a generated subframe $\mathfrak{G}$ of $\mathfrak{F}$ is not in general a subframe of $\mathfrak{F}$, since V may be not in P.

Thus, the characterisation of frames for **GL** can be reformulated like this: $\mathfrak{F} \not\models \boldsymbol{la}$ iff $\mathfrak{F}$ is subreducible to $\circ$. Here are two more examples:

- A frame $\mathfrak{F}$ refutes the *Grzegorczyk axiom* $\Box(\Box(p \to \Box p) \to p) \to p$ iff it is subreducible to $\bullet$ or to ②.
- A quasi-order $\mathfrak{F}$ refutes the *Dummett axiom* $\Box(\Box p \to q) \vee \Box(\Box q \to p)$ iff $\mathfrak{F}$ is subreducible to  .

Now let us consider the logic $\mathbf{GL.2} = \mathbf{GL} \oplus \boldsymbol{ga}$, where $\boldsymbol{ga}$ is the *Geach axiom* $\Diamond\Box p \to \Box\Diamond p$. It is easy to see that every Kripke frame refuting $\boldsymbol{ga}$ must contain the fork



as a subframe, and in general, if $\mathfrak{F} \not\models \boldsymbol{ga}$ then $\mathfrak{F}$ is subreducible to this fork. However, the converse does not hold—just add a point $\bullet$ above the spikes of the fork to obtain a

counterexample. What we actually need is a fork-like subframe with its spikes having no common successor. A good mathematical notion that is capable of describing this and other similar cases is the notion of cofinality.

A subreduction f of $\mathfrak{F}$ to $\mathfrak{G}$ is called *cofinal* if

$$\mathrm{dom} f\uparrow \quad \subseteq \quad \mathrm{dom}\, f \cup \mathrm{dom}\, f\downarrow$$

or in English: if a point x is accessible from the domain of f then either x belongs to the domain of f itself or 'sees' a point in $\mathrm{dom}\, f$. For example, if we add to the fork a top point as above, then the resulting frame is subreducible to the original fork, but *not cofinally* because the top point cannot belong to the domain of the subreduction.

Returning back to the Geach axiom $\boldsymbol{ga}$, it is an easy exercise to show that a frame $\mathfrak{F}$ for **GL** refutes $\boldsymbol{ga}$ iff $\mathfrak{F}$ is cofinally subreducible to . Another example: a transitive $\mathfrak{F}$ refutes $\Diamond\top$ iff $\mathfrak{F}$ is cofinally subreducible to $\bullet$.

For the majority of standard modal axioms these two notions—plain and cofinal subreductions—are enough. But not for all. The simplest counterexample is the *density axiom* $\boldsymbol{den} = \Box\Box p \to \Box p$. It is refuted by the chain $\mathfrak{H}$ of two irreflexive points but becomes valid if we insert between them a reflexive one. In fact, $\mathfrak{F} \not\models \boldsymbol{den}$ iff there is a subreduction f of $\mathfrak{F}$ to $\mathfrak{H}$ such that $f(x\uparrow) = \{a\}$ for no point x in $\mathrm{dom}\, f\uparrow - \mathrm{dom}\, f$, where a is the final point in $\mathfrak{H}$.

Intuitively, every refutation frame for formulas like $\boldsymbol{la}$ can be constructed by adding new points to a frame $\mathfrak{G}$ that is reducible to some finite refutation frame of fixed size. For formulas like $\boldsymbol{ga}$ we have to take into account the cofinality condition and do not place new points 'above' $\mathfrak{G}$. And formulas like $\boldsymbol{den}$ impose another restriction: some places inside $\mathfrak{G}$ may be 'closed' for inserting new points. These 'closed domains' can be singled out in the following way.

Suppose $\mathfrak{N} = \langle \mathfrak{H}, \mathfrak{U} \rangle$ is a model and $\mathfrak{a}$ an *antichain* in $\mathfrak{H}$—i.e., the points in $\mathfrak{a}$ do not see each other. Say that $\mathfrak{a}$ is an *open domain* in $\mathfrak{N}$ relative to a formula φ if there is a pair $t_{\mathfrak{a}} = (\Gamma_{\mathfrak{a}}, \Delta_{\mathfrak{a}})$ such that $\Gamma_{\mathfrak{a}} \cup \Delta_{\mathfrak{a}} = \mathsf{sub}\,\varphi$, $\bigwedge \Gamma_{\mathfrak{a}} \to \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{K4}$ and

- $\Box\psi \in \Gamma_{\mathfrak{a}}$ implies $\psi \in \Gamma_{\mathfrak{a}}$,
- $\Box\psi \in \Gamma_{\mathfrak{a}}$ iff $a \models \Box^+\psi$ for all $a \in \mathfrak{a}$.

Otherwise $\mathfrak{a}$ is called a *closed domain* in $\mathfrak{N}$ relative to φ. A reflexive singleton $\mathfrak{a} = \{a\}$ is always open: just take $t_{\mathfrak{a}} = (\{\psi \in \mathsf{sub}\,\varphi \mid a \models \psi\}, \{\psi \in \mathsf{sub}\,\varphi \mid a \not\models \psi\})$. It is easy to see also that antichains consisting of points from the same clusters are open or closed simultaneously; we will not distinguish between such antichains.

Given a frame $\mathfrak{H}$ and a (possibly empty) set $\mathfrak{D}$ of antichains in $\mathfrak{H}$, we say that a subreduction f of $\mathfrak{F}$ to $\mathfrak{H}$ satisfies the *closed domain condition* for $\mathfrak{D}$ if

$$\text{(CDC)} \qquad \neg\exists x \in \mathrm{dom}\, f\uparrow - \mathrm{dom}\, f \;\exists \mathfrak{d} \in \mathfrak{D} \quad f(x\uparrow) \;=\; \mathfrak{d} \cup \mathfrak{d}\uparrow.$$

In terms of (CDC) refutation frames for the density axiom $\boldsymbol{den}$ can be characterised as follows: $\mathfrak{F} \not\models \boldsymbol{den}$ iff there is a subreduction of $\mathfrak{F}$ to  satisfying (CDC) for $\{\{a\}\}$.

Suppose now that $\mathfrak{N} = \langle \mathfrak{H}, \mathfrak{U} \rangle$ is a finite countermodel for φ and $\mathfrak{D}$ is the set of all closed domains in $\mathfrak{N}$ relative to φ. We claim that in this case $\mathfrak{F} \not\models \varphi$ whenever there is a cofinal subreduction f of $\mathfrak{F}$ to $\mathfrak{H}$ satisfying (CDC) for $\mathfrak{D}$. Moreover, if φ is *negation free* (i.e., contains no $\bot$, $\neg$, $\Diamond$) then a plain subreduction satisfying (CDC) for $\mathfrak{D}$ is enough. Indeed, if f is cofinal and $\mathfrak{F} = \langle W, R, P \rangle$ then we can assume that $\operatorname{dom} f \cup \operatorname{dom} \uparrow = W$. Define a valuation $\mathfrak{V}$ in $\mathfrak{F}$ as follows. If $x \in \operatorname{dom} f$ then we take $x \models p$ iff $f(x) \models p$, for every variable p in φ. If $x \notin \operatorname{dom} f$ then $f(x\uparrow) \neq \emptyset$, since f is cofinal. Let $\mathfrak{a}$ be an antichain in $\mathfrak{H}$ such that $\mathfrak{a} \cup \mathfrak{a} \uparrow = f(x\uparrow)$. By (CDC), $\mathfrak{a}$ is an open domain in $\mathfrak{N}$, and we put $y \models p$ iff $p \in \Gamma_{\mathfrak{a}}$, for every $y \notin \operatorname{dom} f$ such that $f(y\uparrow) = f(x\uparrow)$. It is easy to check that under this valuation $x \models \psi$ iff $f(x) \models \psi$ in the case $x \in \operatorname{dom} f$, and $x \models \psi$ iff $\psi \in \Gamma_{\mathfrak{a}}$, where $\mathfrak{a}$ is the open domain in $\mathfrak{N}$ associated with x, in the case $x \notin \operatorname{dom} f$, for every $\psi \in \mathsf{sub}\, \varphi$. If φ is negation free and f is a plain subreduction then $f(x\uparrow)$ may be empty. In such a case we just put $x \models p$, for all variables p.

Moreover, given an arbitrary formula φ, one can effectively construct a finite collection of finite rooted frames $\mathfrak{F}_1, \dots, \mathfrak{F}_n$ (of some fixed size that depends on the size of φ) and select in them sets $\mathfrak{D}_1, \dots, \mathfrak{D}_n$ of antichains such that, for any frame $\mathfrak{F}$, $\mathfrak{F} \not\models \varphi$ iff there is a cofinal subreduction of $\mathfrak{F}$ to $\mathfrak{F}_i$, for some i, satisfying (CDC) for $\mathfrak{D}_i$. If φ is negation free then a plain subreduction satisfying (CDC) is enough. Details can be found in [172, 24].

This 'explicit finitely presentable' characterisation of the constitution of refutation transitive frames can be expressed in the language of modal formulas similarly to the equation

$$\mathbf{K}/\mathfrak{F} \quad = \quad \mathbf{K} \;\oplus\; \Box^{\leq n}\delta_{\mathfrak{F}} \to \neg p_r.$$

Indeed, with every finite frame $\mathfrak{F} = \langle W, R \rangle$ with root r and every (possibly empty) set $\mathfrak{D}$ of antichains in $\mathfrak{F}$ we can associate formulas $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ such that $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ ($\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D})$) iff there is a cofinal (respectively, plain) subreduction of $\mathfrak{G}$ to $\mathfrak{F}$ satisfying (CDC) for $\mathfrak{D}$. Consider, for example, the following formulas

$$\alpha(\mathfrak{F}, \mathfrak{D}, \bot) \quad = \quad \Box^{+}\delta(\mathfrak{F}, \mathfrak{D}) \to \neg p_r,$$

where

$$\begin{aligned}
\delta(\mathfrak{F}, \mathfrak{D}) \quad = \quad & \bigwedge_{xRy} (p_x \to \Diamond p_y) \wedge \bigwedge_{\neg xRy} (p_x \to \neg\Diamond p_y) \wedge \bigwedge_{x \neq y} (p_x \to \neg p_y) \wedge \\
& \bigwedge_{\mathfrak{d} \in \mathfrak{D}} \Big(\bigwedge_{\substack{x \in \mathfrak{d} \cup \mathfrak{d}\uparrow \\ y \notin \mathfrak{d} \cup \mathfrak{d}\uparrow}} (\Diamond p_x \wedge \neg\Diamond p_y) \to \bigvee_{z \in W} p_z \Big) \wedge \\
& \bigwedge_{x \in W} (p_x \to \Diamond \bigvee_{y \in W} p_y)
\end{aligned}$$

and $\alpha(\mathfrak{F}, \mathfrak{D})$ is obtained by omitting the last conjunct from $\delta(\mathfrak{F}, \mathfrak{D})$. The formulas $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ (or any other deductively equivalent formulas) are called the *canonical* and *negation free canonical formulas* for $\mathfrak{F}$ and $\mathfrak{D}$, respectively (it is not hard to get rid of $\neg$ and $\Diamond$ in the latter formula; see, e.g., [24]). The semantical meaning of these formulas should be clear: $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ is refuted in a frame $\mathfrak{G}$ iff there is a cofinal subreduction of $\mathfrak{G}$ to $\mathfrak{F}$ satisfying (CDC) for $\mathfrak{D}$.

K4.2	$=$	$\mathbf{K4} \oplus \alpha\left(\begin{smallmatrix}\bullet\\ \uparrow\\ \bullet\\ \uparrow\\ \bullet\end{smallmatrix}, \bot\right) \oplus \alpha\left(\begin{smallmatrix}\bullet\\ \uparrow\\ \circ\end{smallmatrix}, \bot\right) \oplus \alpha\left(\begin{smallmatrix}* & & *\\ \nwarrow & & \nearrow\\ & * & \end{smallmatrix}, \bot\right)$ (8 axioms)
K4.3	$=$	$\mathbf{K4} \oplus \alpha\left(\begin{smallmatrix}* & & *\\ \nwarrow & & \nearrow\\ & * & \end{smallmatrix}\right)$ (6 axioms)
Dum	$=$	$\mathbf{S4} \oplus \alpha\left(\begin{smallmatrix}② & & \circ\\ \nwarrow & & \nearrow\\ & \circ & \end{smallmatrix}\right) \oplus \alpha\left(\begin{smallmatrix}\circ\\ \uparrow\\ ②\end{smallmatrix}\right)$

Table 1. Canonical axioms of standard modal logics

THEOREM 32. *There is an algorithm which, given an $\mathcal{ML}_1$-formula φ, returns canonical formulas $\alpha(\mathfrak{F}_1, \mathfrak{D}_1, \bot), \dots, \alpha(\mathfrak{F}_n, \mathfrak{D}_n, \bot)$ such that*

$$\mathbf{K4} \oplus \varphi = \mathbf{K4} \oplus \alpha(\mathfrak{F}_1, \mathfrak{D}_1, \bot) \oplus \cdots \oplus \alpha(\mathfrak{F}_n, \mathfrak{D}_n, \bot).$$

If φ is negation free then one can use negation free canonical formulas.

Table 1 shows canonical axiomatisations of some standard modal logics in the field of **K4**. For brevity we write $\alpha(\mathfrak{F}, \bot)$ instead of $\alpha(\mathfrak{F}, \emptyset, \bot)$ and $\alpha(\mathfrak{F})$ instead of $\alpha(\mathfrak{F}, \emptyset)$. Each $*$ in the table is to be replaced by both $\circ$ and $\bullet$.

Theorem 32 provides a solution to problem (A) formulated at the beginning of this section. It shows that as far as such properties of modal logics (from NExt **K4**) as decidability, completeness, the fmp, etc. are concerned, we can always deal with canonical formulas—which explicitly describe their frames. And the following observation gives a *partial* solution to problem (B).

THEOREM 33. (1) *For every logic $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \emptyset) \mid i \in I\}$ and every canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$, we have $\alpha(\mathfrak{F}, \mathfrak{D}, \bot) \in L$ iff $\mathfrak{F}$ is subreducible to $\mathfrak{F}_i$ for some $i \in I$.*

(2) *For every logic $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \emptyset, \bot) \mid i \in I\}$ and every canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$, we have $\alpha(\mathfrak{F}, \mathfrak{D}, \bot) \in L$ iff $\mathfrak{F}$ is cofinally subreducible to $\mathfrak{F}_i$ for some $i \in I$.*

(3) *For every logic $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \mathfrak{D}_i, \bot) \mid i \in I\}$ and every canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}^\sharp, \bot)$ where $\mathfrak{D}^\sharp$ is the set of all antichains in $\mathfrak{F}$, we have $\alpha(\mathfrak{F}, \mathfrak{D}^\sharp, \bot) \in L$ iff there is a generated subframe of $\mathfrak{F}$ that is reducible to $\mathfrak{F}_i$ for some $i \in I$.*

It follows from (3) that $\mathbf{K4} \oplus \varphi$ is a splitting of NExt $\mathbf{K4}$ iff φ is deductively equivalent in NExt $\mathbf{K4}$ to a formula of the form $\alpha(\mathfrak{F}, \mathfrak{D}^\sharp, \bot)$, where $\mathfrak{D}^\sharp$ is the set of all antichains in $\mathfrak{F}$ (in this case $\mathbf{K4}/\mathfrak{F} = \mathbf{K4} \oplus \alpha(\mathfrak{F}, \mathfrak{D}^\sharp, \bot)$). Such formulas are known as *Jankov formulas* (Jankov [66] introduced them for intuitionistic logic in the algebraic setting), or *frame formulas* (used by Fine [43]), or *Jankov–Fine formulas*.

But the most interesting consequence can be drawn from (1) or (2): all logics mentioned in (1) and (2) of Theorem 33 have the fmp, and so are decidable if finitely axiomatisable. It follows, for instance, that all logics in NExt $\mathbf{S4.3}$—which can be represented in the form (2) because antichains in frames for $\mathbf{S4.3}$ are reflexive singletons—have the fmp. It is not hard to see also that all these logics are finitely axiomatisable which gives the well-known result of Bull [14] and Fine [40] from Theorem 27.

As we have already mentioned, practically all 'standard' modal logics in the field of $\mathbf{K4}$ can be axiomatised by canonical formulas of the form $\alpha(\mathfrak{F}, \emptyset, \bot)$ or $\alpha(\mathfrak{F}, \emptyset)$. This yields an answer to the question 'why modal logic is so robustly decidable?' of Vardi [158] for the case of transitive unimodal logics. Although it is impossible to effectively recognise whether a logic $\mathbf{K4} \oplus \varphi$ can be axiomatised by such formulas [25], there is a simple model-theoretic characterisation of logics from (1) and (2) of Theorem 33 discovered in [45, 174]:

THEOREM 34. (1) *A logic $L \in$ NExt $\mathbf{K4}$ is axiomatisable by canonical formulas of the form $\alpha(\mathfrak{F}, \emptyset)$ iff L is characterised by a class of (general) frames that is closed under the formation of subframes.*

(2) *A logic $L \in$ NExt $\mathbf{K4}$ is axiomatisable by canonical formulas of the form $\alpha(\mathfrak{F}, \emptyset, \bot)$ iff L is characterised by a class of (general) frames that is closed under the formation of cofinal subframes.*

The logics from (1) and (2) are called *subframe* and *cofinal subframe logics*, respectively. It turns out that for these logics the notions of first-order definability, canonicity and strong Kripke completeness are equivalent; see [45, 174] and Theorem 44 below. It is worth noting that the fmp of (cofinal) subframe logics and the decidability of those of them that are finitely axiomatisable (there are a continuum of subframe logics [174]) is obtained from Theorems 32 and 33 for free: it suffices to check whether the frame of the tested canonical formula is (cofinally) subreducible to the frame of one of the canonical axioms of a given logic. This provides us with another general method of proving that a given logic is Kripke complete, decidable, canonical, has the finite model property, etc.: usually it is much easier to check that the class of general frames for a given logic is closed under cofinal subframes and to find the logic's canonical axioms than to use filtration and/or canonical models.

PROBLEM 13. Characterise the computational complexity of finitely axiomatisable cofinal subframe logics (e.g., all such extensions of $\mathbf{K4.3}$ are coNP-complete).

PROBLEM 14. Give a syntactical characterisation of subframe and cofinal subframe logics (cf. Theorem 53).

Note that, for every (cofinal) subframe logic L and every formula $\varphi \notin L$, there is a frame for L refuting φ whose size is exponential in the length of φ.

In general, question (B) does not seem to have such an elegant answer as for the case of cofinal subframe logics (see, however, [147] for a recent attempt to introduce 'canonical formulas' for NExt $\mathbf{K}$). We can only console ourselves with a number of sufficient

conditions of decidability, the fmp (in particular, Theorems 16 and 19) and some other properties imposed on the canonical axioms; for details consult [25, 175, 24, 177].

6.2 Canonical formulas for tense logics of linear time flows

In this section we consider normal bimodal logics containing the tense logic **Lin** of linear orders (the class of all frames $\langle W, R_1, R_2\rangle$ in which R_2 is the converse of R_1 and R_1 is a linear order, i.e., R_1 is transitive and connected $(\forall x \forall y xR_1y \vee yR_1x \vee x = y)$). These logics are of interest in this chapter for two reasons. First, many natural and useful modal logics are contained in this class, e.g., the logics determined by the flows of time $\langle \mathbb{N}, <\rangle$, $\langle \mathbb{Z}, <\rangle$, $\langle \mathbb{Q}, <\rangle$, and $\langle \mathbb{R}, <\rangle$ [15, 128, 135]. And second, this class is of exceptional interest because currently NExt **Lin** is the only lattice of modal logics for which *almost every decision problem is decidable* and which, nevertheless, contains numerous Kripke incomplete modal logics—where the standard techniques based on proving the finite model property or tree model property do not work.

The decidability results for logics in NExt **Lin** are based on two ingredients. First, they can be axiomatised by canonical formulas which explicitly show the geometrical and topological conditions they define. And second, a general completeness result establishes that they are determined by general frames which are composed from a set of rather simple 'atomic' general frames. In this part we introduce the canonical formulas. In the next section we discuss the general completeness theorem and survey its consequences regarding decision problems for logics in NExt **Lin**.

The logic **Lin** is obviously axiomatised as

$$\mathbf{Lin} \quad = \quad \mathbf{K4}_2 \oplus p \to \Box_1\Diamond_2 p \oplus p \to \Box_2\Diamond_1 p \oplus \Diamond_1\Diamond_2 p \vee \Diamond_2\Diamond_1 p \to p \vee \Diamond_1 p \vee \Diamond_2 p.$$

To begin our discussion of canonical formulas for logics extending NExt **Lin** observe that Dedekind cuts can be characterised by means of splittings with the frame $\circ\!\!\to\!\!\circ$. In fact, one can show that

$$\mathsf{Log}\,\{\langle \mathbb{R}, <, >\rangle\} \quad = \quad \mathsf{Log}\,\{\langle \mathbb{Q}, <, >\rangle\}/\ \circ\!\!\to\!\!\circ.$$

The intuition behind this equation should be clear from the observation that the class of rooted general frames for the logic $\mathsf{Log}\,\{\langle \mathbb{Q}, <, >\rangle\}/\ \circ\!\!\to\!\!\circ$ consists of all general frames $\left\langle W, R, R^{-1}, P\right\rangle$ such that

- $\langle W, R\rangle$ is a dense linear order without endpoints (i.e., it satisfies the properties $\forall x\forall y(xRy \to \exists z(xRz \wedge zRy))$, $\forall x \exists y\, xRy$ and $\forall x\exists y\, yRx$) and
- there is no p-morphism from $\left\langle W, R, R^{-1}, P\right\rangle$ onto $\circ\!\!\to\!\!\circ$.

But such a p-morphism exists iff there is a partition $X, Y \in P$ of W such that

$$\forall x \in X \forall y \in Y\ xRy, \qquad \forall x \in X \exists y \in X\ xRy, \qquad \forall x \in Y \exists y \in Y\ yRx. \tag{10}$$

Observe that $\langle \mathbb{Q}, <, >\rangle \notin \mathsf{Fr}\,\mathsf{Log}\,\{\langle \mathbb{Q}, <, >\rangle\}/\ \circ\!\!\to\!\!\circ$ since, e.g., $X = \{x \in \mathbb{Q} \mid x < \sqrt{2}\}$ and $Y = \{y \in \mathbb{Q} \mid y > \sqrt{2}\}$ form such a partition.

To characterise the class of *all linear orders* without partitions satisfying (10), we have to weaken the splitting formula. For example, the frame $\langle \{x \geq 0 \mid x \in \mathbb{Q}\}, <, >\rangle$ (which obviously has a partition satisfying (10)) validates

$$\mathbf{Lin}/\circ\!\!\to\!\!\circ,$$

simply because it contains an irreflexive left endpoint and, therefore, cannot be p-morphically mapped onto $\circ\!\!\rightarrow\!\!\circ$. To obtain the class of all linear orders without partitions satisfying (10) the point a in $\overset{a}{\circ}\!\!\rightarrow\!\!\overset{b}{\circ}$ should be regarded as reflexive by the operator $\Box_1$ for the future but as an arbitrary linear order by the operator $\Box_2$ for the past. To make this idea precise, we introduce the notion of a *type assignment* $\mathbf{t} = (\mathbf{t}_1, \mathbf{t}_2)$ which is a map from the set of clusters C of a finite linear order into the set of pairs over $\{\mathsf{j}, \mathsf{m}\}$ such that $\mathbf{t}C = (\mathbf{t}_1 C, \mathbf{t}_2 C) = (\mathsf{m}, \mathsf{m})$ for every cluster C consisting of an irreflexive point. Here j stands for 'joker' and m stands for 'maximal.' For example, $\mathbf{t}C = (\mathsf{m}, \mathsf{j})$ means intuitively that cluster C should be regarded as 'what it is' by $\Box_1$ and as an arbitrary linear order by $\Box_2$. The condition that irreflexive points are mapped to (m, m) means that they are always regarded as what they are, that is, irreflexive points. Before we associate with every finite linear order with type assignment $\langle \mathfrak{F}, \mathbf{t} \rangle$ a formula $\alpha(\mathfrak{F}, \mathbf{t})$ with the corresponding meaning some notation is required.

Given a finite sequence $\overline{\mathfrak{F}} = \left\langle \mathfrak{F}_i = \left\langle W_i, R_i, R_i^{-1}, P_i \right\rangle \mid 1 \le i \le n \right\rangle$ of disjoint frames, we denote by $[\overline{\mathfrak{F}}] = \mathfrak{F}_1 \lhd \cdots \lhd \mathfrak{F}_n$ the ordered sum of them, i.e., the frame $\left\langle W, R, R^{-1}, P \right\rangle$ in which

$$W \quad = \quad \bigcup_{i=1}^{n} W_i, \qquad R \quad = \quad \bigcup_{i=1}^{n} R_i \cup \bigcup_{1 \le i < j \le n} (W_i \times W_j)$$

and $P = \{X_1 \cup \cdots \cup X_n \mid X_i \in P_i\}$. Each finite frame can be represented then as the ordered sum $C_1 \lhd \cdots \lhd C_n$ of its clusters.

With every finite tense frame $\mathfrak{F} = \langle W, R \rangle = C_1 \lhd \cdots \lhd C_n$ with cluster assignment $\mathbf{t} = (\mathbf{t}_1, \mathbf{t}_2)$ we associate the formula

$$\alpha(\mathfrak{F}, \mathbf{t}) \quad = \quad \neg \overline{\delta}(\mathfrak{F}, \mathbf{t}),$$

where

$$\overline{\delta}(\mathfrak{F}, \mathbf{t}) \quad = \quad \delta(\mathfrak{F}, \mathbf{t}) \wedge \Box_2 \delta(\mathfrak{F}, \mathbf{t}) \wedge \Box_1 \delta(\mathfrak{F}, \mathbf{t})),$$

and

$$\begin{aligned}
\delta(\mathfrak{F}, \mathbf{t}) \quad = \quad & \bigwedge \{p_x \to \neg p_y \mid x \neq y\} \wedge \\
& \bigwedge \{p_x \to \neg \Diamond_1 p_y \mid \neg(xRy)\} \wedge \\
& \bigwedge \{p_x \to \Diamond_1 p_y \mid \exists i \le n \ (\mathbf{t}_1 C_i = \mathsf{m} \wedge x, y \in C_i \wedge xRy)\} \wedge \\
& \bigwedge \{p_x \to \Diamond_2 p_y \mid \exists i \le n \ (\mathbf{t}_2 C_i = \mathsf{m} \wedge x, y \in C_i \wedge xR^{-1}y)\} \wedge \\
& \bigvee \{p_y \mid y \in W\} \wedge \\
& \bigwedge \{\Diamond_1 p_y \vee p_y \vee \Diamond_2 p_y \mid y \in W\}.
\end{aligned}$$

To explain the semantical meaning of these formulas, notice first that if $\mathbf{t}C = (\mathsf{m}, \mathsf{m})$ for all clusters C then $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathbf{t})$ is iff $\mathfrak{G}$ there exists a p-morphism from $\mathfrak{G}$ onto $\mathfrak{F}$. Therefore,

$$\mathbf{Lin}/\mathfrak{F} \quad = \quad \mathbf{Lin} \oplus \alpha(\mathfrak{F}, \mathbf{t}).$$

If $\mathbf{t}_i C = \mathsf{j}$ for some $i \in \{1, 2\}$ and some cluster C in $\mathfrak{F}$, then the formula $\alpha(\mathfrak{F}, \mathbf{t})$ can be refuted in frames that do not necessarily have $\mathfrak{F}$ as a p-morphic image. In this case $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathbf{t})$ iff there exist frames $\mathfrak{G}_i$, for $1 \le i \le n$, such that $\mathfrak{G} = \mathfrak{G}_1 \lhd \cdots \lhd \mathfrak{G}_n$ and

$\mathbf{Ord}_t$	$=$	$\mathsf{Log}\,\{\langle\xi,<,>\rangle \mid \xi \text{ an ordinal}\} = \mathbf{Lin} \oplus \alpha(-,(\circ,(\mathsf{j},\mathsf{m})))$
$\mathbf{E}_t$	$=$	$\mathbf{Lin} \oplus \Diamond_1\top \oplus \Diamond_2\top =$
		$\mathbf{Lin} \oplus \alpha(-,(\bullet,(\mathsf{m},\mathsf{m}))) \oplus \alpha((\bullet,(\mathsf{m},\mathsf{m})),-)$
$\mathbf{RD}$	$=$	$\mathsf{Log}\,\{\mathfrak{G} \mid \forall x(\neg xRx \to \exists y(xRy \wedge \{z \mid xRzRy\} = \emptyset))\} =$
		$\mathbf{Lin} \oplus \alpha(-,(\bullet,(\mathsf{m},\mathsf{m}))) \oplus \alpha(-,(\bullet,(\mathsf{m},\mathsf{m})) \lhd (\circ,(\mathsf{m},\mathsf{j})))$
$\mathbf{LD}$	$=$	the mirror image of $\mathbf{RD}$
$\mathbf{Z}_t$	$=$	$\mathsf{Log}\,\langle\mathbb{Z},<,>\rangle =$
		$\mathbf{RD} \oplus \mathbf{LD} \oplus \alpha((\circ,(\mathsf{j},\mathsf{j})) \lhd (\circ,(\mathsf{j},\mathsf{m}))) \oplus \alpha((\circ,(\mathsf{m},\mathsf{j})) \lhd (\circ,(\mathsf{j},\mathsf{j})))$
$\mathbf{Ds}_n$	$=$	$\mathbf{Lin} \oplus \Box_1^{n+1}p \to \Box_1^n p =$
		$\mathbf{Lin} \oplus \alpha(-,\underbrace{(\bullet,(\mathsf{m},\mathsf{m}) \lhd \cdots \lhd (\bullet,(\mathsf{m},\mathsf{m}))}_{n+1},-)$
$\mathbf{Q}_t$	$=$	$\mathsf{Log}\,\langle\mathbb{Q},<,>\rangle = \mathbf{Ds}_1 \oplus \mathbf{E}_t$
$\mathbf{R}_t$	$=$	$\mathsf{Log}\,\langle\mathbb{R},<,>\rangle = \mathbf{Q}_t \oplus \alpha((\circ,(\mathsf{m},\mathsf{j})) \lhd (\circ,(\mathsf{j},\mathsf{m})))$

Table 2. Axiomatisations of standard tense logics

$\mathfrak{G}_i \not\models \alpha(C_i, \mathbf{t}\restriction C_i)$ for all $1 \leq i \leq n$. So it suffices to consider $\mathfrak{G} \not\models \alpha(C,\mathbf{t})$ for a cluster C. Assume for simplicity that $\mathfrak{G}$ is a Kripke frame. *Case 1:* $\mathbf{t}C = (\mathsf{j},\mathsf{j})$. Then $\mathfrak{G} \not\models \alpha(C,\mathbf{t})$ iff $|\mathfrak{G}| \geq |C|$. *Case 2:* $\mathbf{t}C = (\mathsf{m},\mathsf{j})$. Then C is nondegenerate and $\mathfrak{G} \not\models \alpha(C,\mathbf{t})$ iff either $\mathfrak{G}$ contains an R-final cluster of cardinality $\geq |C|$ or it has no R-final point at all. *Case 3:* $\mathbf{t}C = (\mathsf{j},\mathsf{m})$. This is the mirror image of Case 2. *Case 4:* $\mathbf{t}C = (\mathsf{m},\mathsf{m})$. If C is an irreflexive point then $\mathfrak{G}$ is an irreflexive point as well whenever $\mathfrak{G} \not\models \alpha(C,\mathbf{t})$. If C is non-degenerate and $\mathfrak{G} \not\models \alpha(C,\mathbf{t})$ then $\mathfrak{G}$ satisfies the conditions of Cases 2 and 3.

Now, the following is proved in [163]:

THEOREM 35. *There exists an algorithm which, given a formula φ, returns canonical formulas $\alpha(\mathfrak{F}_1,\mathbf{t}_1),\dots,\alpha(\mathfrak{F}_n,\mathbf{t}_n)$ such that*

$$\mathbf{Lin} \oplus \varphi \quad = \quad \mathbf{Lin} \ \oplus\ \alpha(\mathfrak{F}_1,\mathbf{t}_1) \ \oplus\ \dots\ \oplus\ \alpha(\mathfrak{F}_n,\mathbf{t}_n).$$

Canonical axiomatisations of some standard linear tense logics are shown in Table 2, where we use the following notation. Given a finite frame $\mathfrak{F} = C_1 \lhd \cdots \lhd C_n$, we write $\alpha((C_1,\mathbf{t}C_1) \lhd \cdots \lhd (C_n,\mathbf{t}C_n))$ instead of $\alpha(\mathfrak{F},\mathbf{t})$ and $\alpha(-,(C_1,\mathbf{t}C_1) \lhd \cdots \lhd (C_n,\mathbf{t}C_n))$ instead of

$$\alpha((C_1,\mathbf{t}C_1) \lhd \cdots \lhd (C_n,\mathbf{t}C_n)) \ \oplus\ \alpha((\circ,(\mathsf{j},\mathsf{j})) \lhd (C_1,\mathbf{t}C_1) \lhd \cdots \lhd (C_n,\mathbf{t}C_n)).$$

$\alpha((C_1,\mathbf{t}C_1) \lhd \cdots \lhd (C_n,\mathbf{t}C_n),-)$ is defined analogously.

Applications of this result will be discussed in the section below.

7 DECISION PROBLEMS FOR TENSE LOGICS

In this section we show that in NExt **Lin** almost all decision problems are decidable. For example, we can decide whether a finitely axiomatisable logic is Kripke complete, has the finite model property, is canonical, etc. Moreover, finitely axiomatisable linear tense logics turn out to be coNP-complete. Thus, NExt **Lin** is an example of a class of logics for which the original research programme has a complete and 'positive' solution.

The first step in understanding logics in NExt **Lin** was done in the section above, where we saw that they can be axiomatised by canonical formulas $\alpha(\mathfrak{F}, \mathbf{t})$ which show directly the geometric and topological conditions definable on linear orders by means of bimodal formulas. The second step is a completeness result which determines a class of rather simple general frames which respect to which every logic in NExt **Lin** is complete. We require the following notation:

(1) Denote by ⓚ the non-degenerate cluster with $k > 0$ points.

(2) Let $\omega^<(0)$ be the strictly ascending chain $\langle \omega, <, > \rangle$ of natural numbers, $\omega^<(1)$ the chain $\langle \omega, \leq, \geq \rangle$, $\omega^<(2)$ the ascending chain of natural numbers in which precisely the even points are reflexive, $\omega^<(3)$ the chain in which precisely the multiples of 3 are reflexive, and so on; $\omega^>(n)$ is the mirror image of $\omega^<(n)$.

(3) $\mathfrak{C}(0, ①) = \langle \omega^<(0) \lhd ①, P \rangle$, where P consists of all cofinite sets containing ① and their complements. We generalise this construction to chains $\omega^<(n)$ and clusters ⓚ. Namely, for $n < \omega$, $k > 1$ and ⓚ $= \{a_0, \ldots, a_{k-1}\}$, we put

$$\mathfrak{C}(n, ⓚ) \quad = \quad \langle \omega^<(n) \lhd ⓚ, P \rangle,$$

where P is the set generated by means of the Boolean operators from the set of finite subsets of $\omega^<(n)$ and the sets $\{X_i \mid 0 \leq i \leq k-1\}$, for $X_i = \{a_i\} \cup \{kj + i \mid j \in \omega\}$, $0 \leq i \leq k-1$. $\mathfrak{C}(ⓚ, n)$ denotes the mirror image of $\mathfrak{C}(n, ⓚ)$.

(4) $\mathfrak{C}(0, ①, 0) = \langle \omega^<(0) \lhd ① \lhd \omega^>(0), P \rangle$, where P consists of all cofinite sets containing ① and their complements.

It is easy to check that the frames defined in (3) and (4) are descriptive and a singleton $\{x\}$ is in P iff $x \notin$ ⓚ. Notice also that the logics $\mathsf{Log}(\mathfrak{C}(n, ⓚ))$, $\mathsf{Log}(\mathfrak{C}(ⓚ, n))$, $k \geq 2$, and $\mathsf{Log}\mathfrak{C}(0, ①, 0)$ are Kripke incomplete.

For a class of frames $\mathcal{C}$, we denote by $\mathcal{C}^*$ the class of finite sequences of frames from $\mathcal{C}$ and let $[\mathcal{C}^*] = \{[\overline{\mathfrak{F}}] \mid \overline{\mathfrak{F}} \in \mathcal{C}^*\}$. The class of finite clusters and the frames of the form (3) and (4) is denoted by $\mathcal{B}$. We are now in a position to formulate the completeness result:

THEOREM 36. *Each logic $L \in$ NExt **Lin** is determined by a set $\mathcal{C} \subseteq [\mathcal{B}^*]$.*

Proof. We briefly explain the idea of the proof. Suppose that $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ is a countermodel for $\alpha = \alpha((C_1, \mathbf{t}C_1) \lhd \cdots \lhd (C_n, \mathbf{t}C_n))$ based on a descriptive frame $\mathfrak{F} = \langle W, R, R^{-1}, P \rangle$. We must show that there exists $\mathfrak{G} \in [\mathcal{B}^*]$ refuting α and such that $\mathsf{Log}\,\mathfrak{G} \supseteq \mathsf{Log}\,\mathfrak{F}$. Consider the sets

$$W_i \quad = \quad \{y \in W \mid (\mathfrak{M}, y) \models \bigvee \{p_x \mid x \in C_i\}\}.$$

One can easily show that W_i are intervals in $\mathfrak{F}$ and $\mathfrak{F} = \mathfrak{F}_1 \lhd \cdots \lhd \mathfrak{F}_n$, for the subframes $\mathfrak{F}_i$ of $\mathfrak{F}$ induced by W_i. Moreover, $\mathfrak{G} = [\overline{\mathfrak{G}}]$ is as required if $\overline{\mathfrak{G}} = \langle \mathfrak{G}_1, \ldots, \mathfrak{G}_n \rangle$ is a sequence in $\mathcal{B}^*$ such that $\mathsf{Log}\,\mathfrak{G}_i \supseteq \mathsf{Log}\,\mathfrak{F}_i$, and $\mathfrak{G}_i \not\models \alpha(C_i, \mathbf{t}C_i)$, for $1 \leq i \leq n$. Frames $\mathfrak{G}_i$ with those properties are constructed in [163]. ❑

EXAMPLE 37. The logic $\mathbf{Q}_t$ of the rational numbers is determined by the frames $\mathfrak{F} \in [\mathcal{B}^*]$ which contain no pair of adjacent irreflexive points. The logic $\mathbf{R}_t$ of the real line is determined by the frames $\mathfrak{F} \in [\mathcal{B}^*]$ which contain neither a pair of adjacent irreflexive points nor a pair of adjacent non-degenerate clusters.

Now, based on both the canonical formulas for logics in NExt **Lin** and this completeness result, [93] shows:

THEOREM 38. (i) *All finitely axiomatisable logics in* NExt **Lin** *are coNP-complete.*
(ii) *All logics determined by a frame* $\mathfrak{G} \in [\mathcal{B}^*]$ *are coNP-complete.*

Proof. (ii) is proved by showing that, given a formula ψ, it can be checked in nondeterministic polynomial time in the length of ψ whether it is satisfiable in a given $\mathfrak{G} \in [\mathcal{B}^*]$. To this end, [93] shows that it is sufficient to check satisfiability of ψ in a certain finite subframe of $\mathfrak{G}$ (whose size is polynomial in ψ) under certain 'good' valuations.

(i) Suppose

$$L \quad = \quad \mathbf{Lin} \oplus \alpha(\mathfrak{F}_1, \mathbf{t}_1) \oplus \cdots \oplus \alpha(\mathfrak{F}, \mathbf{t}_n)$$

is given. Then [93] shows that any given formula ψ which is satisfiable in a frame $\mathfrak{G} \in [\mathcal{B}^*]$ validating L is satisfiable in a frame of this type whose parameters (i.e., the number of blocks required, the size of its clusters, and the maximal n such that $\mathfrak{C}(n, \textcircled{k})$ or $\mathfrak{C}(\textcircled{k}, n)$ occurs in it) are polynomial in ψ. By the proof of (ii), it can be checked in nondeterministic polynomial time whether ψ is satisfiable in such a frame. Additionally, one can show that it can be checked in polynomial time (in the length of ψ) whether such a frame validates a formula of the form $\alpha(\mathfrak{F}, \mathbf{t})$. ❑

Given the coNP-completeness of all finitely axiomatisable tense logics, at least two questions arise: First, are there interesting classes of finitely axiomatisable linear tense logics? Second, how complex are non-finitely axiomatisable linear tense logics? Regarding the second question, consider, for any $M \subseteq \mathbb{N}$, the logic L_M determined by the class of frames

$$\{\langle\{1, \ldots, m\}, <\rangle \mid m \in M\}.$$

Set $\bot = p \wedge \neg p$ and $\top = p \vee \neg p$. Then the formula

$$\varphi_m \quad = \quad \Box_2 \bot \wedge \Box_1^{m+1} \bot \wedge \Diamond_1^m \top$$

is satisfiable in a frame validating L_M iff $m+1 \in M$. Thus, for any set of natural numbers M there exists a tense logic of the same complexity as M. Regarding the first question, [163] determines a number of classes of finitely axiomatisable linear tense logics. For example, the following result is proved using Kruskal's tree theorem [80]:

THEOREM 39. *A linear tense logic L is finitely axiomatisable whenever there exists $n < \omega$ such that $\Box_1^{n+1} p \to \Box_1^n p \in L$. In particular, all linear tense logics of reflexive frames as well as all extensions of the tense logic of $\langle \mathbb{Q}, < \rangle$ are finitely axiomatisable.*

Where are the Kripke incomplete modal logics in NExt **Lin**? The reader can get an impression from the following result, proved in [163] and stated here without proof:

THEOREM 40. *Suppose that $L \in$* NExt **Lin** *and there is a Kripke frame of infinite length validating L. Then there exists a Kripke incomplete logic in* NExt L.

As promised at the beginning of this section, we conclude by discussing a complete solution to our original research problem relativised to the set of logics in NExt**Lin**. The proofs can be found in [162, 165].

THEOREM 41. *There are algorithms which, given a formula φ, decide whether* $\mathbf{Lin} \oplus \varphi$

- *has the finite model property;*
- *has the interpolation property;*
- *is Kripke complete;*
- *is strongly complete;*
- *is canonical.*

We shall not go into details of the proof here. But the reader can get some impression regarding the combinatorics and methods involved from the criteria which allow us to decide whether a linear tense logic is canonical and strongly complete. Denote by $\mathcal{B}_+$ the class of frames containing $\mathcal{B}$ together with frames $\mathfrak{C}(n_1, ⓚ, n_2)$ defined as follows. Suppose $k > 1$, $n_1, n_2 < \omega$ are such that $n_1 + n_2 > 0$ and $ⓚ = \{a_0, \dots, a_{k-1}\}$. Then

$$\mathfrak{C}(n_1, ⓚ, n_2) \quad = \quad \langle \omega^<(n_1) \lhd ⓚ \lhd \omega^>(n_2), P\rangle,$$

where P is the set of possible values generated by $\{X_i \mid 0 \le i \le k-1\}$, for

$$X_i \quad = \quad \{a_i\} \cup \{kj + i \mid j \in \omega\} \cup \{k^*j^* + i^* \mid j \in \omega\}$$

and $\{0^*, 1^*, \dots, n^*, \dots\}$ being the points in $\omega^>(n_2)$.

Let $\mathcal{F}$ be the class of frames of the form

$$\langle \{0, \dots, n_1\}, <, >\rangle \lhd ① \lhd \langle \{0, \dots, n_2\}, <, >\rangle \quad \text{or} \quad \langle \{0, \dots, n\}, <, >\rangle\,.$$

THEOREM 42. (i) *A logic $L \in$* NExt**Lin** *is canonical iff the underlying Kripke frame of each frame $\mathfrak{F} \in [\mathcal{B}_+^*]$ for L validates L as well.*

(ii) *A logic $L \in$* NExt**Lin** *is strongly complete iff for each frame $\mathfrak{F} \in [\mathcal{B}_+^*]$ validating L, there exists a Kripke frame $\mathfrak{G}$ for L which results from $\mathfrak{F}$ by replacing*

- *every $\mathfrak{C}(n, ⓚ)$ with $\omega^<(n)$ or $\omega^<(n) \lhd \mathfrak{H} \lhd ⓚ$, for some $\mathfrak{H} \in \mathcal{F}$, and*
- *every $\mathfrak{C}(ⓚ, n)$ with $\omega^>(n)$ or $ⓚ \lhd \mathfrak{H} \lhd \omega^>(n)$, for some $\mathfrak{H} \in \mathcal{F}$, and*
- *every $\mathfrak{C}(n_1, ⓚ, n_2)$ with $\omega^<(n_1) \lhd \mathfrak{H} \lhd \omega^>(n_2)$, for some $\mathfrak{H} \in \mathcal{F}$.*

EXAMPLE 43. The logic $\mathbf{R}_t$ of the real line is not canonical because $\mathfrak{C}(2, ②) \models \mathbf{R}_t$, but $\omega^<(2) \lhd ② \not\models \mathbf{R}_t$. However, $\mathbf{R}_t$ is strongly complete, since $\mathfrak{F} \models \mathbf{R}_t$ whenever $\mathfrak{G} \in [\mathcal{B}_+^*]$ validates $\mathbf{R}_t$ and $\mathfrak{F}$ is obtained from $\mathfrak{G}$ as in the formulation of Theorem 42 with $\mathfrak{H} = \bullet \in \mathcal{F}$.

8 SUBFRAME LOGICS

If you randomly pick a logic from the list of Modal Logic celebrities introduced in this handbook, it is very likely that its frames are closed under the *formation of subframes* (as before, a Kripke frame $\mathfrak{G} = \langle V, S_1, \dots, S_n \rangle$ is a *subframe* of a Kripke frame $\mathfrak{F} = \langle W, R_1, \dots, R_n \rangle$ if $V \subseteq W$ and $S_i = R_i \restriction V$, for $1 \leq i \leq n$). Examples are the standard unimodal logics **K** (because the class of all frames is closed under subframes), **K4**, **S5**, and **K4.3** (because transitivity, symmetry, reflexivity, and right-linearity are definable using universal first-order formulas and therefore preserved under the formation subframes), as well as **GL** and **Grz** (because the class of Noetherian frames is closed under subframes).

Moreover, many important operations on classes of frames preserve the property of being closed under forming subframes:

- the union and intersection of two classes of frames;
- the *fusion* $\mathcal{K}_1 \otimes \mathcal{K}_1$ of classes of frames $\mathcal{K}_1$ and $\mathcal{K}_2$ (see Chapter 15 which, in the unimodal case, is defined by
$$\mathcal{K}_1 \otimes \mathcal{K}_2 \quad = \quad \{\langle W, R_1, R_2 \rangle \mid \langle W, R_1 \rangle \in \mathcal{K}_1, \langle W_2, R_2 \rangle \in \mathcal{K}_2\};$$
- the *tense extension* (or addition of converse) $\mathcal{K}_t$ of a class of frames $\mathcal{K}$, where
$$\mathcal{K}_t \quad = \quad \{\langle W, R, R^{-1} \rangle \mid \langle W, R \rangle \in \mathcal{K}\};$$
- the *Boolean extension* $\mathcal{K}^{\cap,\neg}$ of a class of frames $\mathcal{K}$ which consists of all frames
$$\langle W, R_1, \dots, R_n, R_1 \cap R_2, W - R_1, \dots \rangle$$
with 2^{2^n} relations corresponding to the Boolean combinations of the R_i, where $\langle W, R_1, \dots, R_n \rangle \in \mathcal{K}$.

Using these operators we obtain numerous additional important modal 'subframe logics:' multimodal fusions like $\mathbf{S5}_n$, minimal tense extensions like $\mathbf{K4.3}_t$, and Boolean Modal Logics like $\mathbf{K}^{\cap,-}$ are all examples of modal logics determined by classes of frames closed under subframes.

In this section we explore the extent to which the restriction to 'subframe logics' leads to general 'positive' results for properties like axiomatisability, decidability, Kripke completeness, and the fmp. A systematic investigation of subframe logics in NExt **K4** was launched by Fine [45] (see also [174]). Subframe logics in NExt $\mathbf{K}_n$ as well as subframe tense and provability logics were investigated in [166, 167, 164].

We begin by observing the fact that all the 'negative' results above were obtained using logics whose frames were not closed under subframes. So one might conjecture that 'subframe logics' behave better than arbitrary modal logics. The answer to this question is 'yes' and 'no.' Yes, because indeed there are general decidability (fmp, completeness, etc.) results explaining the nice behaviour of standard 'subframe logics.' The answer is 'no,' because still one can find intuitively 'simple' subframe logics with 'bad' properties.

First, we note, however, that for subframe logics a number of otherwise separable properties of modal logics fall together; for a proof see [166] or [177]. For logics from NExt **K4** this result was first obtained by Fine [45].

THEOREM 44. *Suppose L is determined by a class of Kripke frames closed under subframes. Then the following conditions are equivalent:*

(i) $\mathsf{Fr}\, L$ *is universal,*

(ii) $\mathsf{Fr}\, L$ *is first-order definable,*

(iii) L *is $\mathcal{D}$-persistent,*

(iv) L *is strongly Kripke complete,*

(v) $\mathsf{Fr}\, L$ *has the finite embedding property—i.e., $\mathfrak{F} \in \mathsf{Fr}\, L$ iff every finite subframe of $\mathfrak{F}$ is in $\mathsf{Fr}\, L$.*

Note that for cofinal subframe logics $L \in \mathrm{NExt}\,\mathbf{K4}$ conditions (ii)–(iv) are equivalent [174].

Thomason's analysis for subframe logics

Now let us see to which extent Thomason's results (Theorem 1) hold for modal logics determined by classes of frames $\mathsf{Fr}\,\varphi$ closed under subframes.

THEOREM 45. (a) *There is an $\mathcal{ML}_6$-formula φ such that $\mathsf{Fr}\,\{\varphi\}$ is closed under subframes and the set*

$$\mathsf{Th}\,\mathsf{Fr}\,\{\varphi\} \quad = \quad \{\psi \in \mathcal{ML}_6 \mid \varphi \models\!\!\!\!\!\!\approx \psi\}$$

is Π^1_1-complete.

(b) *It is decidable whether, given $\varphi \in \mathcal{ML}_n$ with $\mathsf{Fr}\,\{\varphi\}$ closed under subframes, $\mathsf{Log}\,\mathsf{Fr}\,\{\varphi\}$ is consistent.*

(c) *There is a set Γ of $\mathcal{ML}_1$-formulas and an $\mathcal{ML}_1$-formula φ such that $\Gamma \models\!\!\!\!\!\!\approx \varphi$, but $\Delta \not\models\!\!\!\!\!\!\approx \varphi$ for any finite $\Delta \subset \Gamma$.*

(d) *Given a formula φ such that $\mathsf{Fr}\,\{\varphi\}$ is closed under subframes, every ψ with $\varphi \not\models\!\!\!\!\!\!\approx \psi$ is refutable in a countable frame validating φ.*

Claim (a) can be proved by modifying the proof of Theorem 1 (a) discussed above by introducing modalities for the converse relations of the relations R_1 and R_2 and modalities for the immediate successor relations for R_1 and R_2 and describing in $\mathcal{ML}_6$ by means of a single formula φ sufficiently many properties of the class of all subframes of the product frame $\langle \omega, <, +1\rangle \times \langle \omega, <, +1\rangle$. (Notice, however, that those subframes are not necessarily product frames).

As the reduction of multimodal logics to unimodal logics employed in the proof of Theorem 1 (a) does not preserve the property of being a subframe logic, it is an open problem whether such examples of unimodal logics exist.

Claim (c) still holds since the example provided in the proof of Theorem 1 (c) was closed under subframes. Claims (b) and (d) are now 'positive:' (b) is trivial because it is sufficient to check whether φ is valid in at least one singleton frame. (d) can be proved by constructing inductively from a frame refuting ψ a countable subframe by selecting the witnesses required to satisfy $\Diamond$-formulas; see [166] for details.

Normal subframe logics

We have not defined yet the notion of a subframe logic in a formal way because a proper definition should be slightly more general than the one suggested by considering Kripke frames only: to be able to provide a syntactic characterisation of subframe logics, to ensure that $\mathbf{K}_n \oplus \Sigma_1 \oplus \Sigma_2$ is a subframe logic whenever both $\mathbf{K}_n \oplus \Sigma_1$ and $\mathbf{K}_n \oplus \Sigma_2$ are

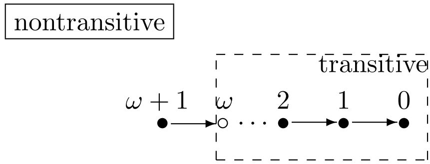

Figure 4.

subframe logics, and finally, to cover a number of interesting Kripke incomplete logics (like bimodal provability logics), we extend the definition of a subframe to general frames. Recall that a frame $\mathfrak{G} = \langle V, S_1, \dots, S_n, P \rangle$ is a *subframe* of a frame $\mathfrak{F} = \langle W, R_1, \dots, R_n, Q \rangle$ if $V \subseteq W$, $P = \{A \cap V \mid A \in Q\}$, and $S_i = R_i \restriction V$, for $1 \le i \le n$. A logic L is a *subframe logic* if its class of general frames is closed under subframes.

To describe subframe logics syntactically, define inductively the *relativisation* φ^p of a formula φ to a propositional variable p (which does not occur in φ) by taking

$$\begin{array}{lcl} q^p & = & q \wedge p, \quad q \text{ an atom}, \\ (\psi \odot \chi)^p & = & \psi^p \odot \chi^p, \quad \text{for } \odot \in \{\wedge, \vee, \rightarrow\}, \\ (\Box_i \psi)^p & = & \Box_i (p \rightarrow \psi^p) \wedge p \end{array}$$

and put $\varphi^{sf} = p \rightarrow \varphi^p$. It is not difficult to show that φ^{sf} is valid in a frame $\mathfrak{F}$ iff φ is valid in all subframes of $\mathfrak{F}$. (Notice that if $\mathfrak{M}$ is a model based on $\mathfrak{F}$, $\mathfrak{M}'$ a model based on the subframe of $\mathfrak{F}$ induced by $\{y \mid (\mathfrak{M}, y) \models p\}$ and $(\mathfrak{M}, x) \models q$ iff $(\mathfrak{M}', x) \models q$, for all variables q, then $(\mathfrak{M}, x) \models \varphi^p$ iff $(\mathfrak{M}', x) \models \varphi$.) Therefore, we obtain

PROPOSITION 46. *The following conditions are equivalent for any $L \in \mathrm{NExt}\,\mathbf{K}_n$:*

(i) *L is a subframe logic,*

(ii) *$L = \mathbf{K}_n \oplus \{\varphi^{sf} \mid \varphi \in \Gamma\}$, for some set of formulas Γ,*

(iii) *L is characterised by a class of frames closed under subframes.*

Based on this proposition, it is not difficult to see that the class of subframe logics forms a complete sublattice of $\mathrm{NExt}\,\mathbf{K}_n$. Now, the first question to address is whether there are Kripke incomplete subframe logics at all:

EXAMPLE 47. (Van Benthem 1979) Let $\mathfrak{F} = \langle W, R, P \rangle$ be the frame whose underlying Kripke frame is shown in Fig. 4 ($\omega + 1$ sees only ω and the subframe generated by ω is transitive) and $X \subseteq W$ is in P iff either X is finite and $\omega \notin X$ or X is cofinite in W and $\omega \in X$. It is easy to see that P is closed under $\cap$, $-$ and $\Diamond$.

Let L be the logic of the frame $\mathfrak{F}$ constructed in Example 47. Since every rooted subframe $\mathfrak{G}$ of $\mathfrak{F}$ is isomorphic to a generated subframe of $\mathfrak{F}$, L is a subframe logic. We show that L has the same Kripke frames as $\mathbf{GL.3}$. Suppose $\mathfrak{G}$ is a rooted Kripke frame for $\mathbf{GL.3}$ refuting $\varphi \in L$. Then clearly $\mathfrak{G}$ contains a finite subframe $\mathfrak{H}$ refuting φ. Since $\mathfrak{H}$ is a finite chain of irreflexive points, it is isomorphic to a generated subframe of $\mathfrak{F}$, contrary to $\mathfrak{F} \not\models \varphi$. Thus $\mathfrak{G} \models L$. Conversely, suppose $\mathfrak{G}$ is a Kripke frame for L. Then $\mathfrak{G}$ is irreflexive. For otherwise $\mathfrak{G}$ refutes the formula $\varphi = \Box^2(\Box p \rightarrow p) \wedge \Box(\Box p \rightarrow p) \rightarrow \Box p$, which is valid in $\mathfrak{F}$. Let us show now that $\mathfrak{G}$ is transitive. Suppose otherwise. Then $\mathfrak{G}$ refutes the formula $\Box p \rightarrow \Box(\Box p \vee (\Box q \rightarrow q))$, which is valid in $\mathfrak{F}$ because ω is a reflexive point. Finally, since $\mathfrak{G} \models \varphi$, $\mathfrak{G}$ is Noetherian and since $\mathfrak{F}$ is of width 1, we may conclude that $\mathfrak{G} \models \mathbf{GL.3}$. It follows that the subframe logic L is Kripke incomplete. Indeed, it shares the same class of Kripke frames with $\mathbf{GL.3}$ but $\Box p \rightarrow \Box\Box p \in \mathbf{GL.3} - L$.

We now follow the path described above for NExt $\mathbf{K}_n$ and analyse the location of Kripke complete and decidable subframe logics within the lattice of subframe logics.

Subframe logics of frames with transitive relations

A number of surprisingly general decidability and completeness results have been obtained for subframe logics whose frames are based on transitive relations. The first fundamental result on the finite model property (and therefore decidability and Kripke completeness) of subframe logics is due to Fine [45]. Although the following theorem can be obtained for free using the machinery of canonical formulas, here we show its proof using the *maximal points technique* of [43].

THEOREM 48 (Fine). *All unimodal subframe logics of transitive general frames (i.e., extensions of* **K4**) *have the finite model property. All finitely axiomatisable ones are decidable.*

Proof. The proof is based on the following fundamental observation: call a point x in a transitive frame $\mathfrak{F} = \langle W, R, P\rangle$ *non-eliminable* if there is $X \in P$ such that $x \in X$ but no proper successor of x is in X (in other words, x is *maximal* in X); in this case we write $x \in \max_R X$. Then one can show the following: if $\mathfrak{F}$ is descriptive and $x \in X \in P$, then there exists a point $y \in \max_R X$ such that $x = y$ or xRy.

Now suppose that $L \supseteq \mathbf{K4}$ is a subframe logic. To prove that L has the finite model property, suppose that $\varphi \notin L$. Take a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V}\rangle$ refuting φ at a point x and based on a descriptive frame $\mathfrak{F} = \langle W, R, P\rangle$ for L. Say that a point $x \in W$ is *non-eliminable* relative to φ if there is a subformula ψ of φ such that $x \in \max_R\{y \in W \mid y \models \psi\}$ or $x \in \max_R\{y \in W \mid y \models \neg\psi\}$. Now select recursively a set of points W^φ as follows:

- Set $V = \{x\}$.
- If there exist $y \in V$ and $\Box\psi \in \mathsf{sub}\,\varphi$ such that $y \models \neg\Box\psi$, and there does not exist $z \in V$ with $z \models \neg\psi$ and yRz, then set $V = V \cup \{z\}$ for some non-eliminable z (relative to φ) with yRz and $z \models \neg\psi$. Otherwise, set $W^\varphi = V$ and stop.

Construct a new model $\mathfrak{M}^\varphi$ based on the frame $\mathfrak{F}^\varphi = \langle W^\varphi, R{\restriction}W^\varphi\rangle$ by taking $\mathfrak{V}^\varphi(p) = \mathfrak{V}(p) \cap W^\varphi$ for all variables p in φ. Clearly, the Kripke frame $\mathfrak{F}^\varphi$ is rooted, of depth $\leq l(\varphi)$, and no point has more than $\ell(\varphi)$ successors. Besides, one can easily show that $(\mathfrak{M}^\varphi, y) \models \psi$ iff $(\mathfrak{M}, y) \models \psi$, for all $\psi \in \mathsf{sub}\,\varphi$ and $y \in W^\varphi$. Finally, one can show that $\mathfrak{F}^\varphi$ is a frame for L (this is trivial if L is $\mathcal{D}$-persistent; considerably more work is required if L is not $\mathcal{D}$-persistent.) ❑

Let us consider now what happens if we move from a unimodal subframe logic $L \in$ NExt **K4** to the tense logic determined by $(\mathsf{Fr}\,L)_t$. In other words, we move from unimodal logics to bimodal logics, where the second operator is interpreted by the inverse of the accessibility relation of the first operator. From a syntactic viewpoint, this semantic condition is captured by the axioms

$$p \to \Box_1\Diamond_2 p \qquad \text{and} \qquad p \to \Box_2\Diamond_1 p.$$

So, we set, for any normal unimodal logic $L = \mathbf{K} \oplus \Gamma$,

$$L_t \quad = \quad \mathbf{K}_2 \;\oplus\; \Gamma \;\oplus\; \{p \to \Box_1\Diamond_2 p, p \to \Box_2\Diamond_1 p\}$$

and call L the *minimal tense extension* of L. General questions regarding minimal tense extensions are: What is the relation between L_t and the logic determined by the class of frames $(\mathsf{Fr}\,L)_t$? Are Kripke completeness and decidability inherited from unimodal logics to minimal tense extensions? As far as Kripke completeness is concerned, the answer is negative: [161] gives an example of a logic $L \in \mathrm{NExt}\,\mathbf{K4}$ with the finite model property such that L_t is not Kripke complete. Transfer of decidability is an open problem. However, for minimal tense extensions of subframe logics in $\mathrm{NExt}\,\mathbf{K4}$ a complete answer has been given in [160, 164]:

THEOREM 49. *If $L \in \mathrm{NExt}\mathbf{K4}$ is a subframe logic then*
(i) *L_t is Kripke complete and determined by $(\mathsf{Fr}\,L)_t$;*
(ii) *L_t has the finite model property iff L is canonical iff $\mathsf{Fr}\,L$ is first-order definable;*
(iii) *L_t is decidable whenever L is finitely axiomatisable.*

So, by (i), L_t is indeed Kripke complete whenever L is a subframe logic containing **K4**. The first exciting bit of this theorem is (ii). It connects the finite model property of minimal tense extensions with first-order definability: for first-order definable subframe logics like **K4**, **S4**, **K4.3**, and **S4.3** we obtain that their minimal tense extensions still have the finite model property, while minimal tense extensions of subframe logics that are not first-order definable, say, $\mathbf{GL}_t$ and $\mathbf{Grz}_t$, do not enjoy this property. For some examples, such as $\mathbf{Grz}_t$, this can be proved easily: just observe that the Grzegorczyk axiom

$$\Box_2(\Box_2(p \to \Box_2 p) \to p) \to p$$

is refuted in $\langle \omega, \geq, \leq \rangle$ and so does not belong to $\mathbf{Grz}_t$; however, it is clearly valid in all finite partial orders (which coincide with the finite frames in $(\mathsf{Fr}\,\mathbf{Grz})_t$).

The second interesting news here is that (iii) provides us with a decidability result for a class of logics which (in general) neither have the finite model property nor the tree model property. In fact, to prove (iii) [164] introduces so-called quasi-frames, that is, frames which come together with type assignments (similar to those in Section 6.2) and with respect to which minimal tense extensions of subframe logics have the bounded finite model property.

The decidability result in Theorem 49 does not cover Kripke incomplete logics, and one may wonder whether there exist at all natural and interesting classes of *decidable* modal logics containing Kripke incomplete ones. The answer is 'yes:' one such class is the set of all finitely axiomatisable (possibly non-normal) subframe logics containing the bimodal provability logic

$$\mathbf{CSM}_0 \quad = \quad \mathbf{GL} \otimes \mathbf{GL} \oplus \{\Box_1 \to \Box_2 p, \Box_2 p \to \Box_1 \Box_2 p\}$$

(named so in [159] after Carlson, Smorynski and Montagna). Almost all bimodal provability logics discussed and investigated in the literature [112, 137] are indeed (sometimes non-normal) subframe logics. For the proof of this result see [167].

The lattice of all subframe logics

We have seen above a lot of beautiful and useful decidability results for subframe logics over transitive relations. Unfortunately, the situation changes drastically as soon as not all accessibility relations are transitive. In this part we summarise what is known in this case. First we shall see that at least the 'upper part' of the lattice of subframe logics is

quite well-behaved. Recall that $\mathbf{K} \oplus \boldsymbol{alt}_n$ is the logic determined by the frames in which no point has more than n successors. The following result is proved by first showing that all subframe logics containing $\mathbf{K} \oplus \boldsymbol{alt}_n$ are Kripke complete [1] and then proving that if a formula φ is refuted in a frame validating $\boldsymbol{alt}_n$ then one can always select finitely many points from that frame in which φ is refuted. (It should be clear from the proof that this result still holds for multimodal subframe logics in which for each operator an axiom of the form $\boldsymbol{alt}_n$ holds.)

THEOREM 50. *All subframe logics containing some* $\mathbf{K} \oplus \boldsymbol{alt}_n$ *have the finite model property.*

Now we say that a subframe logic L is *strictly sf-complete* if there does not exist another subframe logic L' with the same Kripke frames as L. In comparison with NExt $\mathbf{K}$, where according to Blok's dichotomy for almost every interesting L there exist uncountably many modal logic L' with the same Kripke frames as L, the situation is much more diverse in the lattice of subframe logics. Example 47 shows that **GL.3** is not strictly sf-complete. However, the logics **T**, **S4** and **Grz** turn out to be strictly sf-complete. As in the full lattice of normal modal logics, the notion of strict sf-completeness is closely related to the notion of splittings (now in the lattice of subframe logics) and the decidability of the axiomatisation problem for formulas axiomatising subframe logics. Say that a subframe logic $L \in$ NExt $\mathbf{K}$ is a *subframe union-splitting* by a set $\mathcal{F}$ of finite rooted frames, in symbols

$$L \quad = \quad \mathbf{K}/^{sf}\mathcal{F},$$

if L is the smallest subframe logic such that $\mathfrak{F} \not\models L$, for at least one $\mathfrak{F} \in \mathcal{F}$. For example,

$$\mathbf{T} \quad = \quad \mathbf{K}/^{sf} \circ .$$

It is now readily checked that any Kripke complete subframe logic L which is a subframe union-splitting by finitely many rooted frames is strictly sf-complete and that the set $\{\varphi \mid \mathbf{K} \oplus \varphi^{sf} = L\}$ is recursive whenever L is decidable. Based on these observations, the following partial results were obtained in [166]:

THEOREM 51. (a) *A subframe logic L containing* **K4** *is strictly sf-complete iff $L \not\subseteq$* **GL.3** *iff L is a subframe union-splitting. Moreover, if $L \not\subseteq$* **GL.3** *is finitely axiomatisable, then $\{\varphi \mid \mathbf{K} \oplus \varphi^{sf} = L\}$ is recursive.*

(b) *All subframe logics $L \in$ NExt$\mathbf{K} \oplus \boldsymbol{alt}_n$ are strictly sf-complete and subframe union-splittings. Moreover, if L is finitely axiomatisable, then $\{\varphi \mid \mathbf{K} \oplus \varphi^{sf} = L\}$ is recursive.*

(c) *It is decidable whether a finitely axiomatised subframe logic is determined by a finite number of finite frames* (*is tabular*).

No general *undecidability results* have been proved so far for subframe logics.

PROBLEM 15. Characterise the class of subframe logics L for which $\{\varphi \mid \mathbf{K} \oplus \varphi^{sf} = L\}$ is recursive.

For example, although **K4** is not a subframe union-splitting it is an open question whether $\{\varphi \mid \mathbf{K} \oplus \varphi^{sf} = \mathbf{K4}\}$ is recursive.

Cl	$=$	$\mathbf{Int} + p \vee \neg p$
SmL	$=$	$\mathbf{Int} + (\neg q \to p) \to (((p \to q) \to p) \to p)$
KC	$=$	$\mathbf{Int} + \neg p \vee \neg\neg p$
LC	$=$	$\mathbf{Int} + (p \to q) \vee (q \to p)$
SL	$=$	$\mathbf{Int} + ((\neg\neg p \to p) \to \neg p \vee p) \to \neg p \vee \neg\neg p$

Table 3. A list of standard superintuitionistic logics

9 SUPERINTUITIONISTIC LOGICS

Although C.I. Lewis constructed his first modal calculus **S3** in 1918, it was Gödel's [52] two page note that attracted serious attention of mathematical logicians to modal systems. While Lewis [90] used an abstract necessity operator to avoid paradoxes of the material implication, Gödel and earlier Orlov [117][7] treated $\Box$ as 'it is provable' to give a classical interpretation of intuitionistic propositional logic **Int** of Brouwer [12, 13] and Heyting [63] by means of embedding it into a modal 'provability' system which turned out to be equivalent to Lewis' **S4**.

Approximately at the same time Gödel [51] observed that there are infinitely many logics located between **Int** and classical logic **Cl**, which—together with the creation of constructive (proper) extensions of **Int** by Kleene [74] and Rose [122] (realisability logic), Medvedev [109] (logic of finite problems), Kreisel and Putnam [78]—gave an impetus to studying the class of logics intermediate between **Int** and **Cl**, started by Umezawa [149, 150]. Gödel's embedding of **Int** into **S4**, presented in an algebraic form by McKinsey and Tarski [108] and extended to all intermediate logics by Dummett and Lemmon [33], made it possible to develop theories of modal and intermediate logics in parallel ways. And the structural results of Blok [9] and Esakia [36, 36] establishing an isomorphism between the lattices Ext **Int** and NExt **Grz**, along with preservation results of Maksimova and Rybakov [100] and Zakharyaschev [171], transferring various properties from modal to intermediate logics and back, showed that in many respects the theory of intermediate logics is reducible to the theory of logics in NExt **S4**.

To demonstrate this as well as some features of superintuitionistic logics is the main aim of this section. We will use the same system of notation as in the modal case. In particular, Ext **Int** is the lattice of all logics of the form $\mathbf{Int} + \Gamma$ (where Γ is an arbitrary set of formulas in the language of **Int** and $+$ means taking the closure under *modus ponens* and substitution); we call them *superintuitionistic logics* or *si-logics* for short. Basic facts about the syntax and semantics of **Int** and relevant references can be found in [157, 24]. A list of some 'standard' si-logics is given in Table 3.

9.1 Intuitionistic frames

As in the case of modal logics, the adequate relational semantics for si-logics can be constructed on the base of the Stone representation of the algebraic 'models' for **Int**, known as *Heyting* (or *pseudo-Boolean*) *algebras*. It is hard to trace now who was the first to introduce intuitionistic general frames—the earliest references we know are [35] and

[7] Orlov's paper remained unnoticed till the end of the 1980s. It is remarkable also for constructing the first system of relevant logic.

[119]—but in any case, having at hand [71] and [54], the construction must have been clear.

An *intuitionistic* (*general*) *frame* is a triple $\mathfrak{F} = \langle W, R, P\rangle$ in which R is a partial order on $W \neq \emptyset$ and P is a collection of upward closed subsets (cones) in W containing $\emptyset$ and closed under $\cap$, $\cup$, and the operation $\supset$ (for $\to$) defined by

$$X \supset Y \quad = \quad \{x \in W \mid \forall y \in x\!\uparrow (y \in X \to y \in Y)\}.$$

If P contains all upward closed subsets of W then $\mathfrak{F}$ is called an *intuitionistic Kripke frame* and denoted by $\mathfrak{F} = \langle W, R\rangle$. An important feature of intuitionistic models $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V}\rangle$ (where $\mathfrak{V}$ maps propositional variables to sets in P) is that $\mathfrak{V}(\varphi)$, the value of a formula φ in $\mathfrak{M}$, is always upward closed. Every intuitionistic frame $\mathfrak{F} = \langle W, R, P\rangle$ gives rise to the Heyting algebra $\mathfrak{F}^+ = \langle P, \cap, \cup, \supset, \emptyset\rangle$ called the *dual* of $\mathfrak{F}$. Conversely, given a Heyting algebra $\mathfrak{A} = \langle A, \wedge, \vee, \to, \bot\rangle$, we construct its relational representation $\mathfrak{A}_+ = \langle W, R\rangle$ by taking W to be the set of all prime filters in $\mathfrak{A}$ (a filter ∇ is *prime* if it is proper and $a \vee b \in \nabla$ implies $a \in \nabla$ or $b \in \nabla$), R to be the set-theoretic inclusion $\subseteq$ and

$$P \quad = \quad \{\{\nabla \in W \mid a \in \nabla\} \mid a \in A\}.$$

It is readily checked that $\mathfrak{A}_+$, the *dual* of $\mathfrak{A}$, is an intuitionistic frame and $\mathfrak{A} \cong (\mathfrak{A}_+)^+$. A frame $\mathfrak{F}$ is called *descriptive* if $\mathfrak{F} \cong (\mathfrak{F}^+)_+$. Duality between the basic truth-preserving operations on algebras and descriptive frames (taking p-morphic images, generated subframes and disjoint unions) is established by the same technique as in the modal case.

Since every consistent si-logic L is characterised by its Tarski–Lindenbaum algebra $\mathfrak{A}_L$, we conclude that L is also characterised by a class of intuitionistic frames, say, by the dual of $\mathfrak{A}_L$.

At the algebraic level, the connection between **Int** and **S4** discovered by Gödel is reflected by the fact, established in [107], that the algebra of open elements (i.e., elements a such that $\Box a = a$) of every modal algebra for **S4** (known as a *topological Boolean algebra*; see [118]) is a Heyting algebra and, conversely, every Heyting algebra is isomorphic to the algebra of open elements of a suitable algebra for **S4**. We explain this result in the frame-theoretic language.

Given a frame $\mathfrak{F} = \langle W, R, P\rangle$ for **S4** (which means that R is a quasi-order on W), we denote by $\boldsymbol{\rho} W$ the set of clusters in $\mathfrak{F}$—more generally, $\boldsymbol{\rho} X = \{C(x) \mid x \in X\}$—and put $C(x)\boldsymbol{\rho} C(y)$ iff xRy,

$$\boldsymbol{\rho} P \quad = \quad \{\boldsymbol{\rho} X \mid\ X \in P \,\&\, X = \Box X\} \quad = \quad \{\boldsymbol{\rho} X \mid X \in P \wedge X \,\&\, X\!\uparrow\}.$$

It is readily checked that $\boldsymbol{\rho}\mathfrak{F} = \langle \boldsymbol{\rho} W, \boldsymbol{\rho} R, \boldsymbol{\rho} P\rangle$ is an intuitionistic frame; we call it the *skeleton* of $\mathfrak{F}$. The *skeleton* of a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V}\rangle$ for **S4** is the model $\boldsymbol{\rho}\mathfrak{M} = \langle \boldsymbol{\rho}\mathfrak{F}, \boldsymbol{\rho}\mathfrak{V}\rangle$, where $\boldsymbol{\rho}\mathfrak{V}(p) = \mathfrak{V}(\Box p)$.

Denote by T the *Gödel translation* prefixing $\Box$ to all subformulas of a given intuitionistic formula.[8] Then for every model $\mathfrak{M}$ for **S4**, every intuitionistic formula φ and every point x in $\mathfrak{M}$,

$$(\boldsymbol{\rho}\mathfrak{M}, C(x)) \models \varphi \qquad \text{iff} \qquad (\mathfrak{M}, x) \models T(\varphi).$$

It follows that $\varphi \in$ **Int** implies $T(\varphi) \in$ **S4**. To prove the converse, we should be able to convert intuitionistic frames $\mathfrak{F}$ into modal ones with the skeleton (isomorphic to) $\mathfrak{F}$.

[8]The translation defined in [52] does not prefix $\Box$ to conjunctions and disjunctions. However, this difference is of no importance as far as embeddings into logics in NExt**S4** are concerned.

This is trivial if $\mathfrak{F}$ is a Kripke frame—we can just regard it to be a frame for **S4**, which in view of the Kripke completeness of both **Int** and **S4**, shows that T really embeds the former into the latter, i.e.,

$$\varphi \in \mathbf{Int} \qquad \text{iff} \qquad T(\varphi) \in \mathbf{S4}.$$

In general, one can construct a modal frame from an intuitionistic frame $\mathfrak{F} = \langle W, R, P\rangle$ by taking the closure $\boldsymbol{\sigma} P$ of P under the Boolean operations. Then $\langle W, R, \boldsymbol{\sigma} P\rangle$ is a partially ordered modal frame; we denote it by $\boldsymbol{\sigma}\mathfrak{F}$. Moreover, we clearly have $\mathfrak{F} \cong \boldsymbol{\rho\sigma}\mathfrak{F}$. It is worth noting that if $\mathfrak{F} = \langle W, R\rangle$ is a finite intuitionistic Kripke frame then $\boldsymbol{\sigma}\mathfrak{F}$ is also a Kripke frame. However, for an infinite $\mathfrak{F}$, $\boldsymbol{\sigma}\mathfrak{F}$ is not in general a Kripke frame—witness $\langle \omega, \leq\rangle$.

9.2 Canonical formulas

The language of canonical formulas, axiomatising all si-logics and characterising the structure of their frames, can be easily developed following the scheme of constructing the canonical formulas for **K4** and using the connection between modal and intuitionistic frames established above. We confine ourselves here only to pointing out the differences from the modal case and some interesting peculiarities; details can be found in [169, 170, 24]. Actually, there are two important differences. First, in the definition of subreduction of $\mathfrak{F} = \langle W, R, P\rangle$ to $\mathfrak{G}$ the third condition does not correspond to the fact that all sets in P are upward closed. We replace it by the following condition

- $\forall X \in \overline{Q}\ f^{-1}(X){\downarrow} \in \overline{P}$, where $\overline{Q} = \{V - X \mid X \in Q\}$ and $\overline{P} = \{W - X \mid X \in P\}$.

$\mathfrak{G}$ is a *subframe* of $\mathfrak{F}$ if there is an injective subreduction of $\mathfrak{F}$ to $\mathfrak{G}$. It is of interest to note that in the intuitionistic case (cofinal) subreductions are dual to IC(N)-subalgebras of Heyting algebras which only preserve implication, conjunction (and negation) but do not necessarily preserve disjunction.

Second, we have to change the definition of open domains. Now we say an antichain $\mathfrak{a}$ (of at least two points) is an *open domain* in an intuitionistic model $\mathfrak{N}$ relative to a formula φ if there ia a pair $t_{\mathfrak{a}} = (\Gamma_{\mathfrak{a}}, \Delta_{\mathfrak{a}})$ such that $\Gamma_{\mathfrak{a}} \cup \Delta_{\mathfrak{a}} = \mathsf{sub}\,\varphi$, $\bigwedge \Gamma_{\mathfrak{a}} \to \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{Int}$ and

- $\psi \in \Gamma_{\mathfrak{a}}$ iff $a \models \psi$ for all $a \in \mathfrak{a}$.

It is worth noting that in any intuitionistic model every antichain $\mathfrak{a}$ is open relative to every disjunction free formula φ. Indeed, let $\Gamma_{\mathfrak{a}}$ be defined by condition above and $\Delta_{\mathfrak{a}} = \mathsf{sub}\,\varphi - \Gamma_{\mathfrak{a}}$. It should be clear that $\psi \wedge \chi \in \Gamma_{\mathfrak{a}}$ iff $\psi \in \Gamma_{\mathfrak{a}}$ and $\chi \in \Gamma_{\mathfrak{a}}$. And if $\psi \to \chi \in \Gamma_{\mathfrak{a}}$, $\psi \in \Gamma_{\mathfrak{a}}$ but $\chi \in \Delta_{\mathfrak{a}}$ then $a \models \psi$ for every $a \in \mathfrak{a}$ and $b \not\models \chi$ for some $b \in \mathfrak{a}$, whence $b \not\models \psi \to \chi$, which is a contradiction. It follows that $\bigwedge \Gamma_{\mathfrak{a}} \to \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{Int}$.

Now, as in the modal case, with every finite rooted intuitionistic frame $\mathfrak{F} = \langle W, R\rangle$ and a set $\mathfrak{D}$ of antichains in it we can associate two formulas $\beta(\mathfrak{F}, \mathfrak{D}, \bot)$ and $\beta(\mathfrak{F}, \mathfrak{D})$, called the *canonical* and *negation free canonical formulas*, respectively, so that $\mathfrak{G} \not\models \beta(\mathfrak{F}, \mathfrak{D}, \bot)$ ($\mathfrak{G} \not\models \beta(\mathfrak{F}, \mathfrak{D})$) iff there is a (cofinal) subreduction of $\mathfrak{G}$ to $\mathfrak{F}$ satisfying (CDC) for $\mathfrak{D}$.

THEOREM 52. *There is an algorithm which, given an intuitionistic φ, returns canonical formulas $\beta(\mathfrak{F}_1, \mathfrak{D}_1, \bot), \dots, \beta(\mathfrak{F}_n, \mathfrak{D}_n, \bot)$ such that*

$$\mathbf{Int} + \varphi \quad = \quad \mathbf{Int} + \beta(\mathfrak{F}_1, \mathfrak{D}_1, \bot) + \cdots + \beta(\mathfrak{F}_n, \mathfrak{D}_n, \bot).$$

Cl	=	**Int** $+ \beta($  $)$
SmL	=	**Int** $+ \beta($  $) + \beta($  $)$
KC	=	**Int** $+ \beta($  $, \bot)$
LC	=	**Int** $+ \beta($  $)$
SL	=	**Int** $+ \beta^\sharp($  $, \bot)$

Table 4. Canonical axioms of standard superintuitionistic logics

If φ is negation free then one can use only negation free canonical formulas. And if φ is disjunction free then all the $\mathfrak{D}_i$ are empty.

In the intuitionistic case we have the following syntactical characterisation of subframe and cofinal subframe si-logics:

THEOREM 53. (1) *A si-logic is axiomatisable by implicative formulas iff it is determined by a class of* (*finite*) *frames closed under subframes.*

(2) *A si-logic is axiomatisable by disjunction-free formulas iff it is determined by a class of* (*finite*) *frames closed under cofinal subframes.*

It follows from these two theorems (and the refutability criterion for the canonical formulas) that all cofinal subframe si-logics have the finite model property and are decidable if finitely axiomatisable. In fact, there are a continuum of subframe logics [173]. That all si-logics with disjunction-free axioms have the fmp was first proved by McKay [104] with the help of Diego's [31] theorem according to which there are only finitely many pairwise nonequivalent in **Int** disjunction free formulas in variables $p_1, \ldots, p_n$ (see also [151]). An algebraic approach to superintuitionistic (cofinal) subframe logics has been recently developed in [2].

PROBLEM 16. Characterise the computational complexity of cofinal subframe si-logics.

Table 4 shows canonical axiomatisations of the si-logics in Table 3. Using this 'geometrical' representation it is not hard to see, for instance, that **SmL**, known as the *Smetanich logic*, is the greatest consistent extension of **Int** different from **Cl**; it is the logic of the two-point rooted frame. **KC**, the logic of the *Weak Law of the Excluded Middle*, is characterised by the class of directed frames. It is the greatest si-logic containing the same negation free formulas as **Int** [68]. **LC**, the *Dummett* or *chain logic*, is characterised by the class of linear frames [32].

Jankov [69] proved that logics of the form **Int**$+\beta(\mathfrak{F}, \mathfrak{D}^\sharp, \bot)$ and only them are splittings of Ext **Int**. However, not every si-logic is a union-splitting of Ext **Int**.

PROBLEM 17. Characterise the degree of Kripke incompleteness of si-logics.

9.3 Modal companions and preservation theorems

The fact that the Gödel translation T embeds **Int** into **S4** and the relationship between intuitionistic and modal frames shown above can be used to reduce various problems concerning **Int** (e.g., proving decidability, Kripke completeness or the fmp) to those for **S4** and vice versa. Moreover, it turns out that each logic in Ext **Int** is embedded by T into some logics in NExt **S4**, and for each logic in NExt **S4** there is a logic in Ext **Int** embeddable in it.

We say a modal logic $M \in$ NExt **S4** is a *modal companion* of a si-logic L if L is embedded in M by T, i.e., if for every intuitionistic formula φ, we have $\varphi \in L$ iff $T(\varphi) \in M$. If M is a modal companion of L then L is called the *si-fragment* of M and denoted by $\boldsymbol{\rho} M$. The reason for denoting the operator 'modal logic $\mapsto$ its si-fragment' by the same symbol we used for the skeleton operator is explained by the simple fact that $\boldsymbol{\rho} M = \{\varphi \mid T(\varphi) \in M\}$ and, moreover, if M is characterised by a class $\mathcal{C}$ of modal frames then $\boldsymbol{\rho} M$ is characterised by the class $\boldsymbol{\rho}\mathcal{C} = \{\boldsymbol{\rho}\mathfrak{F} \mid \mathfrak{F} \in \mathcal{C}\}$ of intuitionistic frames.

Thus, $\boldsymbol{\rho}$ maps NExt**S4** into Ext**Int**. The following observation of [33] shows that actually $\boldsymbol{\rho}$ is a surjection. Given a logic $L \in$ Ext **Int**, let

$$\boldsymbol{\tau} L \quad = \quad \mathbf{S4} \oplus \{T(\varphi) \mid \varphi \in L\}.$$

Then, for every si-logic L, $\boldsymbol{\tau} L$ is a modal companion of L.

Now we use the language of canonical formulas to show a general characterisation of all modal companions of a given si-logic L obtained in [170, 171]. Notice first that for every modal frame $\mathfrak{G}$ and every intuitionistic canonical formula $\beta(\mathfrak{F}, \mathfrak{D}, \bot)$, $\mathfrak{G} \models \alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ iff $\boldsymbol{\rho}\mathfrak{G} \models \beta(\mathfrak{F}, \mathfrak{D}, \bot)$, and so $\mathbf{S4} \oplus T(\beta(\mathfrak{F}, \mathfrak{D}, \bot)) = \mathbf{S4} \oplus \alpha(\mathfrak{F}, \mathfrak{D}, \bot)$. The same holds for the negation free canonical formulas.

THEOREM 54. *$M \in$ NExt **S4** is a modal companion of $L = \mathbf{Int} + \{\beta(\mathfrak{F}_i, \mathfrak{D}_i, \bot) \mid i \in I\}$ iff M can be represented in the form*

$$M \quad = \quad \mathbf{S4} \quad \oplus \quad \{\alpha(\mathfrak{F}_i, \mathfrak{D}_i, \bot) \mid i \in I\} \quad \oplus \quad \{\alpha(\mathfrak{F}_j, \mathfrak{D}_j, \bot) \mid j \in J\},$$

where every frame $\mathfrak{F}_j$, for $j \in J$, contains a proper cluster.

Thus, we have:

$$\boldsymbol{\rho}\mathbf{S4} \;=\; \boldsymbol{\rho}\mathbf{S4.1} \;=\; \boldsymbol{\rho}\mathbf{Dum} \;=\; \boldsymbol{\rho}\mathbf{Grz} \;=\; \mathbf{Int},$$

$$\boldsymbol{\rho}\mathbf{S4.2} \;=\; \boldsymbol{\rho}(\mathbf{S4.2} \oplus \mathbf{Grz}) \;=\; \mathbf{KC},$$

$$\boldsymbol{\rho}\mathbf{S4.3} \;=\; \boldsymbol{\rho}(\mathbf{S4.3} \oplus \mathbf{Grz}) \;=\; \mathbf{LC},$$

$$\boldsymbol{\rho}\mathbf{S5} \;=\; \boldsymbol{\rho}(\mathbf{S5} \oplus \mathbf{Grz}) \;=\; \mathbf{Cl}.$$

COROLLARY 55. *The set of modal companions of every consistent si-logic L forms the interval*

$$\boldsymbol{\rho}^{-1}(L) \quad = \quad [\boldsymbol{\tau} L, \boldsymbol{\tau} L \oplus \alpha(②)] \quad = \quad \{M \in \text{NExt}\,\mathbf{S4} \mid \boldsymbol{\tau} L \subseteq M \subseteq \boldsymbol{\tau} L \oplus \mathbf{Grz}\}$$

and contains an infinite descending chain of logics.

Proof. Notice first that $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ are in **Grz** iff $\mathfrak{F}$ contains a proper cluster. So $\boldsymbol{\rho}^{-1}(L) \subseteq [\boldsymbol{\tau} L, \, \boldsymbol{\tau} L \oplus \alpha(②)]$. On the other hand, the si-fragments of all logics

Property of logics	Preserved under		
	$\boldsymbol{\rho}$	$\boldsymbol{\tau}$	$\boldsymbol{\sigma}$
Decidability	Yes	Yes	Yes
Kripke completeness	Yes	Yes	No
Finite model property	Yes	Yes	Yes
Tabularity	Yes	No	Yes
Interpolation property	Yes	No	No
First-order definability	Yes	Yes	No

Table 5. Preservation theorems

in the interval are the same, namely L. Therefore, $\boldsymbol{\rho}^{-1}(L) = [\boldsymbol{\tau}L, \boldsymbol{\tau}L \oplus \alpha(②)]$. Now, if L is consistent then $\beta(\circ) \notin L$ and so

$$\boldsymbol{\tau}L \subset \ldots \subset \boldsymbol{\tau}L \oplus \alpha(ⓚ) \subset \cdots \subset \boldsymbol{\tau}L \oplus \alpha(②) \subset \boldsymbol{\tau}L \oplus \alpha(①) = \mathbf{For},$$

where **For** is the set of all intuitionistic formulas. ❑

This result is due to Maksimova and Rybakov [100], Blok [9] and Esakia [37]. Thus, all modal companions of every si-logic L are contained between the least companion $\boldsymbol{\tau}L$ and the greatest one, viz., $\boldsymbol{\tau}L \oplus \alpha(②)$, which will be denoted by $\boldsymbol{\sigma}L$.

The following theorem, which is also a consequence of Theorem 54, describes lattice-theoretic properties of the maps $\boldsymbol{\rho}$, $\boldsymbol{\tau}$ and $\boldsymbol{\sigma}$. Items (i), (ii) and (iv) in it were first proved in [100]; (iii) is known as the Blok–Esakia theorem [9, 37].

THEOREM 56. (i) *The map $\boldsymbol{\rho}$ is a homomorphism of the lattice* NExt **S4** *onto the lattice* Ext **Int**.

(ii) *The map $\boldsymbol{\tau}$ is an isomorphism from* Ext **Int** *into* NExt **S4**.

(iii) *The map $\boldsymbol{\sigma}$ is an isomorphism from* Ext **Int** *onto* NExt **Grz**.

(iv) *All these maps preserve infinite sums and intersections of logics.*

The following theorem provides a deductive characterisation of the maps $\boldsymbol{\tau}$ and $\boldsymbol{\sigma}$.

THEOREM 57. *For every si-logic L and every modal canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \bot)$ built on a quasi-ordered frame $\mathfrak{F}$,*

(i) $\alpha(\mathfrak{F}, \mathfrak{D}, \bot) \in \boldsymbol{\tau}L$ *iff* $\beta(\boldsymbol{\rho}\mathfrak{F}, \boldsymbol{\rho}\mathfrak{D}, \bot) \in L$;

(ii) $\alpha(\mathfrak{F}, \mathfrak{D}, \bot) \in \boldsymbol{\sigma}L$ *iff either $\mathfrak{F}$ is partially ordered and* $\beta(\mathfrak{F}, \mathfrak{D}, \bot) \in L$ *or $\mathfrak{F}$ contains a proper cluster.*

The theorems above can be used for transferring various properties of modal logics to their si-fragments and back. Some results of that sort are collected in Table 5; for proofs see [24].

9.4 Completeness

In this section we briefly discuss the most important general results concerning completeness of si-logics with respect to various classes of Kripke frames. (As in the modal case, the fmp and decidability of a good many concrete si-logics was proved using various forms of filtration; see, e.g., [46, 116, 136, 47, 39].)

That not all si-logics are complete with respect to Kripke frames was discovered by Shehtman [132], who found a way to adjust Fine's [43] idea to the intuitionistic case. As to general positive results, notice first that the preservation theorems yield the following translation of Theorems 24–25 (si-logics of finite width were studied by Sobolev [138]).

THEOREM 58. (1) *Every si-logic of finite depth has the fmp* (*in fact, is locally tabular*).

(2) *Every si-logic of width n is characterised by a class of Noetherian Kripke frames of width $\leq n$.*

PROBLEM 18. Are finitely axiomatisable si-logics of width $n > 1$ decidable? What is their computational complexity?

An intuitionistic formula is said to be *essentially negative* if every occurrence of a variable in it is in the scope of some $\neg$. If φ is essentially negative then $T(\varphi)$ is a $\Box\Diamond$-formula, which—together with Theorem 14—yields the following result of McKay [105]:

THEOREM 59 (McKay). *If a si-logic L is decidable* (*or has the fmp*) *and φ is an essentially negative formula then $L + \varphi$ is decidable* (*has the fmp*).

Say that an occurrence of a variable in a formula is *essential* if it is not in the scope of any $\neg$. A formula φ is *mild* if every two essential occurrences of the same variable in φ are either both positive or both negative. Kuznetsov [83] claimed (we have not seen the proof) that all si-logics whose extra axioms do not contain negative occurrences of essential variables have the fmp. And Wroński [168] announced that if L is a decidable si-logic and φ a mild formula then $L + \varphi$ is also decidable.

Since frames for **Int** contain no clusters, Theorem 44 and its analogue for cofinal subframe logics reduce in the intuitionistic case to the following result which is due to [28, 121, 134, 174]:

THEOREM 60. *All si-logics with disjunction free axioms are first-order definable* (*definable by $\forall\exists$-sentences*) *and $\mathcal{D}$-persistent.*

Nishimura [115] described all si-logics axiomatisable by one-variable formulas. As a consequence of his result and Theorem 19 we obtain the following theorem due to Sobolev [138]:

THEOREM 61 (Sobolev). *All si-logics with extra axioms in one variable have the fmp and are decidable.*

In fact, Sobolev proved a more general (but rather complicated) syntactical sufficient condition of the fmp and constructed a formula in two variables axiomatising a si-logic without the fmp (Shehtman's [132] incomplete si-logic has also axioms in two variables).

By the Blok–Esakia and preservation theorems, the situation with tabular logics in Ext**Int** is the same as in NExt **Grz**. In particular, there are only three pretabular logics in Ext**Int** [95], and the tabularity problem is decidable in Ext**Int**.

9.5 Medvedev's logic

Although this chapter's main concern is *classes* of logics rather than individual systems, we conclude it with a brief discussion of a very elegant and interesting si-logic introduced by Medvedev [109, 110, 111] and known as the *logic of finite problems* or the *Medvedev logic* **ML**. Semantically it can be defined as the set of intuitionistic formulas that are

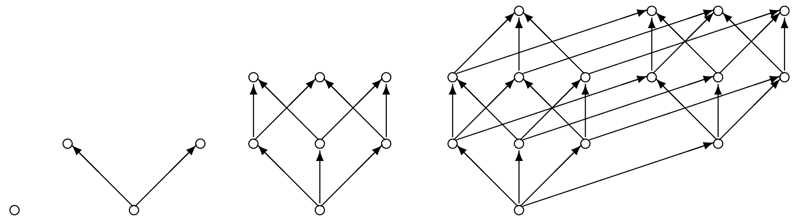

Figure 5.

valid in all 'topless' n-ary Boolean cubes depicted in Fig. 5 for $n = 1, 2, 3, 4$. More precisely, let W_n be the family of nonempty subsets of a set with $n > 0$ elements and xR_ny means $y \subseteq x$, for $x, y \in W_n$. Then

$$\mathbf{ML} \quad = \quad \{\varphi \mid \langle W_n, R_n\rangle \models \varphi \ \text{ for all } n \geq 1\}.$$

It turns out that **ML** is a *constructive* si-logic in the sense that it enjoys the following *disjunction property*

$$\varphi \vee \psi \in \mathbf{ML} \quad \text{implies} \quad \varphi \in \mathbf{ML} \ \text{ or } \ \psi \in \mathbf{ML}$$

and, moreover, no proper extension of **ML** is constructive in this sense [89, 99]. In fact, there are a continuum of maximal constructive si-logics [73, 98, 20, 39], and not a single one of them is known to be finitely axiomatisable or decidable. In particular, [101] shows that **ML** is not finitely axiomatisable.

PROBLEM 19. Does there exist a decidable maximal si-logic with the disjunction property? In particular, is **ML** decidable?

PROBLEM 20. Does there exist a finitely axiomatisable maximal si-logic with the disjunction property?

ACKNOWLEDGEMENTS

We are grateful to our friends and colleagues Aleksander Chagrov and Ian Hodkinson for providing some material for this chapter. Thanks are also due to R. Iemhoff and V. Shehtman for their constructive comments and suggestions. The work on this chapter was partially supported by the U.K. EPSRC grants GR/S61966/01, GR/S63182/01, GR/S63175/01, GR/S61973/01.

1 INTRODUCTION

Logic is generally defined as the science of reasoning. Mathematical logic is mainly concerned with forms of reasoning that lead from true premises to true conclusions. Thus we say that the argument from $\sigma_0; \sigma_1; \cdots ; \sigma_{n-1}$ to δ is *logically correct* if whenever σ_i is true for all $i < n$, then so is δ. In place of 'argument' one also speaks of 'inference'. The language object '$\sigma_0; \sigma_1; \cdots ; \sigma_{n-1}/\delta$' is is called a *rule*, of which arguments are instances. A rule is *valid* if all its instances are. Central to this approach is the notion of a *consequence relation*, which is a relation between sets of formulae and formulae. A consequence relation $\vdash$ specifies which arguments are valid; the argument from a set Σ to a formula δ is valid in $\vdash$ iff $\langle \Sigma, \delta \rangle \in \vdash$, for which we write $\Sigma \vdash \delta$. δ is a *tautology* of $\vdash$ if $\varnothing \vdash \delta$, for which we also write $\vdash \delta$.

In the early years, research into modal logic was concerned with the question of finding the correct inference rules. This research line is still there but has been marginalized by the research into modal *logics*, where a logic is just a set of formulae; this set is the set of tautologies of a certain consequence relation, but many consequence relations share the same tautologies. The shift of focus in the research has to do in part with the precedent set by predicate logic: predicate logic is standardly axiomatized in a Hilbert-style fashion, which fixes the inference rules and leaves only the axioms as a parameter. Another source may have been the fact that there is a biunique correspondence between varieties of modal algebras and axiomatic extensions of K, which allowed for rather deep investigations into the space of logics, using the machinery of equational theories. This research led to deep results on the structure of the lattice of modal logics and benefits also the research into consequence relations. Recently, however, algebraic logic has provided more and more tools that allow to extend the algebraic method to the study of consequence relations in general (see for example [60] and [14]). In particular the investigations into the Leibniz operator initiated by Blok and Pigozzi in [5] have brought new life into the discussion and allow to see a much broader picture than before.

Now, even if one is comfortable with classical logic, it is not immediately clear what the correct inferences are in modal logic. The first problem is that it is not generally agreed what the meaning of the modal operator(s) is or should be. In fact, rather than a drawback, the availability of very many different interpretations is the strength of modal logic; it gives flexibility, however at the price that there is not one modal logic, there are uncountably many. For example, $\Box$ as metaphysical necessity satisfies **S5**, $\Box$ as provability in **PA** satisfies **G**, $\Box$ as future necessity (arguably) satisfies **S4.3**, and so on. This is in part because the interpretation decides which algebras are suitable (intended) and which ones are not. However, there is another parameter of variation, and this is the notion of truth itself. In the most popular interpretation, truth is truth at a world; but we could also understand it as truth in every world of the structure. The two give rise to two distinct consequence relations, the *local* and the *global*, which very often do not coincide even though they always have the same set of tautologies. If truth is defined to be truth at every world under all substitutions we finally arrive at the maximal consequence relation compatible with a logic, in which a rule is derived iff it is admissible for that logic. It is this plurality of interpretations that gives rise to the different topics of this contribution and provides the underlying thread that connects them.

The paper is organised as follows. We shall first review basic concepts from universal algebra and basic logical notions such as consequence relations, rules, the deduction theorem and interpolation; then we shall briefly look at modal consequence relations and the structure of the lattice they form; finally, we turn to the notion of a splitting. This concludes Section 2. In Section 3 we shall look at local and global consequence relations. The first part will deal with consequence relations from an algebraic perspective; the second part studies global consequence relations in more detail and the third part outlines the connection between semisimple varieties of modal algebras and weak transitivity. The next section deals with reductions of polymodal and polyadic modal logics to monomodal logic. It reviews results that establish that the lattices of polymodal and polyadic logics can be naturally embedded into the lattice of monomodal logics preserving and reflecting a good deal of properties. This justifies ex post the almost exclusive study of monomodal logics in spite of the practical usefulness of polymodal and polyadic logics. Section 5 looks at interpolation. In detail, it shall give an algebraic characterisation of interpolation and ways of establishing interpolation for logics. Next we shall look at Beth-definability and fixed point theorems and finally at uniform interpolation. Section 6 is devoted to admissible rules. In particular, it deals with questions of axiomatisability of the set of admissible rules, and with the problem of deciding whether a given rule is admissible in a logic. Finally, in Section 7 we take a brief look at more general notions of a rule, like multiple conclusion rules.

2 BASIC THEORY OF MODAL CONSEQUENCE RELATIONS

This chapter makes heavy use of notions from universal algebra. The reader is referred to Chapter 6 for background information concerning universal algebra and in particular the theory of BAOs and how they relate to (general) frames. We shall quickly review some terminology. A **signature** is a pair $\langle F, \nu\rangle$, where F is a set of so-called **function symbols** or **connectives** and $\nu : F \to \omega$ a function assigning to each symbol an arity. **Terms** are expressions of this language based on variables. We shall also refer to ν alone as a signature. We shall assume that the reader is acquainted with basic notions of universal algebra, such as a **ν-algebra**. Given a map $v : X \to A$ from a set X of variables into the underlying set of A, there is at most one homomorphic extension $\overline{v} : \mathfrak{Tm}_\nu(X) \to \mathfrak{A}$, where $\mathfrak{Tm}_\nu(X)$ denotes the algebra of terms in the signature ν over the set X (whose underlying set is $\mathrm{Tm}_\nu(X)$). On a ν-algebra $\mathfrak{A}$, terms induce **term functions** in the obvious way. If we allow to expand the signature by a constant $\underline{a}$ for every $a \in A$, the term functions induced by this enriched language on $\mathfrak{A}$ are called **polynomials**. In what is to follow, terms will also be called **formulae**, F will always contain $\top$, $\wedge$ and $\neg$, and $\nu(\top) = 0$, $\nu(\neg) = 1$ and $\nu(\wedge) = 2$. Moreover, F will additionally contain connectives $\Box_i$, $i < \kappa$, called **modal operators**, which are unary unless otherwise stated. κ need not be finite. The relation corresponding to $\Box_i$ will standardly be denoted by $\lhd_i$. The set of variables is $V := \{p_i : i \in \omega\}$. Sets of formulae are denoted in the usual way using the semicolon notation: $\Delta; \chi$ abbreviates $\Delta \cup \{\chi\}$. We write $\mathrm{var}(\varphi)$ for the set of variables occurring in φ, and $\mathrm{sf}(\varphi)$ for the set of subformulae of φ. Similarly, $\mathrm{var}(\Delta)$ and $\mathrm{sf}(\Delta)$ are used for sets of formulae. A **substitution** is defined by a map $s : V \to \mathrm{Tm}_\nu(V)$. $s(\varphi)$ or φ^s denotes the effect on φ of performing the substitution s.

2.1 Consequence Relations

DEFINITION 1. Let $\mathrm{Tm}_\nu(V)$ be a propositional language. A **consequence relation** over $\mathrm{Tm}_\nu(V)$ is a relation $\vdash \subseteq \wp(\mathrm{Tm}_\nu(V)) \times \mathrm{Tm}_\nu(V)$ between sets of formulae and a single formula such that

1. $\varphi \vdash \varphi$
2. $\Delta \vdash \varphi$ and $\Delta \subseteq \Delta'$ implies $\Delta' \vdash \varphi$.
3. $\Delta \vdash \chi$ and $\Sigma; \chi \vdash \varphi$ implies $\Delta; \Sigma \vdash \varphi$.

$\vdash$ is **structural** if from $\Delta \vdash \varphi$ follows $\Delta^s \vdash \varphi^s$, where s is a substitution. $\vdash$ is **finitary** (or **compact**) if from $\Delta \vdash \varphi$ follows that there is a finite $\Delta' \subseteq \Delta$ such that $\Delta' \vdash \varphi$. A **tautology** of $\vdash$ is a formula φ such that $\vdash \varphi$. $\mathrm{Taut}(\vdash)$ is the set of tautologies of $\vdash$.

There is an alternative approach via deductively closed sets and via closure operators (see Surma [55] for a discussion of alternatives to consequence relations). Given $\vdash$, let $\Sigma^\vdash := \{\varphi : \Sigma \vdash \varphi\}$. The sets of the form $\Sigma^\vdash$ are called **theories** of $\vdash$. Then the following holds.

1. $\Sigma \subseteq \Sigma^\vdash$.
2. $\Sigma^{\vdash\vdash} \subseteq \Sigma^\vdash$.

$\vdash$ is structural iff for all substitutions s and all Σ

$$\Sigma^{\vdash s} \subseteq \Sigma^{s\vdash} \tag{1}$$

$\vdash$ is finitary iff for all Σ

$$\Sigma^\vdash = \bigcup\{\Sigma_0^\vdash : \Sigma_0 \subseteq \Sigma, \Sigma_0 \text{ finite}\} \tag{2}$$

A characterisation of a finitary structural consequence relation in terms of its theories is as follows.

1. The language is a $\vdash$-theory.
2. Every intersection of $\vdash$-theories is a $\vdash$-theory.
3. If T is a $\vdash$-theory, so is $s^{-1}(T)$.
4. If T_i, $i \in \omega$, is an ascending chain of $\vdash$-theories, $\bigcup T_i$ is a $\vdash$-theory.

For the general theory of consequence relation see [60]. For consequence relations and modal logic see [50]. In the sequel, unless otherwise stated, consequence relations are assumed to be finitary and structural. The signatures are signatures extending classical propositional logic by some (typically unary) modal operators.

One can think of a finitary consequence relation as a first order theory of formulae in the following way. A statement of the form $\Delta \vdash \varphi$ is rendered

$$(\forall \vec{x})(\bigwedge\langle T(\delta) : \delta \in \Delta\rangle) \to T(\varphi) \tag{3}$$

where T is a newly introduced predicate; the universal quantifier binds off the free variables occurring in all the formulae. Given this interpretation, the appropriate structures to interpret consequence relation in are matrices in the sense of the following definition.

DEFINITION 2. A ν-**matrix** for a signature ν is a pair $\mathfrak{M} = \langle \mathfrak{A}, D\rangle$ where $\mathfrak{A}$ is a ν-algebra and $D \subseteq A$ a subset. A is called the set of **truth values** and D the set of **designated truth values**. An **assignment** or a **valuation** into $\mathfrak{M}$ is a map v from the set of variables into A. v makes φ **true** in $\mathfrak{M}$ if $\overline{v}(\varphi) \in D$; otherwise it makes φ **false**.

Given a matrix $\mathfrak{M}$ we can define a relation $\vdash_{\mathfrak{M}}$ by

$$(4) \qquad \Delta \vdash_{\mathfrak{M}} \varphi \quad \Leftrightarrow \quad \text{for all assignments } v: \text{ If } \overline{v}[\Delta] \subseteq D \text{ then } \overline{v}(\varphi) \in D$$

If $\vdash \subseteq \vdash_{\mathfrak{M}}$ then we also say that $\mathfrak{M}$ is a **matrix for** $\vdash$. Given $\mathfrak{A}$, we say that D is a **filter** for $\vdash$ if D is closed under the rules; equivalently D is a filter if $\vdash_{\langle \mathfrak{A}, D\rangle} \supseteq \vdash$. Given a class $\mathcal{S}$ of matrices (for the same signature) we define

$$(5) \qquad \vdash_{\mathcal{S}} := \bigcap \langle \vdash_{\mathfrak{M}} : \mathfrak{M} \in \mathcal{S}\rangle$$

THEOREM 3. *Let ν be a signature. For each class $\mathcal{S}$ of ν-matrices $\vdash_{\mathcal{S}}$ is a (possibly nonfinitary) consequence relation.*

THEOREM 4 (Wójcicki). *For every structural consequence relation $\vdash$ there exists a class $\mathcal{S}$ of matrices such that $\vdash = \vdash_{\mathcal{S}}$.*

Proof. Given the language, let S consist of all $\langle \mathfrak{Tm}_\nu(V), T\rangle$ where T is a theory of $\vdash$. First we show that for each such matrix $\mathfrak{M}$, $\vdash \subseteq \vdash_{\mathfrak{M}}$. To that end, assume $\Sigma \vdash \varphi$ and that $\overline{v}[\Sigma] \subseteq T$. Now $\overline{v}$ is in fact a substitution, and T is deductively closed, and so $\overline{v}(\varphi) \in T$ as well, as required. Now assume $\Sigma \nvdash \varphi$. We have to find a single matrix $\mathfrak{M}$ of this form such that $\Sigma \nvdash_{\mathfrak{M}} \varphi$. For example, $\mathfrak{M} := \langle \mathfrak{Tm}_\nu(V), \Sigma^{\vdash}\rangle$. Then with $\overline{v}$ the identity map, $\overline{v}[\Sigma] = \Sigma \subseteq \Sigma^{\vdash}$. However, $\overline{v}(\varphi) = \varphi \notin \Sigma^{\vdash}$ by definition of $\Sigma^{\vdash}$ and the fact that $\Sigma \nvdash \varphi$. ❑

If $\mathfrak{M}$ is a matrix for $\vdash$, then the set of truth values must be closed under the rules. The previous theorem can be refined somewhat. Let $\mathfrak{M} = \langle \mathfrak{A}, D\rangle$ be a logical matrix, and Θ a congruence on $\mathfrak{A}$. We write $[x]\Theta := \{y : x \;\Theta\; y\}$. The sets $[x]\Theta$ are called **blocks** of the congruence. Θ is called a **matrix congruence** if D is a union of Θ-blocks, that is, if $x \in D$ then $[x]\Theta \subseteq D$. In that case we can reduce the whole matrix by Θ and define $\mathfrak{M}/\Theta := \langle \mathfrak{A}/\Theta, D/\Theta\rangle$. The following is easy to show.

LEMMA 5. *Let $\mathfrak{M}$ be a matrix and Θ a matrix congruence of $\mathfrak{M}$. Then $\vdash_{\mathfrak{M}} = \vdash_{\mathfrak{M}/\Theta}$.*

Call a matrix **reduced** if the diagonal, that is the relation $\Delta = \{\langle x, x\rangle : x \in A\}$, is the only matrix congruence. We can sharpen Theorem 4 to the following

THEOREM 6. *For each logic $\langle \mathcal{L}, \vdash\rangle$ there exists a class S of reduced matrices such that $\vdash = \vdash_S$.*

Let $\mathcal{S}$ be a class of ν-matrices. $\mathcal{S}$ is called a **unital semantics** for $\vdash$ if $\vdash = \vdash_{\mathcal{S}}$ and for all $\langle \mathfrak{A}, D\rangle \in \mathcal{S}$ we have $|D| \leq 1$. (See Janusz Czelakowski [12, 13]. A unital semantics is often called **algebraic**. This, however, is different from the notion of 'algebraic' discussed

by Wim Blok and Don Pigozzi in [5].) The following is a useful fact, which is not hard to verify.

PROPOSITION 7. *Let* $\vdash$ *have a unital semantics. Then in* $\vdash$ *the rules* $p; q; \varphi(p) \vdash \varphi(q)$ *are valid for all formulae* φ.

Notice that when a logic over a language $\mathcal{L}$ is given and an algebra $\mathfrak{A}$ with appropriate signature, the set of designated truth values must always be a deductively closed set, otherwise the resulting matrix is not a matrix for the logic. A theory is **consistent** if it is not the entire language, and **maximal consistent** if it is maximal in the set of consistent theories. Every consistent theory is contained in a maximally consistent theory. For classical logics the construction in the proof of Theorem 4 can be strengthened by taking as matrices in S those containing only maximally consistent theories. For if $\Sigma \nvdash \varphi$ then $\Sigma; \neg\varphi$ is consistent and so for some maximal consistent Δ containing Σ we have $\neg\varphi \in \Delta$. Taking v to be the identity, $\overline{v}[\Sigma] = \Sigma \subseteq \Delta$, but $\overline{v}(\varphi) \notin \Delta$, otherwise Δ is not consistent.

2.2 Rules

A **rule** is a pair $\rho = \langle \Delta, \varphi \rangle$, where Δ is a set of formulae, and δ a single formula. We also write Δ/δ. If Δ is finite, we call ρ **finitary**; and if Δ is empty, we call ρ an **axiom**. ρ is n-ary if $|\Delta| = n$. ρ is a **derived** rule of $\vdash$ if $\rho \in \vdash$. ρ is **admissible** if for every substitution s: if $\Delta^s \subseteq \mathrm{Taut}(\vdash)$ then $\varphi^s \in \mathrm{Taut}(\vdash)$.

If R is a set of finitary rules, $\vdash^R$ denotes the smallest finitary, structural consequence relation that contains R. Given a consequence relation $\vdash$ and a rule ρ, $\vdash^{+\rho}$ is the least consequence relation containing $\vdash$ and ρ. $\vdash$ is called **consistent** if it is not the maximal relation. $\vdash$ is consistent iff p is not a tautology. For a consistent $\vdash$ put

$$(6) \qquad E(\vdash) := \{n : \text{there is an } n\text{-ary rule } \rho \notin \vdash \text{ such that } \nvdash^{+\rho} p\}$$

$\vdash$ is called **Post-complete** if $0 \notin E(\vdash)$. It is **structurally complete** if every admissible rule is derivable.

PROPOSITION 8 (Tokarz). *(1)* $\vdash$ *is structurally complete iff* $E(\vdash) \subseteq \{0\}$. *(2)* $\vdash$ *is maximal consistent iff it is both structurally complete and Post-complete.*

There is a special matrix, $\mathfrak{Taut} = \langle \mathfrak{Tm}_\nu(V), \varnothing^\vdash \rangle$. Recall that $\varnothing^\vdash$ are simply the tautologies of a logic.

THEOREM 9 (Wójcicki). $\vdash$ *is structurally complete iff* $\vdash = \vdash_{\mathfrak{Taut}}$.

$\vdash^R$ can be described as follows. If s is a substitution, say that $\langle \Delta^s, \varphi^s \rangle$ is an **instance** of $\langle \Delta, \varphi \rangle$. An R-**proof** of φ from Σ is a sequence $\langle \delta_i : i < n+1 \rangle$ such that $\delta_n = \varphi$, and for every $i < n+1$: either $\delta_i \in \Sigma$ or there are $j_k < i$, $k < p$, such that $\langle \{\delta_{j_k} : k < p\}, \delta_i \rangle$ is an instance of a rule from R.

PROPOSITION 10. $\Sigma \vdash^R \varphi$ *iff there exists an* R*-proof of* φ *from* Σ.

We remark here that $\vdash$ is finitary iff there is a set R of finitary rules such that $\vdash = \vdash^R$. Of course, R may be infinite. $\vdash$ is **decidable** if for all finite Σ and all φ we can decide whether or not $\Sigma \vdash \varphi$. The following is from [32].

THEOREM 11 (Harrop). *Suppose that* $\mathfrak{M} = \langle \mathfrak{A}, D \rangle$ *is a finite logical matrix. Then* $\vdash_{\mathfrak{M}}$ *is decidable.*

For example, one can use truth-tables. This procedure is generally slower than tableaux-methods, but only mildly so (see [15]).

2.3 The Deduction Theorem

The rule of **modus ponens** ($\mathrm{MP}_{\twoheadrightarrow}$) for a binary connective $\twoheadrightarrow$ is the rule $\langle\{p, p \twoheadrightarrow q\}, q\rangle$. ($\mathrm{MP}_{\rightarrow}$) is called (MP) in classical logic. There are many more connectives $\twoheadrightarrow$ for which ($\mathrm{MP}_{\twoheadrightarrow}$) is a derived rule, for example $\wedge$. $\twoheadrightarrow$ is said to satisfy a **deduction theorem** with respect to $\vdash$ if for all Σ, φ, ψ

$$(7) \qquad \Sigma; \varphi \vdash \psi \quad \Leftrightarrow \quad \Sigma \vdash \varphi \twoheadrightarrow \psi$$

A consequence relation $\vdash$ is said to **satisfy the deduction theorem** (DT) for $\twoheadrightarrow$ if $\twoheadrightarrow$ satisfies ($\mathrm{MP}_{\twoheadrightarrow}$) and (7) holds. (See [14] for a survey of deduction theorems.) Given (DT) it is possible to transform any rule different from ($\mathrm{MP}_{\twoheadrightarrow}$) into an axiom preserving the consequence relation. Hence it is possible to replace the original rule calculus by a Hilbert-style calculus, where ($\mathrm{MP}_{\twoheadrightarrow}$) is the only rule which is not an axiom. Given a set of rules R, we say it has a **deduction theorem** for $\twoheadrightarrow$ if $\vdash^R$ does.

THEOREM 12. *A Hilbert-style calculus for $\twoheadrightarrow$ has a deduction theorem for $\twoheadrightarrow$ iff $\twoheadrightarrow$ satisfies ($MP_{\twoheadrightarrow}$) and the following are axioms of $\vdash$:*

$$(8) \qquad p \twoheadrightarrow (q \twoheadrightarrow p)$$

$$(9) \qquad (p \twoheadrightarrow (q \twoheadrightarrow r)) \twoheadrightarrow ((p \twoheadrightarrow q) \twoheadrightarrow (p \twoheadrightarrow r))$$

Proof. ($\Rightarrow$) Suppose both ($\mathrm{MP}_{\twoheadrightarrow}$) and (7) hold for $\twoheadrightarrow$. Then, since $\varphi \vdash \varphi$, also $\varphi; \psi \vdash \varphi$ and (by (7)) also $\varphi \vdash \psi \twoheadrightarrow \varphi$ and (again by (7)) $\vdash \varphi \twoheadrightarrow (\psi \twoheadrightarrow \varphi)$. For (9) note that the following sequence

$$(10) \qquad \langle \varphi \twoheadrightarrow (\psi \twoheadrightarrow \chi), \varphi \twoheadrightarrow \psi, \varphi, \psi \twoheadrightarrow \chi, \psi, \chi\rangle$$

proves $\varphi \twoheadrightarrow (\psi \twoheadrightarrow \chi); \varphi \twoheadrightarrow \psi; \varphi \vdash \chi$. Apply (DT) three times and the formula is proved. ($\Leftarrow$) By induction on the length of an R-proof $\vec{\alpha}$ of ψ from $\Sigma \cup \{\varphi\}$ we show that $\Sigma \vdash \varphi \twoheadrightarrow \psi$. Suppose the length of $\vec{\alpha}$ is 1. Then $\psi \in \Sigma \cup \{\varphi\}$. There are two cases: (1) $\psi \in \Sigma$. Then observe that $\langle \psi \twoheadrightarrow (\varphi \twoheadrightarrow \psi), \psi, \varphi \twoheadrightarrow \psi\rangle$ is a proof of $\varphi \twoheadrightarrow \psi$ from Σ. (2) $\psi = \varphi$. Then we have to show that $\Sigma \vdash \varphi \twoheadrightarrow \varphi$. Now observe that the following is an instance of (9):

$$(11) \qquad (\varphi \twoheadrightarrow ((\psi \twoheadrightarrow \varphi) \twoheadrightarrow \varphi)) \twoheadrightarrow ((\varphi \twoheadrightarrow (\psi \twoheadrightarrow \varphi)) \twoheadrightarrow (\varphi \twoheadrightarrow \varphi))$$

But $\varphi \twoheadrightarrow ((\psi \twoheadrightarrow \varphi) \twoheadrightarrow \varphi)$ and $\varphi \twoheadrightarrow (\psi \twoheadrightarrow \varphi)$ are both instances of (8) and by applying ($\mathrm{MP}_{\twoheadrightarrow}$) twice we get $\varphi \twoheadrightarrow \varphi$. Now let $\vec{\alpha}$ be of length > 1. Then we may assume that ψ is obtained by an application of ($\mathrm{MP}_{\twoheadrightarrow}$) from some formulae χ and $\chi \twoheadrightarrow \psi$. Thus the proof looks as follows:

$$(12) \qquad \ldots, \chi, \ldots, \chi \twoheadrightarrow \psi, \ldots, \psi, \ldots$$

Now by induction hypothesis $\Sigma \vdash \varphi \twoheadrightarrow \chi$ and $\Sigma \vdash \varphi \twoheadrightarrow (\chi \twoheadrightarrow \psi)$. Now,

$$(13) \qquad (\varphi \twoheadrightarrow (\chi \twoheadrightarrow \psi)) \twoheadrightarrow ((\varphi \twoheadrightarrow \chi) \twoheadrightarrow (\varphi \twoheadrightarrow \psi))$$

is a theorem and so we get that $\Sigma \vdash \varphi \twoheadrightarrow \psi$ with two applications of ($\mathrm{MP}_{\twoheadrightarrow}$). ❑

For any given set Σ there exists at most one (finitary and structural) consequence relation $\vdash$ with a deduction theorem for a given connective such that Σ is the set of tautologies of $\vdash$. For assume $\Delta \vdash \varphi$ for a set Δ. Then since $\vdash$ is finitary, there exists a finite set $\Delta_0 \subseteq \Delta$ such that $\Delta_0 \vdash \varphi$. Let $\Delta_0 := \{\delta_i : i < n\}$. Put

$$\text{(14)} \qquad \mathrm{ded}(\Delta_0, \varphi) := \delta_0 \twoheadrightarrow (\delta_1 \twoheadrightarrow \ldots (\delta_{n-1} \twoheadrightarrow \varphi) \ldots)$$

Then, by the deduction theorem for $\twoheadrightarrow$

$$\text{(15)} \qquad \Delta \vdash \varphi \qquad \Leftrightarrow \qquad \varnothing \vdash \mathrm{ded}(\Delta, \varphi)$$

THEOREM 13. *Let $\vdash$ and $\vdash'$ be consequence relations with* $\mathrm{Taut}(\vdash) = \mathrm{Taut}(\vdash')$. *Suppose that there exists a binary term function $\twoheadrightarrow$ such that $\vdash$ and $\vdash'$ satisfy (DT) for $\twoheadrightarrow$. Then $\vdash = \vdash'$.*

2.4 Interpolation

$\vdash$ has **interpolation** if whenever $\varphi \vdash \psi$ there exists a formula χ (called **interpolant**) with $\mathrm{var}(\chi) \subseteq \mathrm{var}(\varphi) \cap \mathrm{var}(\psi)$ such that both $\varphi \vdash \chi$ and $\chi \vdash \psi$. Interpolation is a rather strong property, and generally logics fail to have it. There is a rather simple theorem which allows to prove interpolation for logics based on a finite matrix. Say that $\vdash$ has a **conjunction** if there is a term $p \wedge q$ such that the following are derivable rules: $\langle \{p, q\}, p \wedge q \rangle$ and both $\langle \{p \wedge q\}, p \rangle$ and $\langle \{p \wedge q\}, q \rangle$. In addition, if $\vdash = \vdash_{\mathfrak{M}}$ for some logical matrix $\mathfrak{M} = \langle M, D \rangle$ we say that $\vdash$ has **all constants** if for each $s \in M$ there exists a nullary term function $\underline{s}$ such that for all valuations v $\overline{v}(\underline{s}) = s$. (Note that since $\mathrm{var}(\underline{s}) = \varnothing$ the value of $\underline{s}$ does not depend at all on v.) This rather complicated definition allows that we do not need to have a constant for each truth-value; it is enough if they are definable from the others. For example in classical logic we may have only $\top = \underline{1}$ as a primitive and then $\underline{0} = \neg \top$. An algebra is **functionally complete** if every function $A^n \to A$ is a term function of $\mathfrak{A}$; $\mathfrak{A}$ is **polynomially complete** if every function $A^n \to A$ is a polynomial function. Every functionally complete algebra is polynomially complete; the converse need not hold, since polynomials may employ constants for the elements of $\mathfrak{A}$. However, if $\mathfrak{A}$ has all constants, then it is functionally complete iff it is polynomially complete.

THEOREM 14. *Suppose that $\mathfrak{M}$ is a finite logical matrix. Suppose that $\vdash_{\mathfrak{M}}$ has a conjunction $\wedge$ and all constants; then $\vdash_{\mathfrak{M}}$ has interpolation.*

(See [39], Theorem 1.6.4, where a proof is given.) A property closely related to interpolation is *Halldén-completeness*, named after Sören Halldén, who discussed it first in [31]. (See also [54].) $\vdash$ is called **Halldén-complete** if for all φ and ψ with $\mathrm{var}(\varphi) \cap \mathrm{var}(\psi) = \varnothing$: if $\varphi \vdash \psi$ and φ is consistent then $\vdash \psi$. 2-valued logics are Halldén-complete. Namely, assume that φ is consistent. Let $v : \mathrm{var}(\psi) \to 2$ be a valuation. Since φ is consistent there exists a $u : \mathrm{var}(\varphi) \to 2$ such that $\overline{u}(\varphi) = 1$. Put $w := u \cup v$. Since u and v have disjoint domains, this is well-defined. Then $\overline{w}(\varphi) = 1$, and so $\overline{w}(\psi) = 1$. So, $\overline{v}(\psi) = 1$. This shows that $\vdash \psi$. The following generalisation is now evident.

THEOREM 15 (Łos & Suszko). *Let $\mathfrak{M}$ be a logical matrix. Then $\vdash_{\mathfrak{M}}$ is Halldén-complete.*

In classical logic, the property of Halldén-completeness can be reformulated in a somewhat more familiar form. Namely, the property says that for φ and ψ disjoint in variables, if $\varphi \vee \psi$ is a tautology then either φ or ψ is a tautology.

Finally notice

THEOREM 16. *Suppose that $\mathfrak{M}$ is a logical matrix and $\vdash_{\mathfrak{M}}$ has all constants. Then $\vdash_{\mathfrak{M}}$ is structurally complete and Post-complete.*

2.5 Modal Logics and Modal Consequence Relations

A **modal consequence relation** is a structural consequence relation of modal formulae which contains at least the classical tautologies and in which the rule $(\mathrm{MP}_{\rightarrow})$ is derived. Unless otherwise stated, modal consequence relations are assumed to be finitary. If in addition for every basic modality $\Box$ the rule $(\mathrm{E}_{\Box}) := \langle\{p \leftrightarrow q\}, \Box p \leftrightarrow \Box q\rangle$ is admissible, $\vdash$ is called **classical**. If the rule $(\mathrm{M}_{\Box}) := \langle\{p \rightarrow q\}, \Box p \rightarrow \Box q\rangle$ is admissible for every basic modality $\Box$, $\vdash$ is called **monotone**. Finally, if all rules $(\mathrm{MN}_{\Box}) := \langle\{p\}, \Box p\rangle$ are admissible, $\vdash$ is called **normal**. For simplicity, we refer to the set of the rules $(\mathrm{MN}_{\Box})$, $\Box$ a basic modality as (MN), and treat it (somewhat inappropriately) as a single rule.

Modal logic is typically the study of modal *logics* and not that of modal *consequence relations.* The relationship is one-to-many. If $\vdash$ is a (modal) consequence relation, then

$$(16) \qquad \mathrm{Taut}(\vdash) := \{\varphi : \varnothing \vdash \varphi\}$$

is a modal logic, where a modal logic is any substitution closed set of formulae which contains all classical tautologies and $(\mathrm{MP}_{\rightarrow})$. There is a converse map. Given a logic L, put

$$(17) \qquad \vdash_L := \vdash^{L;(\mathrm{MP}_{\rightarrow})}$$

where L is here identified with the set of rules $\langle\varnothing, \varphi\rangle$, $\varphi \in L$. Evidently, $\Delta \vdash_L \varphi$ iff $\Delta; L \vdash^{(\mathrm{MP}_{\rightarrow})} \varphi$. By Theorem 12 $\vdash_L$ has a DT for $\rightarrow$. We shall often tacitly identify L with $\vdash_L$.

DEFINITION 17. L is **classical** (**monotone**, **normal**) if $\vdash_L$ is. The smallest normal logic with κ operators is denoted by $\mathbf{K}_\kappa$. L is **quasi-normal** if L contains $\mathbf{K}_\kappa$.

We also call a consequence relation **quasi-normal** if its set of tautologies is. Call a term $t(p)$ a **normal operator** for L if it satisfies (a) $t(\varphi \rightarrow \chi) \rightarrow (t(\varphi) \rightarrow t(\chi)) \in L$, and (b) if $t(\varphi) \in L$ then $\Box_i t(\varphi) \in L$. There is a class of formulae that generally are normal if all basic modalities are; these are the so-called compound modalities. A term $t(p)$ with just one variable is called a **compound modality** if it just contains the connectives $\Box_i$, $i < \kappa$ and $\wedge$ in addition to constants; and no variable except for p. One can assign a relation corresponding to $t(p)$ on a frame $\mathfrak{F} = \langle F, \langle \lhd_i : i < \kappa\rangle\rangle$ by induction on its structure as follows.

$$(18) \qquad \begin{aligned} R(p) &:= \{\langle x, x\rangle : x \in F\} \\ R(\Box_i s) &:= \lhd_i \circ R(s) \\ R(s \wedge t) &:= R(s) \cup R(t) \end{aligned}$$

Then for all valuations β and $x \in F$:

$$(19) \qquad \langle \mathfrak{F}, \beta, x\rangle \vDash t(\varphi) \quad \Leftrightarrow \quad \text{for all } y \text{ such that } x\ R(t)\ y\text{: } \langle \mathfrak{F}, \beta, y\rangle \vDash \varphi$$

Let L be a modal logic. Then define

(20) $\mathrm{CRel}(L) := \{\vdash : \mathrm{Taut}(\vdash) = L\}$

Furthermore, let $\vdash_L^m$ be the modal consequence relation containing $\vdash_L$ in which every admissible rule is derived. (It can be obtained by adding to $\vdash_L$ all admissible rules.)

PROPOSITION 18. *Let L be a modal logic. Then*

(21) $\mathrm{CRel}(L) = \{\vdash : \vdash_L \subseteq \vdash \subseteq \vdash_L^m\}$

Moreover, $\vdash_L$ is the unique member of $\mathrm{CRel}(L)$ *having a deduction theorem for $\to$ and $\vdash_L^m$ is the unique member which is structurally complete.*

Now, as is reported in [39], for logics contained in **G.3**, $|\,\mathrm{CRel}(L)| = 2^{\aleph_0}$. However, for tabular logics the situation is actually different (see also Theorem 130 below).

THEOREM 19. *Let L be a tabular modal logic over a finite κ. Then* $\mathrm{CRel}(L)$ *is at most countable, and every member of* $\mathrm{CRel}(L)$*, indeed every extension of $\vdash_L$, is finitely axiomatisable and decidable.*

Proof. First, a tabular logic is finitely axiomatisable. This needs some sophistication. Anticipating the results below, notice first that $\mathcal{V}(L)$ is locally finite. Then, using Corollary 49 we establish that $\mathrm{NExt}(L)$ is continuous, by Theorem 47 that $\mathrm{NExt}(L)$ has a basis, and therefore by Theorem 48 that $\mathrm{NExt}(L)$ has a strong basis. It follows with Theorem 50 that every extension of $\mathrm{NExt}(L)$ is finitely axiomatisable. So, $\vdash_M$ is finitely axiomatisable for every $M \supseteq L$. Also, $\mathcal{V}(L)$ is locally finite. Now, every extension of $\vdash_L$ is determined by some set of matrices verifying the axioms L. This means that they satisfy the axiom that the algebra has at most $|A|$ elements. This reduces the irreducible matrices to those of the form $\langle \mathfrak{B}, D\rangle$ where $|B| \leq |A|$, of which there are only finitely many. (The exact argument is nontrivial, see also [14], Corollary 2.5.20.) Thus, $\vdash_{\mathfrak{A}}$ has finitely many extensions. It is not difficult to show that they are all compact. Being determined by a finite set of finite algebras, they are all decidable. ❑

To see some more examples, consider the rule $\langle\{\Box p\}, p\rangle$. It is admissible in **K**. For assume that $\varphi := p^\sigma$ is not a theorem. Then there exists a model $\langle \mathfrak{F}, \beta, x\rangle \models \neg\varphi$ based on the Kripke-frame $\langle F, \lhd\rangle$. Consider the frame $\mathfrak{G}$ based on $F \cup \{z\}$, where $z \notin F$, and the relation $\blacktriangleleft := \lhd \cup \{\langle z, y\rangle : y \in F\}$. Take $\gamma(p) := \beta(p)$. Then $\langle \mathfrak{G}, \gamma, z\rangle \models \neg\Box\varphi$. The rule $\langle\{p\}, \Diamond p\rangle$ is not admissible in **K** despite the admissibility of $\langle\{\Box p\}, p\rangle$. Take $p := \top$. $\Diamond\top$ is not a theorem of **K**. Similarly, the so-called MacIntosh rule $\langle\{p \to \Box p\}, \Diamond p \to p\rangle$ is not admissible for **K**. Namely, put $p := \Box\bot$. $\Box\bot \to \Box\Box\bot$ is a theorem but $\Diamond\Box\bot \to \Box\bot$ is not. Notice also that if a rule ρ is admissible in a logic L we may not conclude that ρ is admissible in every extension of L. A case in point is the rule $\langle\{\Box p\}, p\rangle$, which is not admissible in $\mathbf{K} \oplus \Box\bot$.

2.6 Lattices of Modal Consequence Relations

Every finitary consequence relation has the form $\vdash^R$ for some set R of finitary rules. Define

(22) $\vdash^R \sqcap \vdash^S := \vdash^R \cap \vdash^S$

(23) $\vdash^R \sqcup \vdash^S := \vdash^{R\cup S}$

We can even define infinitary analogs of the operations:

$$\prod_{i \in I} \vdash_i := \bigcap_{i \in I} \vdash_i \tag{24}$$

$$\bigsqcup_{i \in I} \vdash^{R_i} := \vdash^{(\bigcup_{i \in I} R_i)} \tag{25}$$

It is to be noted, though, that the infinite intersection of finitary consequence relations need not be finitary again. It is also not possible to axiomatize it in terms of the rules for the $\vdash_i$. Therefore in the sequel we shall frequently deal with lattices in which only join is infinitary.

If a finitary rule is derivable in $\vdash^S$, then it is derivable already in $\vdash^{S_0}$ for some finite S_0, since $\vdash^S$ is finitary by assumption. It follows that a consequence relation is compact iff it is finitely axiomatisable. Moreover, the lattice is algebraic, since $\vdash^R = \bigsqcup_{\rho \in R} \vdash^\rho$. Finally, $\vdash'$ is quasi-normal iff $\mathrm{Taut}(\vdash')$ is quasi-normal iff $\mathrm{Taut}(\vdash')$ contains $\mathbf{K}_\kappa$.

PROPOSITION 20. *The set of modal consequence relations over a given language forms an algebraic lattice. The compact elements are exactly the finitely axiomatisable consequence relations. The lattice of quasi-normal consequence relations is the sublattice of consequence relations containing* $\vdash_{\mathbf{K}_\kappa}$.

We write $\mathrm{Ext}(\vdash)$ for the set of extensions of $\vdash$. By abuse of the notation we shall also denote the lattice over this set by $\mathrm{Ext}(\vdash)$. Similarly $\mathrm{QExt}(\vdash)$ denotes the set and the lattice of quasi-normal extensions. $\mathrm{NExt}(L)$ denotes the set and the lattice of normal extensions of a modal logic L.

PROPOSITION 21. *For each quasi-normal logic L and each quasi-normal consequence relation* $\vdash'$,

$$\vdash_L \subseteq \vdash' \quad \Leftrightarrow \quad L \subseteq \mathrm{Taut}(\vdash') \tag{26}$$

$\mathrm{Taut}(-)$ *commutes with infinite intersections,* $\vdash_L$ *with infinite intersections and infinite joins. It follows that* $\mathrm{NExt}(\mathbf{K}_\kappa)$ *is a sublattice of* $\mathrm{Ext}(\vdash_{\mathbf{K}_\kappa})$.

$\mathrm{Taut}(-)$ does not commute with joins. For example, let $\vdash_1 := \vdash^m_{\mathbf{G.3}}$ and $\vdash_2 := \vdash_{\mathbf{K} \oplus \Box\bot}$. Then, by Theorem 28, $\vdash_1$ is maximal, and so $\mathrm{Taut}(\vdash_1 \sqcup \vdash_2) = \mathbf{K} \oplus \bot$. However, $\mathbf{G.3} \sqcup \mathbf{K} \oplus \Box\bot = \mathbf{K} \oplus \Box\bot$.

PROPOSITION 22. *In monomodal logic,* $\vdash_L$ *is maximal iff L is a coatom.*

Proof. Clearly, if $\vdash_L$ is maximal in $\mathrm{Ext}(\vdash_{\mathbf{K}})$, L must be a coatom. To show the converse, we need to show that for a maximal consistent normal logic L, $\vdash_L$ is structurally complete. (It will follow that $\mathrm{CRel}(L)$ has exactly one element.) Now, L is Post-complete iff it contains either the formula $\Box\top$ or the formula $p \leftrightarrow \Box p$. Assume that $\vdash_L$ can be expanded by a rule $\rho = \langle \Delta, \varphi \rangle$. Then, by using the axioms ρ can be transformed into a rule $\rho' = \langle \Delta', \varphi' \rangle$ in which the formulae are nonmodal. (Namely, any formula in a rule may be exchanged by a deductively equivalent formula. Either $\Box\top \in L$ and any subformula $\Box\chi$ may be replaced by $\top$, or $p \leftrightarrow \Box p \in L$ and then $\Box\chi$ may be replaced by χ.) A nonmodal rule not derivable in $\vdash_L$ is also not derivable in its boolean fragment, $\vdash^0_L$. By the maximality of the latter, adding ρ' yields the inconsistent logic. ❑

In polymodal logics matters are a bit more complicated. There exist $2^{\aleph_0}$ logics which are coatoms in $\mathrm{NExt}(\mathbf{K}_2)$ without their consequence relation being maximal. Moreover,

in monomodal logics there exist $2^{\aleph_0}$ maximal consequence relations, which are therefore not of the form $\vdash_L$ (except for the two abovementioned consequence relations). Notice that even though a consequence is maximal iff it is structurally complete and Post-complete, Post-completeness is relative to the derivable rules. Therefore, this does *not* mean that the tautologies form a maximally consistent modal logic.

There is another consequence relation frequently associated with a logic, namely

$$\Vdash_L := \vdash^{L;(\mathrm{MP}_{\rightarrow});(\mathrm{MN})} \tag{27}$$

This is called the **global consequence relation**. Evidently, if (MN) is admissible, the set of tautologies is a normal logic, so $\mathrm{Taut}(\Vdash_L)$ is actually the least normal logic containing L.

PROPOSITION 23. *Let L be a normal logic. Then the following are equivalent.*

1. $\vdash_L = \Vdash_L$.
2. $\Vdash_L$ *admits a deduction theorem for* $\rightarrow$.
3. $L \supseteq \mathbf{K}_\kappa \oplus \{p \rightarrow \Box_j p : j < \kappa\}$.
4. *L is the logic of some set of Kripke-frames containing only one world.*

Clearly, if $\vdash_L \neq \Vdash_L$ then there are several consequence relations for a given logic. We will show now that the converse almost holds. For the purpose of stating the theorem, let $\boxed{\bullet}$ and $\boxed{\circ}$ be the one-point irreflexive and reflexive frame, respectively.

PROPOSITION 24. *Let L be a modal logic. Then the following are equivalent.*

(a) $|\,\mathrm{CRel}(L)| = 1$.

(b) $\vdash_L$ *is structurally complete.*

(c) L is the logic of a single Kripke-frame containing a single world.

(d) L is a fusion of monomodal logics of the frames $\boxed{\bullet}$ *or* $\boxed{\circ}$.

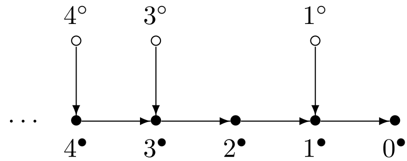
The nontrivial part is to show that (b) $\Leftrightarrow$ (c). Assume (c). Then since $\vdash_L$ is the logic of a single algebra based on two elements, and has all constants, it is structurally complete. Now let (c) fail. There are basically two cases. If L is not the logic of one-point frames, then $\vdash_L$ is anyway not structurally complete by Proposition 22. Otherwise, it is the intersection of logics determined by matrices of the form $\langle \mathfrak{A}, D\rangle$, D an open filter, $\mathfrak{A}$ the free algebra in $\aleph_0$ generators. (In fact, the freely 0-generated algebra is enough.) $\mathfrak{A}$ contains a constant c such that $0 < c < 1$. Namely, take two different one point frames. Then, say, $\Box_0$ is the diagonal on one frame and empty on the other. Then $c := \blacklozenge_0 1$ is a constant of the required form. The rule $\langle\{\Diamond_0\top\}, p\rangle$ is admissible but not derivable.

The method of the last proof can be used in many different ways.

LEMMA 25. *Let L be a logic and χ a constant formula such that neither χ nor $\neg\chi$ are inconsistent. Then the rule $\rho[\chi] := \langle\{\chi\}, \bot\rangle$ is admissible for L but not derivable in $\vdash_L$.*

Since $\chi \notin L$ and $\mathrm{var}(\chi) = \varnothing$, for no substitution s, $\chi^s \in L$. Hence the rule $\rho[\chi]$ is admissible. If it is derivable in $\vdash_L$ then $\vdash_L \chi \rightarrow \bot$, by the DT. So $\neg\chi \in L$, which is not the case. So, $\rho[\chi]$ is not derivable.

Figure 1. $\mathfrak{T}_M$, $M = \{1, 3, 4, \ldots\}$



THEOREM 26. *Let L be a logic such that $\mathfrak{Fr}_L(0)$ has infinitely many elements. Then $|\operatorname{CRel}(L)| = 2^{\aleph_0}$.*

The idea is as follows. There is an infinite set C of constants such that $\chi \wedge \chi' \vdash_L \bot$ whenever χ, χ' are distinct members of C. The relations $\vdash^D$ for $D \subseteq C$ are all pairwise distinct.

COROLLARY 27. *Let L be a monomodal logic and $L \subseteq \mathbf{G.3}$. Then $|\operatorname{CRel}(L)| = 2^{\aleph_0}$.*

In addition, $\vdash^m_{\mathbf{G.3}}$ is maximal. This follows from the following

THEOREM 28. *Let L be the logic of its 0-generated free algebra. Then $\vdash^m_L$ is maximal.*

Proof. Let $\Vdash \supsetneq \vdash^m_L$. Then $\operatorname{Taut}(\Vdash) \supsetneq L$. Since L is determined by its freely 0-generated algebra, there is a constant χ such that $L \subsetneq L \oplus \chi \subseteq \operatorname{Taut}(\Vdash)$. Therefore, we have $\chi \notin L$. (Case 1.) $\neg\chi \notin L$. Then $\rho[\chi]$ is admissible in L and so derivable in $\vdash^m_L$. Therefore $\rho[\chi] \in \Vdash$, and so $\Vdash \bot$. So, $\Vdash$ is inconsistent. (Case 2.) $\neg\chi \in L$. Then $\operatorname{Taut}(\Vdash)$ and also $\Vdash$ is inconsistent. ❑

We will now turn to the set of coatoms in $\operatorname{NExt}(\vdash_{\mathbf{K}})$. Let $M \subseteq \omega$. Put $T_M := \{n^\bullet : n \in \omega\} \cup \{n^\circ : n \in M\}$ and

$$(28) \qquad x \lhd y \quad \Leftrightarrow \quad \left\{ \begin{array}{rl} (1.) & x = m^\bullet, y = n^\bullet \text{ and } m > n \\ \text{or } (2.) & x = m^\circ, y = n^\bullet \text{ and } m \geq n \\ \text{or } (3.) & x = m^\circ, y = n^\circ \text{ and } m = n \end{array} \right.$$

Let $\mathbb{B}_M$ be the algebra of 0-definable sets. Put $\mathfrak{T}_M := \langle T_M, \lhd, \mathbb{B}_M \rangle$. If $M \neq N$ then $\operatorname{Th}(\mathfrak{T}_M) \neq \operatorname{Th}(\mathfrak{T}_N)$. To see this, note that every one-element set $\{n^\circ\}$ in T_M is definable by a formula $\chi(n)$ that depends only on n, not on M. First, take the formula

$$(29) \qquad \delta(n) := \Box^{n+1}\bot \wedge \neg\Box^n\bot$$

$\delta(n)$ defines the set $\{n^\bullet\}$. Now put

$$(30) \qquad \chi(n) := \Diamond\delta(n) \wedge \neg\delta(n+1) \wedge \neg\Diamond\delta(n+1)$$

It is easily checked that $\chi(n)$ defines $\{n^\circ\}$. Hence, if $n \notin M$, $\neg\chi(n) \in \operatorname{Th} \mathfrak{T}_M$. So, $\neg\chi(n) \in \operatorname{Th} \mathfrak{T}_M$ iff $n \notin M$. This establishes that if $M \neq N$, $\operatorname{Th} \mathfrak{T}_M \neq \operatorname{Th} \mathfrak{T}_N$.

THEOREM 29. *The lattice of normal monomodal consequence relations contains $2^{\aleph_0}$ many coatoms.*

2.7 The Locale of Modal Logics—General Theory

Given a normal modal logic L and a set Δ of formulae, $L \oplus \Delta$ denotes the smallest normal logic which contains L and Δ. Recall that $\mathrm{NExt}(L)$ denotes the set (and lattice) of normal logics containing L. For logics $M_i = L \oplus \Delta_i$ we have

(31) $$\bigsqcup_{i \in I} M_i = L \oplus \bigcup_{i \in I} \Delta_i$$

We can also calculate the axiomatisation of the intersection of two logics. Given two formulae, φ and χ, let $\varphi \dot{\vee} \chi$ denote a formula $\varphi \vee \chi^s$, where s is one-to-one and renames the variables of χ so as to make them distinct from the variables of φ. Then

(32) $$(L \oplus \Delta) \sqcap (L \oplus \Sigma) = L \oplus \{\boxplus\varphi \dot{\vee} \boxplus\chi : \varphi \in \Delta, \chi \in \Sigma, \boxplus \text{ a compound modality}\}$$

(See [50] or [39].) This can be used to show that $\mathrm{NExt}(L)$ satisfies the following infinitary distributive law

(33) $$x \sqcap \bigsqcup_{i \in I} y_i = \bigsqcup_{i \in I} x \sqcap y_i$$

In particular, the usual distributivity law holds. This means that the lattice is a locale, where a **locale** is a lattice with infinitary join and finitary meet satisfying (33). Recall that the operation $\bigsqcap$ can be defined from $\bigsqcup$ as follows:

(34) $$\bigsqcap_{i \in I} x_i := \bigsqcup \langle y : \text{for all } i \in I\colon\ y \leq x_i \rangle$$

A locale is **continuous** if also $L \sqcup \bigsqcap_{i \in I} M_i = \bigsqcap_{i \in I} L \sqcup M_i$. Locales $\mathrm{NExt}(L)$ are rarely continuous. An important exception is $\mathrm{NExt}(\mathbf{S4.3})$ (see the remarks following Theorem 47). Call an element x of a locale **meet-irreducible** (**strongly meet-irreducible**) if from $x = y \sqcap z$ follows $x = y$ or $x = z$ (if from $x = \bigsqcap_{i \in I} y_i$ follows $x = y_i$ for some $i \in I$). Call x **meet-prime** (**strongly meet-prime**) if from $x \geq y \sqcap z$ follows $x \geq y$ or $x \geq z$ (if from $x \geq \bigsqcap_{i \in I} y_i$ follows $x \geq y_i$ for some $i \in I$). Dually for **join-irreducible** and **join-prime**. If x is (strongly) meet-prime it is also (strongly) meet-irreducible. In a distributive lattice, meet-prime is equivalent to meet-irreducible, but in general a strongly meet-irreducible element need not be strongly meet-prime. However, in a locale a strongly join-irreducible element is also strongly join-prime.

Given a locale $\mathfrak{L} = \langle L, \sqcap, \bigsqcup \rangle$, let $\mathrm{Irr}(\mathfrak{L})$ be the set of strongly meet-irreducible elements of $\mathfrak{L}$. For $x \in L$ put $x^\circ := \mathrm{Irr}(\mathfrak{L}) - \uparrow x$ where

(35) $$\uparrow x := \{y : y \geq x\} \qquad \downarrow x := \{y : y \leq x\}$$

It turns out that

(36) $$(x \sqcup y)^\circ = x^\circ \cup y^\circ$$

(37) $$(\bigsqcap_{i \in I} x)^\circ = \bigcap_{i \in I} x_i^\circ$$

Thus, $\{x^\circ : x \in L\}$ is a topology of closed sets on $\mathrm{Irr}(\mathfrak{L})$. A locale is **spatial** if it is isomorphic to the locale of open sets of a topological space.

THEOREM 30. *The locale* NExt(L) *is spatial.*

To show that NExt(L) is spatial we need to show that the map $M \mapsto M^\circ$ is injective. For a formula $\varphi \notin M$, the set of logics not containing φ is nonempty (containing, for example, M) and has a maximal element, which we denote by $L^\star_\varphi$. (This follows from Zorn's Lemma, using the fact that NExt(L) is algebraic. $L^\star_\varphi$ is usually not unique.) $L^\star_\varphi$ is easily seen to be strongly meet-irreducible. Now

$$(38) \qquad M = \bigcap_{\varphi \notin M} L^\star_\varphi$$

The topology $\{M^\circ : M \in \mathrm{NExt}(L)\}$ satisfies the T_0-axiom: for every pair M, M' of different logics there is an open set X such that $|X \cap \{M, M'\}| = 1$. Put $M \preccurlyeq M'$ if $M^\circ \subseteq M'^\circ$. It is easy to see that $M \preccurlyeq M'$ iff $M \subseteq M'$ iff $M \leq M'$. Moreover, a closed set is lower closed, that is, if X is closed then $\downarrow X = X$. The converse need not be true. Thus, the lattice is completely reconstructible from the topology. Moreover:

THEOREM 31. NExt(L) *is continuous iff all lower closed sets are closed.*

Indeed, if NExt(L) is continuous, then the arbitrary union of closed sets is closed. Any lower closed set is the union of sets of the form $\downarrow\{x\}$, which are all closed. More on this subject can be found in [39].

It is interesting to know which properties are at all connected with the lattice structure. Completeness, for example, is clearly closed under meet but not under join (for a counterexample see [39]). Elementarity is closed both under intersection and infinitary join. Decidability is closed under intersection, but not under join. Interpolation and Halldén-completeness show no clear connection.

2.8 Splittings

Splittings have been studied in the context of modal logics first by [4], from which most of the results below are drawn. This investigation was carried further in [49, 51]. A **splitting** of a lattice $\langle L, \sqcap, \sqcup\rangle$ is a pair $\langle x, y\rangle$ such that $L = \downarrow x \cup \uparrow y$ and $\downarrow x \cap \uparrow y = \varnothing$. We say that x **splits** $\mathfrak{L}$ if there is y such that $\langle x, y\rangle$ splits $\mathfrak{L}$. We say that y is the **splitting companion** of x and write $\mathfrak{L}/x$ for y (but for logics we write L/M rather than NExt$(L)/M$).

PROPOSITION 32. *If $\langle x, y\rangle$ is a splitting of $\mathfrak{L}$, x is strongly meet-prime and y is strongly join-prime. x splits $\mathfrak{L}$ iff it is strongly meet-prime. If $x < x'$ and $\langle x', y'\rangle$ is a splitting, then $y < y'$.*

Notice that every join-irreducible logic is join-prime. There is a useful corollary for logics. Say that M is **essentially 1-axiomatisable** over L if for every Δ: if $M = L \oplus \Delta$ then there is a $\delta \in \Delta$ such that $M = L \oplus \delta$. It is easy to see that this notion is equivalent to strong join-irreducibility. Hence we have an observation already made in [46].

PROPOSITION 33 (McKenzie). *M is essentially 1-axiomatisable over L iff $M = L/N$ for some splitting logic N.*

Furthermore, this gives rise to an axiomatisability criterion. Suppose that $M = L/N$. Then $M = L \oplus \delta$ iff (a) $\delta \in M$ and (b) $\delta \notin N$. If both M and N are decidable, the problem '$M = L \oplus \delta$' is decidable. For example, $\mathbf{S5} = \mathbf{S4}/N$, where N is the logic of a four element algebra. Then clearly N is decidable; since also $\mathbf{S5}$ is decidable, the problem

'$\mathbf{S5} = \mathbf{S4} \oplus \delta$' is decidable. More can be established. Also the problem '$(\vdash_{\mathbf{S4}})^{+\rho} = \vdash_{\mathbf{S5}}$' is decidable. This is due to the following fact. Recall that $\vdash^m_M$ is the maximal consequence relation that has M as its set of tautologies.

PROPOSITION 34 (Rautenberg). *Suppose that M induces a splitting of* $\mathrm{NExt}(L)$. *Then* $\vdash^m_M$ *splits the lattice* $\mathrm{Ext}(\vdash_L)$, *and* $\mathrm{Ext}(\vdash_L)/\vdash^m_M = \vdash_{L/M}$.

Now, suppose a rule ρ is given. The problem whether $\rho \in \vdash^m_M$ is decidable (see Theorem 19). (Case 1) $\rho \in \vdash^m_M$. Then $(\vdash_{\mathbf{S4}})^{+\rho} \subseteq \vdash^m_M \not\supseteq \vdash_{\mathbf{S5}}$. (Case 2) $\rho \notin \vdash^m_M$. Then $(\vdash_{\mathbf{S4}})^{+\rho} \supsetneq \vdash_{\mathbf{S4}}$. Now we must check whether $\rho \in \vdash_{\mathbf{S5}}$. This is again decidable. If this holds $(\vdash_{\mathbf{S4}})^{+\rho} = \vdash_{\mathbf{S5}}$. The argument generalizes to the case where M is tabular and L/M is decidable.

LEMMA 35. *If M does not split* $\mathrm{NExt}(L)$ *there is a sequence N_i, $i \in \omega$, of logics such that $N_i \not\leq M$ but $\prod_{i\in\omega} N_i \leq M$.*

(And if M does split $\mathrm{NExt}(L)$, no such sequence can obviously exist.) If N splits $\mathrm{NExt}(L)$ it is strongly meet-prime. In particular, it is strongly meet-irreducible. It follows that $N = \mathrm{Th}\,\mathfrak{A}$, where $\mathfrak{A}$ is a subdirectly irreducible (si) algebra. However, there are examples of subdirectly irreducible algebras such that $\mathrm{Th}\,\mathfrak{A}$ is not even meet-irreducible. The algebras that induce splittings can be characterized. Call an element $x < 1$ of an si $\mathfrak{A}$ an **opremum** if for all $a < 1$ there is a compound modality $\boxplus$ such that $\boxplus a \leq x$. Intuitively, in a finite algebra an opremum is easy to find. The dual frame is generated by a single world, w, in the sense that every world is indirectly accessible from it iff the algebra is subdirectly irreducible. (This fails in the infinite, as Giovanni Sambin pointed out, see [39].) Now, the set containing everything but w, is an opremum.

Let $\Delta(\mathfrak{A})$ be the so-called **diagram** of $\mathfrak{A}$, defined by

$$\begin{aligned}(39)\qquad \Delta(\mathfrak{A}) := \quad & \{p_a \vee p_b \leftrightarrow p_{a\vee b} : a, b \in A\}\\ & \cup \{p_{\neg a} \leftrightarrow \neg p_a : a \in A\}\\ & \cup \{p_{\Box_i a} \leftrightarrow \Box_i p_a : a \in A, i < \kappa\}\end{aligned}$$

Suppose that there is an algebra $\mathfrak{B}$, a valuation β, and an ultrafilter U such that $\beta(\neg p_x) \in U$ and for every compound modality $\boxplus$ and every $\delta \in \Delta(\mathfrak{A})$, $\beta(\boxplus\delta) \in U$. Then $\mathfrak{A} \in \mathsf{HS}\,\mathfrak{B}$. Moreover, (by Jónsson's Lemma), $\mathfrak{A} \in \mathsf{HSP}\,\mathfrak{B}$ iff $\mathfrak{A} \in \mathsf{HSUp}\,\mathfrak{B}$ iff every finite subset of $p_x; \bigcup\{\boxplus\Delta(\mathfrak{A}) : \boxplus \text{ a compound modality}\}$ is satisfiable. Let $\mathcal{V}(L)$ denote the variety of L-algebras. The following result appeared in its complete form in [61], generalizing theorems by [51] and [36].

THEOREM 36 (Wolter). *Let $\mathfrak{A}$ be subdirectly irreducible with opremum x. The following are equivalent:*

① $\mathrm{Th}\,\mathfrak{A}$ *splits* $\mathrm{NExt}(L)$.

② *There is a finite $\Delta_0 \subseteq \Delta(\mathfrak{A})$ and a compound modality $\boxplus$ such that for every $\mathfrak{B} \in \mathcal{V}(L)$: if $\neg p_x; \boxplus\Delta_0$ is satisfiable in $\mathfrak{B}$, so is*

$$\neg p_x; \bigcup\{\boxtimes\Delta(\mathfrak{A}) : \boxtimes \textit{ a compound modality}\}$$

If either obtains,

$$(40)\qquad L/\mathrm{Th}\,\mathfrak{A} = L \oplus \bigwedge \boxplus\Delta_0 \to p_x$$

We note that the number of variables needed to axiomatize $L/\operatorname{Th}\mathfrak{A}$ is the minimum number of variables needed to generate $\mathfrak{A}$. This can be used to show that **S4.3** cannot be axiomatized over **S4.2** (and **S4**) using less than two variables. (In tense logic, however, one variable is sufficient.)

2.9 Some Splittings

Let us first look at monomodal logics. A frame $\mathfrak{F}$ is cycle-free if there is an $n \in \omega$ such that $\mathfrak{F} \vDash \Box^n\bot$. **K** is complete with respect to all cycle-free frames. It follows from Lemma 35 that only logics of cycle-free frames can split $\mathrm{NExt}(\mathbf{K})$. So, let $\mathfrak{F}$ be finite, cycle free and generated by a single point. Let $\mathfrak{A}$ be the algebra of its subsets. $\mathfrak{A}$ is si. Since $\mathfrak{A} \vdash \Box^n\bot \to \Box^{n+1}\bot$, it follows that if $\Box^n\bot$ is satisfiable, then $\Box^{n+k}\bot$ is satisfiable for every $k \in \omega$. Thus, since $\Box^n\Delta(\mathfrak{A})$ is finite and implies $\Box^n\bot$, we get that $\Box^n\Delta(\mathfrak{A}) \to \Box^{n+k}\Delta(\mathfrak{A})$ for every k. So, the theory of a finite one-generated cycle free frame splits $\mathrm{NExt}(\mathbf{K})$. This argument generalizes easily for any finite number of operators.

THEOREM 37 (Blok). *L splits* $\mathrm{NExt}(\mathbf{K})$ *iff it is the logic of a finite, one-generated cycle free frame.*

There is an easy corollary. For every splitting logic L there is a splitting logic $L' < L$. (Simply add another irreflexive point before the generator of $\mathfrak{F}$ where $L = \mathrm{Th}(\mathfrak{F})$.) Now, from Proposition 32 we get $\mathrm{NExt}(\mathbf{K})/L' < \mathrm{NExt}(\mathbf{K})/L$. Thus, for every strongly join-prime element there exists a strongly join-prime element strictly below it. Atoms are strongly join-irreducible, and therefore strictly join-prime, hence they are splitting companions. We have established the following result from [3].

THEOREM 38 (Blok). $\mathrm{NExt}(\mathbf{K})$ *is atomless.*

On the other hand we have the following from [41].

THEOREM 39 (Makinson). $\mathrm{NExt}(\mathbf{K})$ *has exactly two coatoms. Moreover, every consistent logic is below one of them.*

The coatoms are the logics of the two two-element algebras, corresponding to the one-element reflexive frame, and the one-element irreflexive frame. Take a general frame $\mathfrak{F}$. Either $\Box\bot$ is satisfiable, in which case the subframe of points satisfying $\Box\bot$ is generated and can be contracted to the single one-generated irreflexive point; or $\Box\bot$ is not satisfiable. Then $\mathfrak{F} \vDash \Diamond\top$, so that $\mathfrak{F}$ is contractible to a one-element reflexive frame. The second fact easily follows from the following observation: if L is finitely axiomatisable, there is no infinite upgoing chain with limit L. The inconsistent logic is finitely axiomatisable, and so it is not the limit of an upgoing chain. Hence every consistent logic must be below a coatom.

Suppose now that $L = \mathbf{K}/M$ for some logic M. It so happens that $\mathrm{NExt}(L)$ may be split by N even though N does not split $\mathrm{NExt}(\mathbf{K})$. This arises exactly once: $L = \mathbf{K}/\boxed{\bullet}$. Then $L = \mathbf{K.D}$, and the new splitting logic is $N = \mathrm{Th}\,\boxed{\circ}$, the logic of the one-element reflexive frame. We call L/N an **iterated splitting** of **K**. L/N is actually inconsistent. However, suppose that X is a set of splitting logics of $\mathrm{NExt}(L)$. Then we may split off the logics of X in any order we like. The results is always the same. Therefore, put

$$L/X := \bigsqcup \langle L/N : N \in X\rangle \tag{41}$$

The following theorem is much harder to establish. Let $\mathrm{Fs}(L)$ be the set of all logics that have the same Kripke-frames as L (the **Fine-spectrum** of L). Call L **intrinsically complete** if $|\,\mathrm{Fs}(L)| = 1$. The following is from [4].

THEOREM 40 (Blok). *L is intrinsically complete iff it is inconsistent or of the form $\mathbf{K}/X$ for a set of splitting logics X. If L is not intrinsically complete, $|\,\mathrm{Fs}(L)| = 2^{\aleph_0}$.*

We say that N has a **splitting representation** over L if it has the form L/X for some set X. Although one can have $N = L/X = L/Y$ for different X and Y, there is a unique set $X^\star$ such that $N = L/X^\star$ and for every X such that $N = L/X$ we have $X \supseteq X^\star$. (The set $X^\star$ is a minimal representation of L.)

Say that a compound modality $\boxplus$ is a **master modality** for L if (a) $\boxplus p \to \Box_i p \in L$ for all $i < \kappa$, and (b) $\boxplus p \to p, \boxplus p \to \boxplus\boxplus p \in L$. L is called **weakly transitive** if it has a master modality. Now suppose that L is weakly transitive, with master modality $\boxplus$. Then if $\mathfrak{A}$ is finite and subdirectly irreducible, it is splitting. (Actually, it is enough that $\mathfrak{A}$ is finitely presentable.) For example, the logic M of a one-generated finite frame splits $\mathrm{NExt}(\mathbf{K4})$ (and every $\mathrm{NExt}(L)$ for $L \geq \mathbf{K4}$ if only $M \geq L$). Many logics above $\mathbf{K4}$ possess a splitting representation above $\mathbf{K4}$.

We present a few applications. [19] shows that there is an infinite antichain L_i, $i \in \omega$, of logics of depth 3 in $\mathrm{NExt}(\mathbf{S4})$. Now, define the following map from subsets of ω into $\mathrm{NExt}(\mathbf{S4})$: $p : U \mapsto \mathbf{S4}/\{L_i : i \in U\}$. This map is injective. Moreover, $p(U) \leq p(V)$ iff $U \subseteq V$. So, the map is a lattice embedding. It follows not only that $\mathrm{NExt}(\mathbf{S4})$ has continuously many elements, but also that it has an infinite upgoing chain of elements.

It is known that every logic $L \supseteq \mathbf{S4.3}$ has the finite model property (see [7]). It follows that it has a representation

$$L = \mathbf{S4.3}/X \tag{42}$$

where X is the set of logics of $\mathbf{S4.3}$-frames which are not L-frames. Identity holds by the fact that both logics have the finite model property and the same finite models. It follows that there is a unique minimal set $X^\star$ such that $L = \mathbf{S4.3}/X^\star$. This means that there is a canonical axiomatisation of every logic in terms of splitting formulae, an axiomatisation base in the sense defined below.

2.10 Axiomatisation Bases

The success of the canonical formulae of Michael Zakharyaschev (see [63, 64]) has sparked off the question whether it is possible to find independent sets of formulae that can axiomatize any given logic above L, where L is a given modal logic (in the best case, $L = \mathbf{K}_\kappa$). The present section reviews conditions on L under which this is possible, but the outcome is, for practical purposes, rather negative: only very strong logics L have this property.

If every extension of L is of the form L/X the locale $\mathrm{NExt}(L)$ is continuous. The finitely axiomatisable logics are closed under finite union, just as the compact elements. An infinite join of finitely axiomatisable logics need not be finitely axiomatisable again. Likewise, the finite meet of finitely axiomatisable logics need not be finitely axiomatisable. However, this is the case when L is weakly transitive.

DEFINITION 41. A locale is **coherent** if (i) every element is the join of compact elements and (ii) the meet of two compact elements is again compact.

Coherent locales allow a stronger representation theorem. Let $\mathfrak{L}$ be a coherent locale, $K(\mathfrak{L})$ be the set of compact elements. They form a lattice $\mathfrak{K}(\mathfrak{L}) := \langle K(\mathfrak{L}), \sqcap, \sqcup \rangle$, by definition of a coherent locale. Given $\mathfrak{K}(\mathfrak{L})$, $\mathfrak{L}$ is uniquely identified by the fact that it is the lattice of ideals of $\mathfrak{K}(\mathfrak{L})$.

LEMMA 42. *A locale is coherent iff it is isomorphic to the locale of ideals of a distributive lattice.*

If we have a lattice homomorphism $\mathfrak{K}(\mathfrak{L}) \to \mathfrak{K}(\mathfrak{M})$ then this map can be extended uniquely to a homomorphism of locales $\mathfrak{L} \to \mathfrak{M}$. Not all locale homomorphisms arise this way, and so not all locale maps derive from lattice homomorphisms. Hence call a map $f : \mathfrak{L} \to \mathfrak{M}$ **coherent** if it maps compact element into compact elements.

THEOREM 43. *The category* DLat *of distributive lattices and lattice homomorphisms is dual to the category* CohLoc *of coherent locales with coherent maps.*

Now if L is weakly transitive, the intersection of two finitely axiomatisable extensions is again finitely axiomatisable. Now, a logic is compact in $\mathrm{NExt}(L)$ iff it is finitely axiomatisable over L. We conclude the following theorem.

PROPOSITION 44. *Let L be weakly transitive. Then* $\mathrm{NExt}(L)$ *is coherent.*

The converse need not hold. $\mathrm{NExt}(\mathbf{K.alt_1}) = \mathbf{K} \oplus \Diamond p \to \Box p$ is coherent (because every logic in this lattice is finitely axiomatisable) but the logic is not weakly transitive.

DEFINITION 45. Let $\mathfrak{L}$ be a complete lattice. A set $X \subseteq L$ is a **generating set** if for every member of L is the join of a subset of X. $\mathfrak{L}$ is said to have a **basis** if there exists a least generating set. Moreover, X is a **strong basis** for $\mathfrak{L}$ if every element has a nonredundant representation, that is, for each x there exists a minimal $Y \subseteq X$ such that $x = \bigsqcup Y$.

THEOREM 46. *Let $\mathfrak{L}$ be a locale. $\mathfrak{L}$ has a basis iff (i) $\mathfrak{L}$ is continuous and (ii) every element is the meet of $\bigsqcap$-irreducible elements. $\mathfrak{L}$ has a strong basis iff it has a basis and there exists no infinite properly ascending chain of $\bigsqcap$-prime elements.*

Let $\mathfrak{L}$ be a locale with a strong basis. Then the elements of $\mathfrak{L}$ are in one-to-one correspondence with antichains of strongly meet-prime elements (via the splitting representation, which must exist).

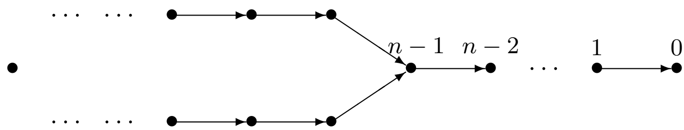
THEOREM 47. *Let L be a modal logic. Then* $\mathrm{NExt}(L)$ *has a basis iff* $\mathrm{NExt}(L)$ *is continuous.*

Since continuous lattices are the exception in modal logic, most extension lattices do not have a basis. We can sharpen the previous theorem somewhat to obtain stricter conditions on continuity. From Theorem 47 and the next theorem it follows that $\mathrm{NExt}(\mathbf{S4.3})$ is continuous (using the result of [7] that all extensions of $\mathbf{S4.3}$ have the fmp).

COROLLARY 48. *Let L be weakly transitive and have the finite model property. Then the following are equivalent.*

1. $\mathrm{NExt}(L)$ *has a basis.*
2. $\mathrm{NExt}(L)$ *has a strong basis.*
3. *Every extension of L has the finite model property.*
4. *Every extension of L is the join of co-splitting logics.*

Figure 2. The Frame $\mathfrak{O}$



5. *Every join of co-splitting logics has the finite model property.*

COROLLARY 49. *Let* $\mathcal{V}(L)$ *be locally finite. Then* $\mathrm{NExt}(L)$ *is continuous.*

The converse does not hold. The lattice $\mathrm{NExt}(\mathbf{S4.3})$ is continuous but **S4.3** fails to be locally finite. The following once more emphasizes the importance of splittings on the structure of the lattice.

THEOREM 50. *Let* $\mathrm{NExt}(L)$ *have a strong basis. Then the following are equivalent.*

1. *Every extension of* $\mathrm{NExt}(L)$ *is finitely axiomatisable.*
2. $\mathrm{NExt}(L)$ *is finite or countably infinite.*
3. *There exists no infinite set of incomparable splitting logics.*

Typically the locales $\mathrm{NExt}(L)$ have no basis. We might ask, however, if for a given logic an independent axiomatisation necessarily exists. This is not so. Call a set Δ of formulae **independent** if for every $\delta \in \Delta$ we have $\delta \notin \mathbf{K} \oplus (\Delta - \{\delta\})$. (For example, a basis is an independent set.) A logic L is **independently axiomatisable** if there exists an independent set Δ such that $L = \mathbf{K} \oplus \Delta$. Every finitely axiomatisable logic is independently axiomatisable. It has been shown in [8] that there exists a logic which is not independently axiomatisable. Furthermore, [37] gives an example of a logic which is not finitely axiomatisable, but all its proper extensions are. Such a logic is called **pre-finitely axiomatisable**. Here is a logic that has both properties.

THEOREM 51. *The logic of the frame* $\mathfrak{O}$ *shown in Figure 2 is pre-finitely axiomatisable. It splits the lattice of extensions of* $\mathbf{G}.\Omega_2$*. Moreover, it is not axiomatisable by a set of independent formulae.*

THEOREM 52. *Let* $\mathfrak{A}$ *be the algebra generated by the singleton sets of* $\mathfrak{O}$*.* $\mathfrak{A}$ *is not finitely presentable. Its logic splits* $\mathrm{NExt}(\mathbf{G}.\Omega_2)$*.*

3 THE LOCAL AND THE GLOBAL

3.1 Equivalential and Algebraisable Logics

In recent years, there have been a lot of results concerning the algebraisability of logics. (See [14] for a general exposition of the topics of this section.) Research has been sparked off mainly by the monograph [5]. In brief, a logic is algebraisable if the notion of truth

and of consequence can be reduced faithfully to the equational calculus. Let us assume that two consequence relations, $\vdash$ over language $\mathcal{L}_1$ and $\succ$ over language $\mathcal{L}_2$, are given. Let $\kappa : \mathcal{L}_1 \to \wp(\mathcal{L}_2)$ be a map from formulae in $\mathcal{L}_1$ to sets of formulae in $\mathcal{L}_2$. We write $\kappa(\Delta)$ for the union of the $\kappa(\delta)$, $\delta \in \Delta$. κ is a **transform** of $\vdash$ into $\succ$ if

(43) $$\Delta \vdash \varphi \quad \Leftrightarrow \quad \text{for all } \chi \in \kappa(\varphi) : \kappa(\Delta) \succ \chi$$

If $\lambda : \mathcal{L}_2 \to \wp(\mathcal{L}_1)$ is a transform of $\succ$ into $\vdash$ and κ a transform of $\vdash$ into $\succ$ we call $\langle \kappa, \lambda \rangle$ a **pair of conjugate transforms** if in addition

(44) $$\varphi \vdash \chi \Leftrightarrow \lambda(\kappa(\varphi)) \vdash \chi$$

(45) $$\varphi \succ \chi \Leftrightarrow \kappa(\lambda(\varphi)) \succ \chi$$

A consequence relation is **algebraisable** if there is a pair of conjugate transforms to a calculus of equations over the same language, and both maps commute with substitutions. Recall that there is also a first-order theory of the algebra, using the function symbols of the signature and equality (=). In equational logic we are mainly interested in Horn-clauses of that languages, to which we turn below.

A key element in the characterisation of algebraisability is that of the Leibniz operator. A logic $\vdash$ defines the following operator $\Omega_{\mathfrak{A}}$ on an algebra $\mathfrak{A}$, called the **Leibniz operator**.

(46) $$\Omega_{\mathfrak{A}}(D) := \{\langle a, b \rangle : \text{for all polynomials } p \text{ of } \mathfrak{A} : p(a) \in D \Leftrightarrow p(b) \in D\}$$

Given D, $\Omega_{\mathfrak{A}}$ is the largest congruence compatible with D. $\langle \mathfrak{A}/\Omega_{\mathfrak{A}}(D), D/\Omega_{\mathfrak{A}} \rangle$ is reduced. We write Ω for the operator defined on the term algebra. As Wim Blok and Don Pigozzi have shown, many properties of the consequence relation can be defined in terms of the Leibniz-operator.

THEOREM 53 (Blok & Pigozzi). *A consequence relation $\vdash$ is algebraisable iff*

① Ω *is monotone on the set of theories of* $\vdash$*;*

② Ω *is injective on the set of theories of* $\vdash$*; and*

③ Ω *commutes with inverse substitutions on the set of theories of* $\vdash$*.*

The first is to be read as follows: if T and T' are theories (deductively closed sets of formulae) and $T \subseteq T'$ then $\Omega(T) \subseteq \Omega(T')$. The latter are congruences. Similarly for the other conditions.

We shall fill the notion of algebraisability with more life. The calculus of equations can be generalized to implications. A **quasi-equation** or **quasi-identity** is an implication of the form

(47) $$\sigma_0 = \tau_0 \wedge \sigma_1 = \tau_1 \wedge \ldots \wedge \sigma_{n-1} = \tau_{n-1} \to \sigma_n = \tau_n$$

Alternatively, it is a Horn-clause in the first-order theory of the algebraic signature. A class of algebras is called a **quasi-variety** if it is characterized by a set of quasi-identities. The following is from [30].

THEOREM 54 (Graetzer & Lakser). *A class of algebras is a quasi-variety iff it is closed under ultraproducts, products and subalgebras. The least quasi-variety containing a given class* $\mathcal{K}$ *is* $\mathsf{SPP_u}(\mathcal{K})$.

Now, in general consequence relations use the notion of truth. They are therefore said to **define truth implicitly** if for every algebra $\mathfrak{A}$ there is at most one deductively closed set D such that $\langle \mathfrak{A}, D\rangle$ is a reduced matrix for $\vdash$. An explicit definition consists in a set $\Delta(p)$ of equations such that $a \in D$ iff $\mathfrak{A} \vDash \alpha(a) = \beta(a)$ for all $\alpha(p) = \beta(p) \in \Delta(p)$. Since $\langle \mathfrak{A}, \{1\}\rangle$ is a matrix for all modal consequence relations, and reduced, a consequence relation defines truth implicitly iff (MN) is derivable.

The following definition is due to [48].

DEFINITION 55. Let $\vdash$ be a consequence relation. A set of formulae $\Delta(p,q) := \{\delta_i(p,q) : i \in I\}$ is called a **set of equivalential terms for** $\vdash$ if the following holds for all basic function symbols f:

$$\text{(48a)} \qquad \vdash \Delta(p,p)$$

$$\text{(48b)} \qquad \Delta(p,q) \vdash \Delta(q,p)$$

$$\text{(48c)} \qquad \Delta(p,q); \Delta(q,r) \vdash \Delta(p,r)$$

$$\text{(48d)} \qquad \bigcup_{i<\nu(f)} \Delta(p_i,q_i) \vdash \Delta(f(\vec{p}), f(\vec{q}))$$

$$\text{(48e)} \qquad p; \Delta(p,q) \vdash q$$

$\vdash$ is called **equivalential** if it has a set of equivalential terms, and **finitely equivalential** if it has a finite set of equivalential terms.

THEOREM 56. $\vdash$ *is finitary and finitely equivalential iff the class of reduced matrices for* $\vdash$ *is a quasi-variety.*

COROLLARY 57. *Let* $\vdash$ *be finitary and finitely equivalential and* $\mathcal{Q}$ *the quasi-variety of reduced matrices for* $\vdash$*. Then the lattice of finitary extensions of* $\vdash$ *is dually isomorphic to the lattice of sub-quasi-varieties of* $\mathcal{Q}$*.*

A logic is algebraisable in the sense of Blok and Pigozzi if it is finitary, algebraisable and finitely equivalential. Ω is said to be **continuous** if for every upgoing chain T_i, $i \in \mu$, of theories whose limit (= union) is a theory

$$\text{(49)} \qquad \Omega(\bigcup_{i\in\mu} T_i) = \bigcup\{\Omega\, T_i : i \in \mu\}$$

Continuity implies monotonicity.

THEOREM 58. $\vdash$ *is equivalential iff* Ω *is monotone on the set of theories, and* $s\Omega(T) \subseteq \Omega((sT)^{\vdash})$ *for all substitutions* s *and theories* T*.* $\vdash$ *is finitely equivalential iff* Ω *is continuous on the set of theories of* $\vdash$*.*

Clearly, for any modal logic L, $\vdash_L$ is always equivalential; a set of equivalential terms is the following.

$$\text{(50)} \qquad \Delta(p,q) := \{\boxplus(p \leftrightarrow q) : \boxplus \text{ a compound modality}\}$$

$\Vdash_L$ is always finitely equivalential; $p \leftrightarrow q$ is an equivalential term for $\Vdash_L$. Note that if a classical consequence relation $\vdash$ is finitely equivalential it also has an equivalential term. For if $\Delta(p,q) = \{\delta_i(p,q) : i < n\}$ is a finite set of equivalential terms for $\vdash$ then $\delta(p,q) := \bigwedge_{i<n} \delta_i(p,q)$ is an equivalential term.

For algebraisability in the Blok and Pigozzi sense we have the following.

THEOREM 59 (Blok & Pigozzi). *Let $\vdash$ be algebraisable in the sense of Blok and Pigozzi and let $\mathcal{K}$ be the corresponding class of algebras. Then $\mathcal{K}$ is a quasi-variety and consists of all reducts of reduced matrices. Moreover, the lattice of axiomatic strengthenings is dually isomorphic to the lattice of sub-quasi-varieties of $\mathcal{K}$.*

It is to be borne in mind that there is a substantial difference between classes of matrices and classes of algebras.

3.2 Global Consequence Relations and Logics

Call a modal consequence relation **global** if the rules (MN) are derived rules. If $\vdash$ is global, then any extension contains (MN), and is also global, by structurality. Hence the lattice of global consequence relations is the lattice of extensions of $\Vdash_{\mathbf{K}}$. A modal consequence relation $\vdash$ is finitely equivalential via $p \leftrightarrow q$ iff it is global; in general, other equivalential formulae might exist, see below. A filter D for a consequence relation $\vdash$ in a modal algebra is a boolean filter. However, if $\vdash$ is global, then every filter D is **open**, that is, if $a \in D$ also $\Box a \in D$ for every modality $\Box$. If D is open, it can be factored, and the factor algebra is unital. Hence, reduced matrices for global consequence relations have only one truth value, namely 1. It follows that truth is defined implicitly—and also explicitly via the equation $p = \top$. Thus, we can replace talk of reduced matrices with talk of algebras.

THEOREM 60. *The lattice of global consequence relations is dually isomorphic to the lattice of quasi-varieties of modal algebras.*

Josep Font and Ramon Jansana [21] have found a way to characterize the strong consequence using the Leibniz operator. Say that a filter F on $\mathfrak{A}$ for $\vdash$ is **Leibniz** if for every $\vdash$-filter $G \subseteq F$, $\Omega_{\mathfrak{A}}(G) = \Omega_{\mathfrak{A}}(F)$. The strong consequence relation corresponding to $\vdash$ is the consequence determined by all matrices $\langle \mathfrak{A}, F\rangle$, where $\langle \mathfrak{A}, F\rangle$ is a matrix for $\vdash$ and F is a Leibniz filter. Given any filter, the largest Leibniz filter contained in F is the intersection of all filters G such that $\Omega_{\mathfrak{A}}(G) = \Omega_{\mathfrak{A}}(F)$. In the present context, this filter is the largest open filter contained in F. It consists of all elements a such that $\boxplus a \in F$ for every compound modality.

There is a difference, though, between quasi-varieties of matrices (to be considered below) and quasi-varieties of algebras. The local and global consequence relations for a logic can be characterized as follows.

THEOREM 61.

① $\Delta \vdash_L \chi$ *iff for every generalized frame $\mathfrak{F}$ such that $\mathfrak{F} \vDash L$, every valuation β and every x: if $\langle \mathfrak{F}, \beta, x\rangle \vDash \delta$ for every $\delta \in \Delta$ then $\langle \mathfrak{F}, \beta, x\rangle \vDash \chi$.*

② $\Delta \Vdash_L \chi$ *iff for every generalized frame $\mathfrak{F}$ such that $\mathfrak{F} \vDash L$, and every valuation β: if $\langle \mathfrak{F}, \beta\rangle \vDash \delta$ for every $\delta \in \Delta$ then $\langle \mathfrak{F}, \beta\rangle \vDash \chi$*

Alternatively, $\Delta \Vdash_L \chi$ if for every algebra $\mathfrak{A} \in \mathcal{V}(L)$ and every valuation β: if $\beta(\delta) = 1$ for every $\delta \in \Delta$ then $\beta(\chi) = 1$.

$\vdash_L$ has a deduction theorem but generally, $\Vdash_L$ does not. If it does, however, the logic is weakly transitive.

PROPOSITION 62. *Suppose that $\boxplus$ is a master modality for L. Then $\langle \mathfrak{F}, \beta, x\rangle \vDash \boxplus\chi$ iff χ is true in the model generated by x.*

THEOREM 63. *$\Vdash_L$ has a deduction theorem iff L is weakly transitive.*

The notion of weak transitivity originated in the work of Wim Blok. In weakly transitive logics, the global consequence can be reduced to the local consequence. For $\vdash_L$ is finitely equivalential if L is weakly transitive. Let $\mathrm{Cg}^{\mathfrak{A}}(a, b)$ denote the least congruence of $\mathfrak{A}$ containing the pair $\langle a, b\rangle$. Say that $\mathcal{V}$ has **elementarily definable principal congruences** if there is a first order formula $\vartheta(x, y, u, v)$ such that for all $\mathfrak{A} \in \mathcal{V}$ and $a, b, c, d \in A$, $c\ \mathrm{Cg}^{\mathfrak{A}}(a, b)\ d$ iff $\mathfrak{A} \vDash \vartheta(a, b, c, d)$. Say that $\mathcal{V}$ has **elementarily definable open filters** if there is a first order formula $\eta(x, u)$ such that for given a, c is in the open filter generated by a iff $\mathfrak{A} \vDash \eta(a, c)$. In [6] we find the following.

THEOREM 64. *The following are equivalent.*

① *$\Vdash_L$ has a deduction theorem.*

② *L is weakly transitive.*

③ *L is finitely equivalential.*

④ *$\mathcal{V}(L)$ has elementarily definable principal congruences.*

⑤ *$\mathcal{V}(L)$ has elementarily definable open filters.*

3.3 Semisimple Varieties of Modal Algebras

Semisimple varieties of modal algebras are special kinds of varieties of weakly transitive logics. There is an exact characterisation of semisimplicity, to be found below. Say that $\blacklozenge$ (the diamond of some compound modality $\blacksquare$) is a **dual** of $\Box$ in L if $p \to \Box\blacklozenge p \in L$. Frame theoretically this means that if $x\ R(\Box)\ y$ then $y\ R(\blacksquare)\ x$. If $\blacksquare$ is compound, $R(\blacksquare)$ is a finite set of finite paths in the frame. A logic is **cyclic** if every basic modality $\Box_i$ has a dual. Notice that the dual need not be basic (although a basic modality playing the role of the dual can be added conservatively). If L is cyclic, also every compound modality has a dual.

LEMMA 65. *If L is cyclic then every finite subdirectly irreducible algebra of $\mathcal{V}(L)$ is simple.*

There are infinite algebras that are si but not simple. For example, take the set of integers and put $x \lhd y$ iff $|x - y| = 1$. Finally, let $\mathbb{O}$ be the set of finite and cofinite elements. The logic of $\mathfrak{Z} := \langle \mathbb{Z}, \lhd, \mathbb{O}\rangle$ is cyclic (with $\Diamond$ the dual of $\Box$), $\mathfrak{Z}$ is si (with opremum $\mathbb{Z} - \{0\}$), but not simple. For the set of cofinite subsets is an open filter.

Call a variety **semisimple** if every si algebra is simple. Further, say that a ternary term $t(x, y, z)$ is a **ternary discriminator** for $\mathfrak{A}$ if for all $a, b, c \in A$: $t(a, b, c) = c$ if $a = b$, and $t(a, b, c) = a$ if $a \neq b$. (See also Chapter 6 on this notion.) A variety $\mathcal{V}$ is a discriminator variety if there is a ternary term $t(x, y, z)$ which is a discriminator for all subdirectly irreducible members of $\mathcal{V}$. Notice that if t is a ternary discriminator, then $u(x) := \neg t(1, x, 0)$ has the property that $u(x) = 1$ if $x = 1$ and $u(x) = 0$ otherwise. (This is the dual notion of the one commonly used.) $u(x)$ is called a **unary discriminator**. If L is weakly transitive it has a master modality $\boxplus$. If it is also cyclic $\boxplus$ has a dual

$\neg \boxtimes \neg$. We can actually assume that $\boxtimes = \boxplus$. Now look at $u(x) := \boxplus x$. By weak transitivity, the open filter generated by $a \in A$ is $\uparrow \boxplus a$. Assume that $a = \boxplus a$. Then $\boxplus \neg \boxplus a = \boxplus \neg \boxplus \neg\neg a \geq \neg a = \neg \boxplus a$, by our assumptions. So, $\uparrow \neg \boxplus a$ also is an open filter. Say that a is **open** if $a = \Box_i a$ for all basic $\Box_i$. The open elements form a boolean algebra. It follows that every si algebra is simple. It also follows that $u(x) := \boxplus x$ is a unary discriminator. The converse is much harder to establish, see [35].

THEOREM 66 (Kracht & Kowalski). *The following are equivalent for modal logics with finitely many operators.*

1. *$\mathcal{V}(L)$ is semisimple.*
2. *$\mathcal{V}(L)$ is a discriminator variety.*
3. *L is weakly transitive and cyclic.*

The remaining part is (1) $\Rightarrow$ (3). Moreover, if a semisimple variety is weakly transitive, cyclicity is easy to show (because both mean that one-generated is the same as connected). So the hard part is to show that semisimple varieties are weakly transitive. We assume that the basic operators are $\Box_i$, $i < n$, and put

$$\Box a := a \wedge \bigwedge_{i<n} \Box_i a \tag{51}$$

The proof is rather involved. It proceeds by first showing that all semisimple varieties of finite type of modal algebras satisfy the property (52) for $r = k$ and $l = 0$.

(52) For every $k \in \omega$ there are $r, l \in \omega$ such that $\mathcal{V} \vDash x \leq \Diamond^l \Box^k \Diamond^r x$.

Note that this is weaker than cyclicity. Now we assume that $\mathcal{V}$ satisfies (52). Define $r(i)$ to be the smallest number such that there exists an $l \in \omega$ with $\mathcal{V} \vDash \Diamond^l \Box^i \Diamond^{r(i)} x \leq x$. The function r is increasing. We define $l(i)$ to be the smallest number such that $\mathcal{V} \vDash \Diamond^{l(i)} \Box^i \Diamond^{r(i)} x \leq x$. Thus, l depends on i via $r(i)$. If $\mathcal{V}$ falsifies $\Diamond^{n+1} x = \Diamond^n x$ for each $n \in \omega$, then for each $i \in \omega$ there is a simple algebra $\mathfrak{A}_i$ in $\mathcal{V}$ and $a_i \in A_i$ such that $\Diamond^{r(i)} a_i < 1$ but $\Diamond^{r(i)+1} a_i = 1$. Now put $b_i := \neg \Diamond^{r(i)} a_i$ and fix an arbitrary $k \in \omega$. Then the following lemma holds.

LEMMA 67. *For every $i \geq k$, we have: $\Diamond^k b_i < 1$ and $\Diamond^{l(k)+r(k)+1} \neg \Diamond^k b_i = 1$.*

Using ultraproducts one obtains an algebra $\mathfrak{B}$ and an element b such that

LEMMA 68. *In $\mathfrak{B}$, for any $k \in \omega$ we have: $\Diamond^k b < 1$ and $\Diamond^{l(k)+r(k)+1} \neg \Diamond^k b = 1$.*

Let $\mathfrak{A} \in \mathcal{V}$ be such that there is a nonzero $a \in A$ with $\Diamond^n a < 1$ for every $n \in \omega$. For instance the free algebra $\mathfrak{Fr}_L(1)$ is such an algebra, as otherwise $\mathcal{V}$ would satisfy $\Diamond^n x = 1$ for some $n \in \omega$. Let $\alpha := \mathrm{Cg}^{\mathfrak{A}}(a, 0)$. α is neither full nor the diagonal. As α is principal, α must have a lower neighbour β in $\mathrm{Cg}(\mathfrak{A})$.

LEMMA 69. *For every congruence β with $\beta \prec \alpha$, there is an $m \in \omega$ such that:*

1. *$\Diamond^{m+1} a \equiv_\beta \Diamond^m a$, and*
2. *$\neg \Diamond^m a \equiv_\beta \Diamond \neg \Diamond^m a$.*

Proof. Let $\Gamma := \{\theta \in \mathrm{Cg}(\mathfrak{A}) : \theta \geq \beta, \theta \not\geq \alpha\}$. If $\Gamma = \{\beta\}$, then $\mathfrak{A}/\beta$ is si but not simple, which cannot be. Thus there is a $\theta \in \Gamma - \{\beta\}$. By congruence distributivity, $\gamma := \bigvee \Gamma \in \Gamma$. Therefore, $\mathfrak{A}/\gamma$ is subdirectly irreducible; hence simple. From this and congruence permutability it follows that $\alpha \circ \gamma = A \times A$. Thus, $(0,1) \in \alpha \circ \gamma$, and there must be a $c \in A$ with $(0,c) \in \alpha$ and $(c,1) \in \gamma$; hence also $(\neg c, 0) \in \gamma$. Now, $(0,c) \in \alpha$ iff for some $m \in \omega$ we have $\Diamond^m a \geq c$. Thus, $\neg\Diamond^m a \leq \neg c$ and therefore $(\neg\Diamond^m a, 0) \in \gamma$. We can then assume $c = \Diamond^m a$. By definition we have $\alpha \cap \gamma = \beta$, that is, $0/\alpha \cap 0/\gamma = 0/\beta$. Now, to prove (i), consider $\Diamond^{m+1} a \wedge \neg\Diamond^m a$. It belongs to $0/\alpha \cap 0/\gamma = 0/\beta$ and thus we obtain $\Diamond^{m+1} a \equiv_\beta \Diamond^m a$. Then, for (ii), consider $\Diamond^m a \wedge \Diamond\neg\Diamond^m a$. It too belongs to $0/\alpha \cap 0/\gamma = 0/\beta$; therefore $\neg\Diamond^m a \equiv_\beta \Diamond\neg\Diamond^m a$. ❑

THEOREM 70. *If $\mathcal{V}$ satisfies* (52) *then $\mathcal{V}$ satisfies $\Diamond^{n+1} x = \Diamond^n x$ for some $n \in \omega$.*

Proof. Suppose $\mathcal{V}$ falsifies $\Diamond^{n+1} x = \Diamond^n x$ for all $n \in \omega$. There is then an algebra $\mathfrak{B} \in \mathcal{V}$ and an element $b \in B$ such that for all $k \in \omega$: $\Diamond^k b < 1$ and $\Diamond^{l(k)+r(k)+1}\neg\Diamond^k b = 1$. Let α be the congruence generated by $\neg b$, and take β and m as in Lemma 69. Then $\neg\Diamond^m b \equiv_\beta \Diamond\neg\Diamond^m b \equiv_\beta \Diamond^{l(m)+r(m)+1}\neg\Diamond^m b = 1$. Thus, $\Diamond^m b \equiv_\beta 0$ and therefore $b \equiv_\beta 0$. It follows that $\beta \geq \alpha$, contradicting the choice of β as a subcover of α. ❑

4 REDUCTION TO MONOMODAL LOGIC

For each cardinality κ, there is a distinct lattice of modal consequence relations over κ operators. Surely, it would be most advantageous if one did not have to study these lattices for each individual κ. While results for the lattices $\mathrm{Ext}(\vdash_{\mathbf{K}_\kappa})$ are yet to be established, there exists fairly powerful theorems that reduce the study of $\mathrm{NExt}(\mathbf{K}_\kappa)$ for finite κ to the study of $\mathrm{NExt}(\mathbf{K}_1)$. It turns out that the locales of logics for several operators are isomorphic to certain subintervals of the locale $\mathrm{NExt}(\mathbf{K}_1)$ and that the isomorphism reflects and preserves many important properties of logic. This means that from a general perspective it is enough to obtain results for the locale of monomodal logics. A theorem that asserts this is called a *transfer theorem*. Results on monomodal logics can be extended to polymodal logics, using a transfer theorem. In practice it has turned out to be the opposite, however. Often, a counterexample to a specific conjecture can be easily constructed using several operators. Using the transfer theorem this counterexample typically yields a counterexample for monomodal logic, and so for every polymodal logic. There are certain lacunae in the theory. First, although there is a simulation of countably many operators by one (see [38]), the induced lattice map is not surjective. As for uncountably many operators, I know of no results so far. The techniques have been applied to polyadic operators and hybrid logics, and we report the results below. Again, the lattice map is not surjective, making the transfer theory less effective. Third, as we have mentioned above, the results cover logics only; no attempt has been made to reduce polymodal consequence relations to monomodal ones, though I speculate that the results will be similar.

4.1 Simulating Two Operators by One

Let $\langle F, \lhd, \blacktriangleleft, \mathbb{F}\rangle$ be a generalized bimodal frame. For a subset $B \subseteq F$ put $B_\circ := \{x_\circ : x \in B\}$ and $B_\bullet := \{x_\bullet : x \in B\}$. Here, $x_\circ$ and $x_\bullet$ are distinct copies of x, $F_\circ$ and $F_\bullet$ are

disjoint and do not contain $*$.

$$
\begin{array}{rl}
F^s := & F_\circ \cup F_\bullet \cup \{*\} \\
\leqslant := & \{\langle x_\circ, y_\circ\rangle : x \lhd y\} \cup \{\langle x_\bullet, y_\bullet\rangle : x \blacktriangleleft y\} \\
& \cup\{\langle x_\circ, x_\bullet\rangle : x \in F\} \cup \{\langle x_\bullet, x_\circ\rangle : x \in F\} \\
& \cup\{\langle x_\circ, *\rangle : x \in F\} \\
\mathbb{F}^s := & \{B_\circ \cup C_\bullet \cup D : B, C \in \mathbb{F}, D \subseteq \{*\}\} \\
\mathfrak{F} := & \langle F^s, \leqslant, \mathbb{F}^s\rangle
\end{array} \tag{53}
$$

$\mathfrak{F}^s$ is a general monomodal frame. We call it the **simulating frame** of $\mathfrak{F}$. Recall that a general frame $\mathfrak{F}$ is **differentiated** if $x \neq y$ implies $x \in a$ and $y \notin a$ for some $a \in \mathbb{F}$; that $\mathfrak{F}$ is **refined** if it is differentiated and **tight**, that is, if $x \ntriangleleft_i y$ then there is an $a \in \mathbb{F}$ such that $x \in \Box_i a$ but $y \notin a$. Finally, $\mathfrak{F}$ is **compact** if for every filter H on $\mathbb{F}$: $\bigcap H \neq \varnothing$.

PROPOSITION 71. *$\mathfrak{F}^s$ is differentiated (refined, compact) iff $\mathfrak{F}$ is.*

Proof. Notice that $F_\circ$, $F_\bullet$ and $\{*\}$ are definable by the constant formulae $\gamma_\circ := \Diamond \boxminus \bot$, $\gamma_\bullet := \Diamond\top \wedge \neg\Diamond \boxminus \bot$, and $\gamma_* := \boxminus\bot$, respectively. (We shall also denote the sets defined by some formula by the formula itself.) Hence if $\mathfrak{F}$ is differentiated, let $x, y \in F^s$ be different. Then if $x = *$, γ_* is the set that contains x but not y. Otherwise if $x = u_\circ$ and $y = v_\bullet$, $\gamma_\circ$ contains x but not y. Finally, if $x = u_\circ$ and $y = v_\circ$ then $u \neq v$ and there is a set O containing x but not y. Then $x \in O_\circ$, but $y \notin O_\circ$. Analogously if $x = u_\bullet$ and $y = v_\bullet$. Also, if $\mathfrak{F}^s$ is differentiated, clearly $\mathfrak{F}$ is differentiated, too. We show that if $\mathfrak{F}$ is refined, so is $\mathfrak{F}^s$. Suppose that $x \leqslant y$ does not hold. The case $x = *$ is easily dealt with. Now assume $x = u_\circ$. We deal with two representative cases. Case 1. $y = v_\circ$. Then $u \ntriangleleft v$. Then refinedness of $\mathfrak{F}$ gives a set O such that $u \in \Box O$ but $v \notin O$. Then $x \in \boxminus(F_\bullet \cup \{*\} \cup O_\circ)$ but $y \notin O_\circ$. Case 2. $y = v_\bullet$. Then $u \neq v$. Then by differentiatedness there is a set O containing u but not v. Then $x = u_\circ \in \boxminus(F_\circ \cup \{*\} \cup O_\bullet)$ but $y \notin O_\bullet$. (Notice that for the transfer of tightness we needed differentiatedness as well.) Transfer of compactness is straightforward. ❑

The notion of simulation is then also defined for Kripke-frames. Denote by $\mathfrak{F}_\sharp$ the Kripke-frame underlying $\mathfrak{F}$. The following is true in virtue of the definitions.

PROPOSITION 72. $(\mathfrak{F}^s)_\sharp = (\mathfrak{F}_\sharp)^s$.

Define

$$
\boxminus_\circ \chi := \boxminus(\gamma_\circ \to \chi) \qquad \boxminus_\bullet \chi := \boxminus(\gamma_\bullet \to \chi) \qquad \boxminus_* \chi := \boxminus(\gamma_* \to \chi) \tag{54}
$$

Also, put

$$
\begin{array}{rl}
p_i^s := & p_i \\
(\neg\varphi)^s := & \neg\varphi)^s \\
(\varphi \wedge \chi)^s := & \varphi^s \wedge \chi^s \\
(\Box\varphi)^s := & \boxminus_\circ \varphi^s \\
(\blacksquare\varphi)^s := & \boxminus_\bullet \boxminus_\bullet \boxminus_\circ \varphi^s
\end{array} \tag{55}
$$

Finally, let β be a valuation and set $\beta^s(p) := \beta(p)_\circ$. Then the following is shown by induction.

$$
\langle \mathfrak{F}, \beta, x\rangle \vDash \varphi \Leftrightarrow \langle \mathfrak{F}^s, \beta^s, x_\circ\rangle \vDash \gamma_\circ \to \varphi^s \tag{56}
$$

Notice that $\langle \mathfrak{F}^s, \beta^s, x_\bullet \rangle \vDash \gamma_\circ \to \varphi^s$ as well as $\langle \mathfrak{F}^s, \beta^s, * \rangle \vDash \gamma_\circ \to \varphi^s$. Not every valuation into $\mathfrak{F}^s$ is of the form β^s. However, if $\gamma(p) \cap F_\circ = \delta(p) \cap F_\circ$ then for every $x \in F^s$

(57) $$\langle \mathfrak{F}^s, \gamma, x \rangle \vDash \gamma_\circ \to \varphi^s \Leftrightarrow \langle \mathfrak{F}^s, \delta, x \rangle \vDash \gamma_\circ \to \varphi^s$$

PROPOSITION 73. *Let $\mathfrak{F}$ be a bimodal generalized frame. $\mathfrak{F}^s \vDash \varphi^s$ iff $\mathfrak{F} \vDash \varphi$.*

For a formula χ and a set Δ put

(58) $$\chi \to \Delta := \{\chi \to \delta : \delta \in \Delta\}$$

We define **Sim** to be the logic of all simulating frames.

DEFINITION 74. Let L be a bimodal logic. Then L^s is the logic of all $\mathfrak{F}^s$, where $\mathfrak{F}$ is a general frame for L.

THEOREM 75. *Let L be a bimodal logic. Then*

(59) $$\Delta \vdash_L \varphi \quad \Leftrightarrow \quad \gamma_\circ \to \Delta^s \vdash_{L^s} \gamma_\circ \to \varphi^s$$

(60) $$\Delta \Vdash_L \varphi \quad \Leftrightarrow \quad \gamma_\circ \to \Delta^s \Vdash_{L^s} \gamma_\circ \to \varphi^s$$

In particular, if $L = \mathbf{K}_2 \oplus \Delta$, $L^s = \mathbf{Sim} \oplus (\gamma_\circ \to \Delta^s)$.

The previous result shows that the bimodal consequence is reduced to the consequence relation based on the 'white points' of the simulating frame.

4.2 Algebraic Properties of the Simulation

Let $p : \mathfrak{F} \to \mathfrak{G}$ be a p-morphism. Define p^s by $p^s(x_\circ) := p(x)_\circ$ and $p^s(x_\bullet) := p(x)_\bullet$, and $p^s(*) := *$. It is easy to see that p^s is a p-morphism from $\mathfrak{F}^s$ to $\mathfrak{G}^s$. Conversely, let $q : \mathfrak{F}^s \to \mathfrak{G}^s$ be a p-morphism. Then $q(*) = *$, $q[F_\circ] \subseteq G_\circ$ and $q[F_\bullet] \subseteq G_\bullet$, since all sets are definable by constant formulae. Next, if $q(x_\circ) = y_\circ$ then also $q(x_\bullet) = y_\bullet$, so that q is completely defined by its action on $F_\circ$. Moreover, $q = p^s$ for some p-morphism $p : \mathfrak{F} \to \mathfrak{G}$. So, the simulation is faithful with respect to embeddings and contractions.

Notice that $(\mathfrak{F} \oplus \mathfrak{G})^s$ is not isomorphic to $\mathfrak{F}^s \oplus \mathfrak{G}^s$ (the former is connected, the latter is not). However, the two are not so different. Basically, the latter has two points satisfying $\boxminus\bot$, the former only one. Thus only the former can be a simulation frame.

LEMMA 76. $(\bigoplus_{i \in I} \mathfrak{F}_i)^s$ *is a contraction of* $\bigoplus_{i \in I} \mathfrak{F}^s$*. The contraction is the one which collapses all points satisfying $\boxminus\bot$ into one.*

The construction can be remodeled algebraically. Let $\mathfrak{A}$ be a bimodal algebra.

(61) $$A^s := A \times A \times \{0, 1\}$$

(62) $$\diamondminus \langle a, b, c \rangle := \begin{cases} \langle \Diamond a \cup b, \blacklozenge b \cup a, 0 \rangle & \text{if } c = 0 \\ \langle A, \blacklozenge b \cup a, 0 \rangle & \text{if } c = 1 \end{cases}$$

$\mathfrak{A}^s$ is the simulating algebra for $\mathfrak{A}$. It is easy to verify that if $\mathfrak{A}$ is the algebra of subsets of $\mathfrak{F}$, $\mathfrak{A}^s$ is the algebra of subsets of $\mathfrak{F}^s$, and conversely. If $h : \mathfrak{A} \to \mathfrak{B}$ is a homomorphism, so is $h^s : \mathfrak{A}^s \to \mathfrak{B}^s$. Moreover, if $q : \mathfrak{A}^s \to \mathfrak{B}^s$ is a homomorphism, then $q = p^s$ for some

$p : \mathfrak{A} \to \mathfrak{B}$. So we have an isomorphism between the category of bimodal algebras and the category of simulation algebras.

We are interested in the varieties generated by simulation algebras. $\mathcal{V}(\mathbf{Sim})$ is the variety generated by all simulation algebras. It is easier to look at the frames. Take a nonempty generated subframe $\mathfrak{G}$ of $\mathfrak{F}^s$. It is easy to see that it must be of the form $\mathfrak{H}^s$. Simply take $H := G \cap F_\circ$ (notice that we do allow frames to be empty). However, the empty subframe is not of that form. So, with the exception of the empty frame every subframe of $\mathfrak{F}^s$ is a simulation frame. It follows that $\mathrm{Cg}(\mathfrak{A}^s) \cong \mathrm{Cg}(\mathfrak{A}) + 1$, where the latter denotes the addition of a new top element to $\mathrm{Cg}(\mathfrak{A})$.

PROPOSITION 77. *$\mathfrak{A}$ is subdirectly irreducible iff $\mathfrak{A}^s$ is.*

Next, let $p : \mathfrak{F}^s \to \mathfrak{G}$ be a contraction. It is easy to see that $p(x_\circ) = p(y_\bullet)$ cannot hold; also, $p(x_\circ) \neq p(*) \neq p(x_\bullet)$. Moreover, $p(x_\circ) \leqslant p(y_\bullet)$ iff $x = y$ iff $p(y_\bullet) \leqslant p(x_\circ)$; and if $p(x_\circ) = p(y_\circ)$ then $p(x_\bullet) = p(y_\bullet)$, and conversely. So, $\mathfrak{G} = \mathfrak{H}^s$ for some $\mathfrak{H}$. It follows that $\mathrm{Sub}(\mathfrak{A}^s) \cong \mathrm{Sub}(\mathfrak{A})$. Finally, we have noticed that $(\prod_{i\in I} \mathfrak{A}_i)^s \in \mathsf{S}(\prod_{i\in I} \mathfrak{A}_i^s)$.

Now, if $\mathcal{K}$ is a class of bimodal algebras, denote by $\mathcal{K}^\sigma := \{\mathfrak{A}^s : \mathfrak{A} \in \mathcal{K}\}$. Also, denote by $\mathcal{K}_{si}$ the class of subdirectly irreducible members of $\mathcal{K}$.

PROPOSITION 78. *If $\mathcal{V}$ is a variety of bimodal algebras, $(\mathcal{V}_{si})^\sigma = (\mathcal{V}^\sigma)_{si}$.*

Now let $\mathcal{V}^s$ be the variety generated by $\mathcal{V}^\sigma$. For any variety generated by simulation algebras, the subdirectly irreducible members are simulation algebras. Hence, any subvariety of $\mathcal{V}(\mathbf{Sim})$, with the exception of the trivial variety, is of the form $\mathcal{V}^s$.

THEOREM 79. *The map $\mathcal{V} \mapsto \mathcal{V}^s$ is an isomorphism from the lattice of varieties of bimodal algebras onto the lattice of nontrivial subvarieties of $\mathcal{V}(\mathbf{Sim})$.*

We now turn to the axiomatisation of the simulations. Put

$$
\begin{aligned}
&*(x) := \neg(\exists y)(x \leqslant y) \\
(63)\qquad &\circ(x) := (\exists y)(x \leqslant y \wedge *(y)) \\
&\bullet(x) := \neg * (x) \wedge \neg \circ (x)
\end{aligned}
$$

A monomodal frame is a simulation frame iff it satisfies the following elementary formulae (here, $\exists!$ is short for: 'there exists exactly one'):

(64a) $\quad (\forall x)(\circ(x) \to (\exists! y)(x \leqslant y \wedge \bullet(y)))$

(64b) $\quad (\forall x)(\bullet(x) \to (\exists! y)(x \leqslant y \wedge \circ(y)))$

(64c) $\quad (\exists! x)(*(x))$

(64a) and (64b) are modally definable, but (64c) is not. It turns out that the class of **Sim**-frames is the class of frames satisfying (64a) and (64b). The axiomatisation can be derived from the correspondence between first-order and modal formulae. Moreover, **Sim** is R-persistent. Hence, any logic containing **Sim** is complete with respect to simulation frames.

4.3 Unsimulation

Let $\mathfrak{F}$ be a **Sim**-frame. Then F° is the set of points satisfying $\circ(x)$, and $F^\bullet$ the set of points satisfying $\bullet(x)$. If $x \in F^\circ$ let $x^\dagger$ be the unique successor in $F^\bullet$, and if $x \in F^\bullet$ then

let $x^\dagger$ be the unique successor in F°. Now put $\mathfrak{F}_s := \langle F_s, \lhd, \blacktriangleleft, \mathbb{F}_s\rangle$, where

$$(65)\qquad \begin{array}{rl} F_s & := F^\circ \\ \lhd & := \leqslant \cap F_s^2 \\ \blacktriangleleft & := \{\langle x^\dagger, y^\dagger\rangle : x \leqslant y, x, y \in F_\bullet\} \\ \mathbb{F}_s & := \{a \in \mathbb{F} : a \subseteq F_s\} \end{array}$$

For the following theorem notice that $(\mathfrak{M}_s)^s$ always is connected, by construction.

PROPOSITION 80. *Let $\mathfrak{M}$ be a monomodal connected* **Sim***-frame, $\mathfrak{B}$ a bimodal frame. Then $\mathfrak{M} \cong (\mathfrak{M}_s)^s$ and $\mathfrak{B} \cong (\mathfrak{B}^s)_s$.*

For each variable p we introduce three variables $p_\circ$, $p_\bullet$, p_*. We call the new set the **extended set of variables**. Think of $p_\circ$ as 'p is true at the region of $\gamma_\circ$ worlds'; $p_\bullet$ as 'is true at the region of $\gamma_\bullet$ worlds' and p_* as 'is true at the region of γ_* worlds'. For formulae χ we define the formulae $\chi_\circ$, $\chi_\bullet$ and χ_* by mutual recursion (and think of them as interpreted in the same way as the new variables).

$$(66)\qquad \begin{array}{lll l} (\neg\varphi)_\alpha & := & \neg\varphi_\alpha & \alpha \in \{\bullet, \circ, *\} \\ (\varphi \wedge \chi)_\alpha & := & \varphi_\alpha \wedge \chi_\alpha & \alpha \in \{\bullet, \circ, *\} \\ (\Diamond\varphi)_\circ & := & \varphi_\bullet \vee \varphi_* \vee \Diamond\varphi_\circ & \\ (\Diamond\varphi)_\bullet & := & \varphi_\circ \vee \blacklozenge\varphi_\bullet & \\ (\Diamond\varphi)_* & := & \bot & \end{array}$$

Let β be a valuation on $\mathfrak{F}^s$. Define β_s on $\mathfrak{F}$ so that for all variables p (assuming $x_* = *$ and $\alpha \in \{\circ, \bullet, *\}$):

$$(67)\qquad \langle \mathfrak{F}, \beta_s, x\rangle \vDash p_\alpha \quad \Leftrightarrow \quad \langle \mathfrak{F}^s, \beta, x_\alpha\rangle \vDash p$$

Then it is established by induction on the formulae that

$$(68)\qquad \begin{array}{rl} & \langle \mathfrak{F}^s, \beta, x_\alpha\rangle \vDash \varphi \\ \Leftrightarrow & \langle \mathfrak{F}, \beta_s, x\rangle \vDash \varphi_\alpha \\ \Leftrightarrow & \langle \mathfrak{F}^s, \beta, x_\alpha\rangle \vDash \varphi^s_\circ(p/p_\circ, \Diamond_\bullet p/p_\bullet, \Diamond_* p/p_*) \end{array}$$

As usual, $\Diamond_\bullet\varphi := \neg \boxminus_\bullet \neg\varphi$ and similarly for $\Diamond_*$, where $\boxminus_\bullet$ and $\boxminus_*$ are as defined in Equation (54). Now, every valuation on $\mathfrak{F}$ of the extended set of variables is of the form β_s for some valuation β on $\mathfrak{F}^s$. Thus we obtain $\langle \mathfrak{F}^s, x_\alpha\rangle \vDash \varphi$ iff $\langle \mathfrak{F}, x\rangle \vDash \varphi_\alpha$, for every $\alpha \in \{\circ, \bullet, *\}$. Finally, this gives

$$(69)\qquad \mathfrak{F}^s \vDash \varphi \quad \Leftrightarrow \quad \mathfrak{F} \vDash \varphi_\circ \wedge \varphi_\bullet \wedge \varphi_*$$

Therefore, let

$$(70)\qquad \varphi_s := \varphi_\circ \wedge \varphi_\bullet \wedge \varphi_*$$

THEOREM 81. *Let $L = \mathbf{Sim} \oplus \Delta$ be consistent. Put $L_s := \mathbf{K}_2 \oplus \Delta_s$. Then $(L_s)^s = L$. Additionally,*

$$(71)\qquad \Delta \vdash_L \varphi \quad \Leftrightarrow \quad \Delta_s \vdash_{L_s} \varphi_s \qquad \textit{and} \qquad \Delta \Vdash_L \varphi \quad \Leftrightarrow \quad \Delta_s \Vdash_{L_s} \varphi_s$$

PROPOSITION 82. $\mathrm{Th}\,\mathfrak{F}^s = \mathbf{Sim} \oplus (\mathrm{Th}\,\mathfrak{F})^s$.

4.4 The Main Theorem

Let StSim be the category of differentiated monomodal **Sim**-frames, with γ_* containing a single point. The morphisms are the p-morphisms. Let Dif_2 be the category of differentiated bimodal frames with p-morphisms as maps.

THEOREM 83. StSim *and* Dif_2 *are naturally equivalent. The map* $(-)_s$ *is a functor from* StSim *to* Dif_2*,* $(-)^s$ *a functor from* Dif_2 *to* StSim*. Moreover, there is a natural transformation from the identity on* Dif_2 *to* $((-)^s)_s$ *and a natural transformation from the identity on* StSim *to* $((-)_s)^s$*.*

From Theorems 75 and 81 follows that $L \mapsto L^s$ preserves and reflects finite and recursive axiomatisability.

Next, if $L = \mathrm{Th}\,\mathcal{K}$ then $L^s = \mathrm{Th}\,\mathcal{K}^s$ and conversely. It follows that completeness, finite model property, tabularity are preserved and reflected.

Second, suppose that L is Df-persistent. Let $\mathfrak{M}$ be a differentiated monomodal frame for L^s. Then $\mathfrak{M}_s$ is differentiated and $\mathfrak{M} \cong (\mathfrak{M}_s)^s$, which is therefore differentiated. It follows that $\mathfrak{M}_s \vDash L$, so that the underlying Kripke-frame $(\mathfrak{M}_s)_\sharp$ is an L^s-frame. Since $(\mathfrak{M}_s)_\sharp \cong (\mathfrak{M}_\sharp)_s$, we have $\mathfrak{M}_\sharp \vDash L^s$. Similarly for R-persistence.

Now we turn to interpolation. Using the algebraic characterisation of interpolation (Theorem 93) the preservation and reflection of interpolation is actually straightforward to show. There are also direct ways. Suppose that the bimodal logic L has interpolation. Now let $\varphi \vdash_{L^s} \psi$. Putting together Equations (56) and (68) we get that for every ρ,

(72) $$\gamma_\circ \vdash_{L^s} \rho \leftrightarrow \sigma(\rho_s)^s$$

where $\sigma : p_\circ \mapsto p, p_\bullet \mapsto \diamondsuit_\bullet p, p_* \mapsto \diamondsuit_* p$. So $\gamma_\circ \to (\varphi_s)^s \vdash_{L^s} \gamma_\circ \to (\psi_s)^s$, and so by Theorem 75, and the fact that $L = (L^s)_s$ we get $\varphi_s \vdash_L \psi_s$. There exists a formula χ such that $\mathrm{var}(\chi) \subseteq \mathrm{var}(\varphi_s) \cap \mathrm{var}(\psi_s)$ and $\varphi_s \vdash_L \chi \vdash_L \psi_s$. Now, χ is in the variables $p_\circ, p_\bullet, p_*$ for $p \in \mathrm{var}(\varphi) \cap \mathrm{var}(\psi)$, and this applies as well to χ^s. Furthermore,

(73) $$\gamma_\circ \to (\varphi_s)^s \vdash_{L^s} \chi^s \vdash_{L^s} \gamma_\circ \to (\psi_s)^s$$

so that

(74) $$\gamma_\circ \to \varphi \equiv \gamma_\circ \to \sigma((\varphi_s)^s) \vdash_{L^s} \sigma(\chi^s) \vdash_{L^s} \gamma_\circ \to \sigma((\psi_s)^s) \equiv \gamma_\circ \to \sigma((\psi_s)^s)$$

Put $\chi^\circ := \gamma_\circ \to \sigma(\chi^s)$. Likewise formulae χ' and χ'' can be found such that

(75) $$\gamma_\bullet \to \varphi \vdash_{L^s} \gamma_\bullet \to \sigma(\chi'^s) \vdash_{L^s} \gamma_\bullet \to \psi$$

(76) $$\gamma_* \to \varphi \vdash_{L^s} \gamma_* \to \sigma(\chi''^s) \vdash_{L^s} \gamma_* \to \psi$$

Put $\chi^\bullet := \gamma_\bullet \to \diamondsuit_\circ \sigma(\chi'^s)$, and $\chi^* := \gamma_* \to \sigma(\chi'')$. Then $\chi^\circ \wedge \chi^\bullet \wedge \chi^*$ is the desired interpolant. The proof works analogously for global interpolation and transfer of local and global Halldén-completeness.

Now look at Sahlqvist formulae. By a theorem of [39] a modal logic is Sahlqvist iff it can be axiomatized by formulae of the form $\varphi \to \psi$, where ψ and φ is composed from compound modalities using only $\wedge$, $\vee$ and diamonds. (Compound modalities are **strongly positive** formulae.) From this it follows immediately that if $\varphi \to \psi$ is Sahlqvist, so is $(\varphi \to \psi)^s = \varphi^s \to \psi^s$. (The original formulation allows a prefix of boxes but this does not

define a larger class of logics.) The converse is similar. We have $(\varphi \to \psi)_s = \varphi_s \to \psi_s$, and the unsimulation translates boxes into boxes and diamonds into diamonds. Finally, note that simulation and unsimulation commute with ultraproducts.

THEOREM 84 (Kracht & Wolter). *The map $L \mapsto L^s$ is an isomorphism from the locale of normal bimodal logics onto the interval $[\mathbf{Sim}, \mathrm{Th}\,\boxed{\bullet}]$ in the locale of normal monomodal logics. Moreover, the following properties of logics are invariant under this map:*

1. *decidability,*
2. *elementarity, Df-persistence, R-persistence, being Sahlqvist,*
3. *finite model property, completeness, compactness,*
4. *local and global interpolation.*

Halldén-completeness is actually *not* preserved under simulation. For example, the logic $\mathbf{D} \otimes \mathbf{D}$ is Halldén-complete (being the fusion of two Halldén-complete logics). However, its simulation has more than two constants, so it cannot be Halldén-complete (see below, Theorem 99).

In general, for $\kappa \in \omega$ there is a similar isomorphism from $\mathrm{NExt}(\mathbf{K}_\kappa)$ onto an interval $[\mathbf{Sim}_\kappa, \mathrm{Th}(\mathfrak{Ch}_{\kappa-1})]$, where $\mathbf{Sim}_\kappa$ is the simulating logic for κ-modal frames, and $\mathfrak{Ch}_{\kappa-1} = \langle\{0, 1, \ldots, \kappa-1\}, \prec\rangle$ $i \prec j$ iff $j = i+1$ if the chain of $\kappa - 1$ many points. The underlying set is $F \times \{0, 1, \ldots, \kappa-1\}$ plus the points of the chain, and we put $\langle x, i\rangle \leqslant \langle y, j\rangle$ iff (a) $x = y$ or (b) $i = j$ and $x \lhd_i y$. Additionally, every point $\langle x, i\rangle$ sees the point $i - 1$. Finally, $i \leqslant j$ iff $i \prec j$. All aforementioned properties are invariant under this simulation. For countable κ, [38] describes an embedding of $\mathrm{NExt}\,\mathbf{K}_\kappa$ into (not necessarily onto) an interval in $\mathrm{NExt}\,\mathbf{K}_1$.

4.5 Simulating Polyadic and Nonstandard Operators by Monadic Operators

Assume that L is a complete logic. Now add two modal operators $\boxright$ and $\boxleft$, together with the following axioms: **G3** for $\boxleft$, **K4.3** for $\boxright$, $p \to \boxright\diamondleft p$, $p \to \boxleft\diamondright p$ and $(\boxright p \wedge \boxleft p \wedge p) \to \boxplus p$ for every basic modality $\boxplus$. Thus, $\boxright$ and $\boxleft$ are tense duals, the relation for $\boxright$ is a well-order, and if $x\ R(\boxplus)\ y$ for any compound modality $\boxplus$ then either $x = y$ or $x\ R(\boxright)\ y$ or $y\ R(\boxright)\ x$. Call this logic L^w. The difference operator of [16, 17] and the universal modality are now definable on all connected frames by

(77) $$[\neq]\chi := \boxright\chi \wedge \boxleft\chi \qquad [u]\chi := \chi \wedge [\neq]\chi$$

Also, [2] has introduced a logic using a special type of variables, called **nominals**, which must be interpreted by singleton sets. Logics that admit both standard variables and nominals are called **hybrid**, see Chapter 14 of this handbook. It turns out that with the difference modality the standard languages have the same expressive power as the hybrid ones. Consider a variable p. Put

(78) $$n(p) := \langle u\rangle(p \wedge [\neq]\neg p)$$

β satisfies $n(p)$ on a Kripke-frame iff the value of p is a singleton set. (In [29] the operator $Op := p \wedge [\neq]p$ is called the 'only' operator. It says that p is true 'only here'.) In absence of the difference modality, the nominals give extra expressive power. Consider the operator $\blacksquare$ defined by the following axiom:

$$n(p) \to (\blacklozenge p \leftrightarrow \neg\Diamond p) \tag{79}$$

Then a frame satisfies this axiom iff $\blacktriangleleft$ is the complement of $\lhd$ (the inaccessibility relation of [34]). Notice that the following holds.

THEOREM 85 (Gargov & Goranko). *A class of frames is definable using the language with nominals and the universal modality iff it is definable using the difference operator.*

Recall the characterisation of the first-order properties axiomatisable by means of Sahlqvist-formulae. Using the inaccessibility relation and the universal modality we can not only express unrestricted quantification (on connected frames) but also negative formulae. This means that all first-order conditions over binary relations are now expressible (over the logic of these structures with enough modal operators) in which an atomic formula contains at least one universally quantified variable whose quantifier is not in the scope of an existential. This last restriction can be circumvented through the introduction of new modalities (to mimic the Skolem functions) on condition that the variable depends only on one other variable. All these codings proceed by adding more operators, not more points. For example, **ZFC** without foundation can be so axiomatized, see [38]. The infinity axiom can be expressed much more succinctly than in that paper. Simply require

$$(\exists x)(\varnothing \in x \wedge (\forall y)(y \in x \to (\exists z)(y \in z \in x))) \tag{80}$$

The outer existential can be massaged away by introducing a constant, and the second existential can be dealt with using a Skolem function. Foundation of course is axiomatisable using the **G**-axioms for $\ni^+$. Even full class comprehension is axiomatisable.

If one is interested in simulating polyadic operators then it is not enough to just add relations (similarly if one wants to simulate predicate logic with a signature containing at least ternary relations symbols). One approach was outlined in [40]. A better one is presented in [28]. It is enough to look at the case of a single binary modal operator ∇. **Kripke-frames** are pairs $\langle F, R\rangle$ where R is a ternary relation. A **generalized frame** is a triple $\mathfrak{F} = \langle F, R, \mathbb{F}\rangle$ where $\mathbb{F} \subseteq \wp(F)$ is a field of sets closed under

$$\mu_R(A_1, A_2) := \{x \in F : (\exists v_1 \in A_1)(\exists v_2 \in A_2)R(x, v_1, v_2)\} \tag{81}$$

Satisfaction of a formula is defined as follows.

$$\langle \mathfrak{F}, \beta, x\rangle \vDash \nabla(\varphi_1, \varphi_2) \quad \Leftrightarrow \quad \begin{array}{r} \text{there are } v_1, v_2 \text{ such that } R(x, v_1, v_2) \\ \text{and } \langle \mathfrak{F}, \beta, v_1\rangle \vDash \varphi_1; \langle \mathfrak{F}, \beta, v_2\rangle \vDash \varphi_2 \end{array} \tag{82}$$

For a triple $\vec{x}$, let $\vec{x}_i$ be the ith component of $\vec{x}$. Given $\mathfrak{F}$, assume $F \cap R = \varnothing$ and put

$$\begin{array}{rl} F^\bullet & := F \cup R \\ R_i & := \{\langle \vec{x}, \vec{x}_i\rangle : \vec{x} \in R\} \\ S & := \{\langle \vec{x}_0, \vec{x}\rangle : \vec{x} \in R\} \\ \mathbb{F}^\bullet & := \{a \cup (R \cap \bigcup_{i<n} a_i \times b_i \times c_i) : a, a_i, b_i, c_i \in \mathbb{F}, n < \omega\} \\ \mathfrak{F}^\bullet & := \langle F^\bullet, S, R_0, R_1, R_2, \mathbb{F}^\bullet\rangle \end{array} \tag{83}$$

$\mathfrak{F}^\bullet$ is a general frame and $\mathbb{F}^\bullet$ is generated by $\mathbb{F}$. The set R is definable by $\mu := \langle R_0 \rangle \top$. The set F in $F^\bullet$ is called the set of **base points**. It too is definable. The simulation is now defined as follows.

(84)
$$\begin{aligned} p^\bullet &:= p \\ (\neg\varphi)^\bullet &:= \neg\varphi^\bullet \\ (\varphi_1 \wedge \varphi_2)^\bullet &:= \varphi_1^\bullet \wedge \varphi_2^\bullet \\ (\nabla(\varphi_1, \varphi_2))^\bullet &:= \langle S \rangle (\langle R_1 \rangle \varphi_1^\bullet \wedge \langle R_2 \rangle \varphi_2^\bullet) \end{aligned}$$

The translation $(\cdot)^\bullet$ preserves truth of formulae at base points. So we get

PROPOSITION 86. $\mathfrak{F} \vDash \varphi \quad \Leftrightarrow \quad \mathfrak{F}^\bullet \vDash \neg\mu \to \varphi^\bullet$.

We remark that $\mathfrak{F}^\bullet$ is differentiated (descriptive) iff $\mathfrak{F}$ is.

Unsimulation is less straightforward. Let $\langle M, S, R_0, R_1, R_2, \mathbb{M} \rangle$ be a monadic frame. Put

(85)
$$\begin{aligned} M_\bullet &:= \{x : x \vDash \neg\mu\} \\ T &:= \{\vec{x} : \exists v : v\, R_0\, \vec{x}_0, v\, R_1\, \vec{x}_1 \text{ and } v\, R_2\, \vec{x}_2\} \\ \mathbb{M}_\bullet &:= \{a \cap M_\bullet : a \in \mathbb{M}\} \end{aligned}$$

It is straightforward to check that for a ternary frame $\mathfrak{F} \cong (\mathfrak{F}^\bullet)_\bullet$.

Now let $\mathbf{Sim}^\bullet$ be the logic of general frames of the form $\mathfrak{F}^\bullet$. The simulation map sends a dyadic logic L to the logic

(86)
$$L^\bullet := \mathbf{Sim}^\bullet \oplus \{\neg\mu \to \varphi^\bullet : \varphi \in L\}$$

This map turns out to be a lattice homomorphism. It is injective but not surjective, unlike in the monadic case (in finite signature). A useful observation is this.

PROPOSITION 87. *Let L be a dyadic logic and $\mathcal{K}$ a class of $\mathbf{Sim}^\bullet$-frames. If $L^\bullet$ is complete with respect to $\mathcal{K}$ then L is complete with respect to $\mathcal{K}_\bullet$.*

Given an extension L of $\mathbf{Sim}^\bullet$, let $L_\bullet$ be the logic generated by all formulae valid on all unsimulations of descriptive L-frames.

PROPOSITION 88. *The following holds for a dyadic logic L and an extension M of $\mathbf{Sim}^\bullet$.*

① $M_\bullet = \{\varphi : \neg\mu \to \varphi^\bullet \in M\}$.

② $L \subseteq M_\bullet$ *iff* $L_\bullet \subseteq M$.

③ $(M_\bullet)^\bullet \subseteq M$.

④ $(L^\bullet)_\bullet = L$.

The following is shown in [28].

THEOREM 89 (Goguadze & Piazza & Venema). *The map $L \mapsto L^\bullet$ is a lattice homomorphism into the lattice* NExt($\mathbf{Sim}^\bullet$). *It preserves and reflects*

1. *finite and recursive axiomatisability,*

2. *completeness, finite model property, tabularity,*

3. canonicity,

4. first-order definability.

It preserves Sahlqvist axiomatisability and it reflects decidability.

5 INTERPOLATION

This section uses some algebraic notions that are either covered at the beginning of this chapter or in Chapter 6. Notice also the discussion on interpolation and fusion in Chapter 14, as well as simulations and fusion discussed in the previous section.

5.1 Algebraic Characterisation

DEFINITION 90. A modal logic L has **local interpolation** if $\vdash_L$ has interpolation; it has **global interpolation** if $\Vdash_L$ has interpolation.

Since $\vdash_L$ has a deduction theorem, local interpolation can also formulated as follows: if $\varphi \to \psi \in L$ there is a χ such that $\mathrm{var}(\chi) \subseteq \mathrm{var}(\varphi) \cap \mathrm{var}(\psi)$ and $\varphi \to \chi, \chi \to \psi \in L$. This property is also known as **Craig interpolation**. Notice that interpolation is a property of the consequence relation not of the logic.

PROPOSITION 91. *If L has local interpolation it also has global interpolation.*

Proof. Assume $\varphi \Vdash_L \psi$. Then for some compound modality $\boxplus$, $\boxplus\varphi \vdash_L \psi$. By assumption there is a χ in the joint variables such that $\boxplus\varphi \vdash_L \chi \vdash_L \psi$. It follows that $\varphi \Vdash_L \chi \Vdash_L \psi$. ❑

DEFINITION 92. A variety $\mathcal{V}$ of modal algebras has the **amalgamation property** if for every triple $\mathfrak{A}_0$, $\mathfrak{A}_1$ and $\mathfrak{A}_2$ from $\mathcal{V}$ and embeddings $\iota_1 : \mathfrak{A}_0 \rightarrowtail \mathfrak{A}_1$, $\iota_2 : \mathfrak{A}_0 \rightarrowtail \mathfrak{A}_2$ there is a $\mathfrak{B} \in \mathcal{V}$ and embeddings $\varepsilon_1 : \mathfrak{A}_1 \to \mathfrak{B}$, $\varepsilon : \mathfrak{A}_2 \to \mathfrak{B}$ such that $\varepsilon_1 \circ \iota_1 = \varepsilon_2 \circ \iota_2$. $\mathcal{V}$ has the **superamalgamation property** if in addition to the above for every $a_1 \in A_1$ and $a_2 \in A_2$: (a) if $\varepsilon_1(a_1) \leq \varepsilon_2(a_2)$ then there is a $c \in A_0$ such that $a_1 \leq \iota_1(c)$ and $\iota_2(c) \leq a_2$ and (b) if $\varepsilon_1(a_1) \geq \varepsilon_2(a_2)$ then there is a $c \in A_0$ such that $a_1 \geq \iota_1(c)$ and $\iota_2(c) \geq a_2$.

$$\begin{tikzcd}
& \mathfrak{A}_1 \arrow[dr, dotted, "\varepsilon_1"] & \\
\mathfrak{A}_0 \arrow[ur, "\iota_1"] \arrow[dr, "\iota_2"'] & & \mathfrak{A}_3 \\
& \mathfrak{A}_2 \arrow[ur, dotted, "\varepsilon_2"'] &
\end{tikzcd} \tag{87}$$

THEOREM 93 (Maksimova). *Let L be a modal logic.*

1. L has local interpolation iff $\mathcal{V}(L)$ has the superamalgamation property.

2. L has global interpolation iff $\mathcal{V}(L)$ has the amalgamation property.

We sketch a proof of the second claim. Suppose that L has global interpolation, and let $\mathfrak{A}_0$, $\mathfrak{A}_1$ and $\mathfrak{A}_2$ plus two embeddings be given. We define $\mathfrak{F}_i := \mathfrak{Fr}_L(A_i)$ and $\mathfrak{F}_3 := \mathfrak{Fr}_L(A_1 \cup A_2)$, where $\mathfrak{Fr}_L(X)$ denotes the algebra freely generated by X in the variety of L-algebras. The embeddings form a commuting square as in (87). The identity map induces a surjective homomorphism $\pi_i : \mathfrak{F}_i \twoheadrightarrow \mathfrak{A}_i$. For $i = 1, 2$ put $T_i := \{\varphi : \pi_i(\varphi) = 1\}$. Let $T := \{\chi : T_1 \cup T_2 \Vdash_L \chi\}$. Then the following holds for $\varphi \in F_1$, $\psi \in F_2$:

$$(88) \qquad T \Vdash_L \varphi \to \psi \quad \Leftrightarrow \quad (\exists \chi \in F_0)(\varphi \to \chi \in T_1 \text{ and } \chi \to \psi \in T_2)$$

For if $T \Vdash_L \varphi \to \psi$ then there are finite $\Gamma_i \subseteq T_i$ and a compound modality such that $\boxplus\Gamma_1; \boxplus\Gamma_2 \vdash_L \varphi \to \psi$, giving $\Gamma_1; \varphi \Vdash_L \boxplus\Gamma_2 \to \psi$. There is an interpolant $\chi \in F_0$, from which we deduce $\varphi \to \chi \in T_1$ and $\chi \to \psi \in T_2$.

Put $\varphi \,\Theta\, \psi$ iff $T \Vdash_L \varphi \leftrightarrow \psi$. This is a congruence on $\mathfrak{F}_3$ and we put $\mathfrak{A}_3 := \mathfrak{F}_3/\Theta$. Using the above property it is shown that for $i = 1, 2$ and $\varphi \in F_i$: $\varphi \,\Theta\, \top$ implies $\varphi \in T_i$. So, the natural map $\mathfrak{F}_i \twoheadrightarrow \mathfrak{A}_3$ factors through π_i, giving a map $\varepsilon_i : \mathfrak{A}_i \to \mathfrak{A}_3$ with the desired properties.

Conversely, assume that $\mathcal{V}(L)$ has the amalgamation property. Let $\varphi = \varphi(\vec{p}, \vec{r})$ and $\psi = \psi(\vec{r}, \vec{q})$ be given such that no global interpolant exists. We shall show that $\varphi \nVdash_L \psi$. Let $\mathfrak{F}_0 := \mathfrak{Fr}_L(\vec{r})$, $\mathfrak{F}_1 := \mathfrak{Fr}_L(\vec{p}, \vec{r})$, $\mathfrak{F}_2 := \mathfrak{Fr}_L(\vec{q}, \vec{r})$, and $\mathfrak{F}_3 := \mathfrak{Fr}_L(\vec{p}, \vec{q}, \vec{r})$. Let O_1 be an open filter in $\mathfrak{F}_1$ containing φ and O_2 an open filter containing $\neg\psi$ and $O_1 \cap F_0$. Then $O_3 := O_2 \cap F_0 = O_1 \cap F_0$. Let Θ_i be the congruence associated with O_i, $\mathfrak{A}_i := \mathfrak{F}_i/\Theta_i$. Then for all $\chi, \chi' \in F_0$, $\chi \,\Theta_1\, \chi'$ iff $\chi \,\Theta_2\, \chi'$. So we have embeddings $\iota_i : \mathfrak{A}_0 \rightarrowtail \mathfrak{A}_i$. Now we get an algebra $\mathfrak{B}$ and maps $\varepsilon_i : \mathfrak{F}_i \to \mathfrak{B}$ such that $\varepsilon_1 \circ \iota_1 = \varepsilon_2 \circ \iota_2$. Define v by $v(p) := \varepsilon_1([p]\Theta_1)$ if $p \in \mathrm{var}(\varphi)$ and $v(p) := \varepsilon_2([p]\Theta_2)$ if $p \in \mathrm{var}(\psi)$. Since $\varphi \in O_1$, $v(\boxplus\varphi) = 1$ for all compound modalities. Since $\overline{v}(\neg\psi) \neq 1$, $\varphi \nVdash_L \psi$.

We remark here that the proof established that the category of L-algebras has pushouts for monomorphisms.

THEOREM 94 (Maksimova). *There are exactly seven consistent logics containing* **Grz** *which have interpolation. There are at most 50 consistent logics containing* **S4** *which have global interpolation and at most 37 logics having interpolation.*

The first result is from [42], the second from [43]. We sketch a proof, restricting our attention to global interpolation. The first step is to notice that if a modal logic L has interpolation, then so does the intermediate logic determined by this class of frames (under the Gödel translation). Notice the following. For a (general) frame $\mathfrak{F}$, define the skeleton $S(\mathfrak{F})$ by reducing every cluster to size 1. If $L \supseteq$ **S4** is determined by the class $\mathcal{K}$ of general frames, then the intermediate logic associated with it is determined by the class $\{S(\mathfrak{F}) : \mathfrak{F} \in \mathcal{K}\}$. It is not hard to see that if $\mathcal{K}$ has amalgamation then so does $S(\mathcal{K})$. Therefore, the first step is to characterize the intermediate logics which have interpolation.

It is best to use the dual characterisation in terms of frames: a necessary condition for a logic to have global interpolation is that if $p_1 : \mathfrak{F}_1 \to \mathfrak{F}_0$ and $p_2 : \mathfrak{F}_2 \to \mathfrak{F}_0$ are surjective p-morphisms of L-frames there is an L-frame $\mathfrak{G}$ and p-morphisms $q_1 : \mathfrak{G} \to \mathfrak{F}_1$ and $q_2 : \mathfrak{G} \to \mathfrak{F}_2$ such that $p_1 \circ q_1 = p_2 \circ q_2$. Call $\mathfrak{G}$ a **fibred product** of the $\mathfrak{F}_i$. Now suppose that the logic contains only frames of depth $\leq n$, where $n > 2$, and that it contains the chain of length n, which is the frame $\mathfrak{L}_n = \langle \{x_i : i < n\}, \lhd \rangle$ with $x_i \lhd x_j$ iff $i \leq j$. Now define two maps: $p_1(x_i) = x_i$ if $i < n-1$ and $p_1(x_{n-1}) = x_{n-2}$; $p_2(x_i) = x_{i-1}$ if $i > 0$, and $p_2(0) = x_0$. It is easily seen that there is no fibred product $\mathfrak{G}$ of depth n; there only is one of depth $n + 1$. This observation leads to the following result.

Table 1. Intermediate Logics with Interpolation

Name	Axiomatisation	Characteristic Frames
Int		all **Grz**-frames
LC	$(p \to q) \vee (q \to p)$	all linear frames
$\mathbf{BD}_2$	$p \vee (p \to (q \vee \neg q))$	all frames of depth 2
KC	$\neg p \vee \neg\neg p$	all confluent frames
$\mathbf{BD}_2.\mathbf{BW}_2$	$p \vee (p \to (q \vee \neg q))$, $(p \to q) \vee (q \to p) \vee (p \leftrightarrow \neg q)$	$\mathfrak{B}_2$
$\mathbf{LC}_2$	$\neg p \vee \neg\neg p, p \vee (p \to (q \vee \neg q))$	the two element chain
PC	$p \vee \neg p$	the one element frame
Inc	p	no frames

LEMMA 95. *Let $L \supseteq$ **S4** have global interpolation. If $\mathfrak{L}_3$ is an L-frame, then every $\mathfrak{L}_n$, $n \in \omega$, is an L-frame.*

Notice that every frame of depth n can be mapped onto $\mathfrak{L}_n$, so that if L contains a frame of depth at least 3, it has frames of any given depth. This can be generalized. Let $\mathfrak{F} = \langle F, \lhd \rangle$ and $\mathfrak{G} = \langle G, \blacktriangleleft \rangle$ be frames with $F \cap G = \varnothing$; then let $\mathfrak{F} \oslash \mathfrak{G} := \langle F \cup G, \prec \rangle$, where $x \prec y$ iff (a) $x, y \in F$ and $x \lhd y$ or (b) $x \in F$, $y \in G$ or (c) $x, y \in \mathfrak{G}$ and $x \blacktriangleleft y$. Further, let $\circ$ denote the one-element reflexive frame.

LEMMA 96. *Let $L \supseteq$ **S4** have global interpolation. If $\mathfrak{F} \oslash \circ \oslash \circ$ is an L-frame, then so is $\mathfrak{F}(\oslash\circ)^n \oslash \circ$ for every $n \in \omega$.*

Notice that for every frame, it is possible to collapse the points of depth j into a single point, if one is doing that for all $j < m$, m given. This means that the previous theorem restricts the set of logics with interpolation enormously.

Now we turn to branching. Let $\mathfrak{B}_n := \langle \{x_i : i < n+1\}, \lhd \rangle$, where $x_0 \lhd x_i$ for every $i < n+1$, and $x_i \lhd x_j$ iff $i = j$ when $i > 0$. Similarly, it is established that if L has interpolation and contains $\mathfrak{B}_3$ then it contains all $\mathfrak{B}_n$. A related result is that if L has a frame in which a node branches into 3 immediate successors, then it has unbounded branching. Finally, let $\mathfrak{K}_n := \langle \{y_i : i < n\} \cup \{x, z\}, \lhd \rangle$, where for all $i < n$ we have (a) $x \lhd x$, (b) $x \lhd z$, (c) $x \lhd y_i$, (d) for all $i, j < n$: $y_i \lhd y_i$, (e) for all $i < n$: $y_i \lhd z$ and (f) $z \lhd z$; and no other relations hold. First consider the p-morphisms $q_0, q_1 : \mathfrak{K}_2 \to \mathfrak{L}_3$ defined by $q_0(x) \neq q_0(y_1) \neq q_0(y_0) = q_0(z)$ and $q_1(x) \neq q_1(y_0) \neq q_1(y_1) = q_1(z)$. The fibred product is the frame $\mathfrak{K}_3$. Iterating this argument gives us that all $\mathfrak{K}_n$ must be L-frames. Next consider the p-morphisms $p_0, p_1 : \mathfrak{K}_2 \to \mathfrak{L}_2$ defined by $p_0(y_0) = p_0(y_1) = p_0(x) \neq p_0(z)$ and $p_1(x) \neq p_1(y_0) = p_1(y_1) = p_1(z)$. The fibred product is a frame of depth 3 which has the structure $\circ \oslash (\circ \oplus \circ \oplus \circ) \oslash (\circ \oplus \circ \oplus \circ) \oslash \circ$. This means that as soon as $\mathfrak{K}_2$ is an L-frame, more and more frames can be shown to be L-frames, so that we can eventually conclude that $L =$ **Int**.

These results shall suffice to motivate the result that at most 7 consistent intermediate logics have interpolation. They are listed in Table 1. Now we turn to **S4**. We repeat the strategy with the clusters. Let $\mathfrak{Cl}_n = \langle \{x_i : i < n\}, \lhd \rangle$ with $x_i \lhd x_j$ for all $i, j < n$ be the n-element cluster. It can be shown that if a logic has a frame with a final 3-element cluster, then it has final clusters of arbitrary size. Similarly for nonfinal clusters. Now let $\mathcal{K}$ be a class of **Grz**-frames that has superamalgamation. Then we can derive the

following nine possibilities for classes of **S4**-frames: (a) allow the final clusters to be of size 1, 2 or limitless, (b) allow the nonfinal clusters to be of size 1, 2 or limitless. Applied to any of the 7 consistent logics we derive a maximum of 63 combinations of logics that have global interpolation. Some of these combinations are meaningless (for example, allowing the nonfinal clusters for **PC** to be proper), so that the list can be further reduced.

The notion of Halldén-completeness also splits into a local and a global version.

DEFINITION 97. A modal logic L is **locally Halldén-complete** if $\vdash_L$ is Halldén-complete; L is **globally Halldén-complete** if $\Vdash_L$ is Halldén-complete.

Global Halldén-completeness is also called the **pseudo relevance property**. The following is clear: if L is locally or globally Halldén-complete, it has up to equivalence at most two constants. For let φ be constant. $\varphi \vdash_L \varphi$, which by Halldén-completeness yields that φ is either inconsistent or a tautology. L has at most two constants iff $\Diamond\top \in L$ (iff $L \supseteq \mathbf{K.D}$) or $\Box\bot \in L$ (iff L is inconsistent or the logic of the one point irreflexive frame).

DEFINITION 98. A variety $\mathcal{V}$ of modal algebras has **fusion** if for every pair $\mathfrak{A}_1, \mathfrak{A}_2 \in \mathcal{V}$ there is a $\mathfrak{B} \in \mathcal{V}$ and embeddings $\varepsilon_1 : \mathfrak{A}_1 \to \mathfrak{B}$, $\varepsilon_2 : \mathfrak{A}_2 \to \mathfrak{B}$. $\mathcal{V}$ has **superfusion** if in addition to the above for every $a \in A_1 - \{0\}$ and every $b \in A_2 - \{1\}$ we have $\varepsilon_1(a) \nleq \varepsilon_2(b)$.

It is not hard to see that $\mathcal{V}(L)$ has fusion iff it has finite coproducts.

THEOREM 99 (Maksimova). *Let L be a modal logic.*

1. *L is locally Halldén-complete iff $\mathcal{V}$ has superfusion and the zero-generated algebras has at most two elements.*

2. *L is globally Halldén-complete iff $\mathcal{V}$ has fusion and the zero-generated algebras has at most two elements.*

The proof is essentially the same as in the case of interpolation. For the algebra $\mathfrak{Fr}_L(0)$ consists of two elements. For given two algebras $\mathfrak{A}_1$ and $\mathfrak{A}_2$, if they are nontrivial there are maps $\iota_i : \mathfrak{Fr}_L(0) \rightarrowtail \mathfrak{A}_i$. Using the same proof we obtain an algebra $\mathfrak{B}$ and embeddings $\varepsilon_i : \mathfrak{A}_i \rightarrowtail \mathfrak{B}$ such that $\varepsilon_1 \circ \iota_1 = \varepsilon_2 \circ \iota_2$.

5.2 Proving Interpolation

Besides the algebraic characterisation there are at least two other methods to prove interpolation. The first is based on tableau calculi and is basically due to [52]. This method can only be used if the tableau rules meet certain structural criteria. We show here only the case of **K**. Given a tableau calculus for L we do the following. Suppose that $\varphi \vdash_L \psi$. Then $\varphi; \neg\psi$ is L-inconsistent. So it has a closing tableau. We label the formulae in the tableau ^{a} if they derive from the formula φ, and ^{c} if they derive from $\neg\psi$. (If χ is a subformula of both, we create two copies of χ, namely χ^a and χ^c.) From the closing tableau we construct *two* closing tableaux, one for $\varphi^a; (\neg\chi)^c$, and one for $\chi^a; \neg\psi^c$. Moreover, χ will be based on the common variables of φ and ψ. This gives $\varphi \vdash_L \chi$ and

$\chi \vdash_L \psi$. Here is the calculus.

$$
(89) \qquad
\begin{array}{llll}
(w) & \dfrac{\Delta; \Sigma}{\Delta} & (\neg E) & \dfrac{\Delta; \neg\neg\varphi}{\Delta; \varphi} \\
(\wedge E) & \dfrac{\Delta; \varphi \wedge \psi}{\Delta; \varphi; \psi} & (\vee E) & \dfrac{\Delta; \neg(\varphi \wedge \psi)}{\Delta; \neg\varphi \mid \Delta; \neg\psi} \\
(\Box E) & \dfrac{\Box\Delta; \neg\Box\varphi}{\Delta; \neg\varphi} & &
\end{array}
$$

A **K-tableau** is a tree $\mathcal{C}$ constructed according to these rules. $\mathcal{C}$ **closes** if all leaves are of the form $\bot$ or $p; \neg p$, p a variable. Suppose $\mathcal{C}$ closes. The construction of the interpolant is bottom up. We show: *If $\Delta^a; \Sigma^c$ has a closed tableau there is a formula χ such that $\Delta^a; (\neg\chi)^c$ and $\Sigma^c; \chi^a$ both have a closed tableau.* The proof is by induction on the length of a closing tableau for $\Delta^a; \Sigma^c$. χ will be an interpolant for the sequent $\Delta \vdash \neg\Sigma$, where $\neg\Sigma$ is read disjunctively.

There are in total six cases for the leaves. (1) $p^a; (\neg p)^a$, (2) $p^a; (\neg p)^c$, (3) $(\neg p)^a; p^c$, (4) $p^c; (\neg p)^c$, (5) $\bot^a$ and (6) $\bot^c$. In Case (1), choose $\chi := \bot$, and the first tableau will end in $p^a; (\neg p)^a; (\neg\bot)^c$, the second in $\bot^a$. In Case (2), choose $\chi := p$. The first tableau will consist in $p^a; (\neg p)^c$, the second in $(\neg p)^c; p^a$. The Cases (3) and (4) are dual to (1) and (2). In Case (5), let $\chi := \bot$, in Case (6) $\chi := \neg\bot$. Now, suppose that the last step has been an application of $(\Box E)$. With labeling, the step is one of the following.

$$
(90) \qquad \frac{(\Box\Delta)^a; (\Box\Sigma)^c; (\neg\Box\varphi)^a}{\Delta^a; \Sigma^c; (\neg\varphi)^a} \qquad \frac{(\Box\Delta)^a; (\Box\Sigma)^c; (\neg\Box\varphi)^c}{\Delta^a; \Sigma^c; (\neg\varphi)^c}
$$

We deal first with the left hand case. By inductive hypothesis there is a closing tableau for $\Delta^a; (\neg\varphi)^a; (\neg\chi)^c$ and a closing tableau for $\chi^a; \Sigma^c$. The following steps are now valid.

$$
(91) \qquad \frac{(\Box\Delta)^a; (\neg\Box\varphi)^a; (\Box\neg\chi)^c}{\Delta^a; (\neg\varphi)^a; (\neg\chi)^c} \qquad \frac{(\Box\Sigma)^c; (\neg\Box\neg\chi)^a}{\Sigma^c; \chi^a}
$$

The desired interpolant is $\neg\Box\neg\chi$.

Now we look at the right hand case. By inductive hypothesis there is a formula χ in the common variables and a closing tableau for $\Sigma^c; (\neg\varphi)^c; \chi^a$ and one for $\Delta^a; (\neg\chi)^c$. Now look at the following tableaux.

$$
(92) \qquad \frac{(\Box\Delta)^a; (\neg\Box\chi)^c}{\Delta^a; (\neg\chi)^c} \qquad \frac{(\Box\Sigma)^c; (\Box\chi)^a; (\neg\Box\varphi)^c}{\Sigma^c; \chi^a; (\neg\varphi)^c}
$$

So, $\Box\chi$ is the desired interpolant. The other induction cases are dealt with similarly.

For extensions of **K** the tableau methods have proved not so useful. The criterion of [52] is not so easy to apply. Here is another method. Call a function X from sets of formulae to sets of formulae a **local reduction function** from logic L to logic M if the following holds for all Δ and φ:

1. $X(\Delta) \subseteq L$.
2. If Δ is finite, so is $X(\Delta)$.
3. $\mathrm{var}(X(\Delta)) \subseteq \mathrm{var}(\Delta)$.

4. $\Delta \vdash_L \varphi$ iff $\Delta; X(\Delta; \varphi) \vdash_M \varphi$.

A **global reduction function** satisfies the same conditions, with Condition 4 replaced by

(93) $\quad \Delta \Vdash_L \varphi$ iff $\Delta; X(\Delta; \varphi) \Vdash_M \varphi$

The following are global reduction functions to **K**. (For a correct formulation, we assume that the primitive function symbols are $\top$, $\wedge$, $\neg$, and $\Box$. All other symbols are abbreviations. $\mathrm{sf}(\Delta)$ denotes the set of subformulae of formulae from Δ.)

(94) $\quad X_{\mathbf{4}}(\Delta) := \{\Box\chi \to \Box\Box\chi : \Box\chi \in \mathrm{sf}(\Delta)\}$

(95) $\quad X_{\mathbf{T}}(\Delta) := \{\Box\chi \to \chi : \Box\chi \in \mathrm{sf}(\Delta)\}$

(96) $\quad X_{\mathbf{B}}(\Delta) := \{\neg\chi \to \Box\neg\Box\chi : \Box\chi \in \mathrm{sf}(\Delta)\}$

(97) $\quad X_{\mathbf{alt_1}}(\Delta) := \{\neg\Box\chi \to \Box\neg\chi : \Box\chi \in \mathrm{sf}(\Delta)\}$

It is easy to see that reduction functions always exist if $M \subseteq L$. For let $X(\Delta) \subseteq L$. Then from $\Delta; X(\Delta; \varphi) \vdash_M \varphi$ follows $\Delta \vdash_L \varphi$. Conversely, if $\Delta \vdash_L \varphi$, there is a finite proof of φ from Δ. It involves a set $T(\Delta; \varphi)$ of finitely many axioms of L, all of which use only variables from Δ. (To see this, take any proof of φ. If the proof contains a variable q not occurring in φ, replace it uniformly throughout the proof by $\top$. This transforms the proof into a new proof not containing q.) Let $X(\Delta)$ be the union of all these sets $T(\Delta'; \varphi)$ such that $\Delta'; \varphi = \Delta$. This is a reduction function from M to L.

Observe that if X is a local reduction function, then it is also a global reduction function. And if X is a global reduction function, there is a function p from sets of formulae to natural numbers such that $Y(\Delta) := \Box^{\leq p(\Delta)} X(\Delta)$ is a local reduction function. And if Y is a local reduction function, X is a global reduction function.

DEFINITION 100. A reduction function X **splits** if $X(\varphi \to \psi) = X(\varphi) \cup X(\psi)$.

THEOREM 101 (Kracht). *Suppose that there is a splitting global reduction function from L to M. If M has local (global) interpolation, then so does L. If M is locally (globally) Halldén-complete, so is L.*

Proof. Suppose that $\varphi \vdash_L \psi$. Then $\vdash_L \varphi \to \psi$ and so $\Vdash_L \varphi \to \psi$. Hence $X(\varphi \to \psi) \Vdash_M \varphi \to \psi$, and by assumption on X, $X(\varphi); X(\psi) \Vdash_M \varphi \to \psi$. There is a compound modality $\boxplus$ such that $\boxplus X(\varphi); \boxplus X(\psi) \vdash_M \varphi \to \psi$, from which $\boxplus X(\varphi); \varphi \vdash_L (\bigwedge \boxplus X(\psi)) \to \psi$. We have $\mathrm{var}(\boxplus X(\varphi); \varphi) = \mathrm{var}(\varphi)$ and $\mathrm{var}(\boxplus X(\psi) \to \psi) = \mathrm{var}(\psi)$. L has local interpolation, so there is a χ in the joint variables of φ and ψ such that

(98) $\quad \boxplus X(\varphi); \varphi \vdash_M \chi \vdash_M (\bigwedge \boxplus X(\psi)) \to \psi$

From this follows $\varphi \vdash_L \chi \vdash_L \psi$. The proof of global interpolation is similar. Likewise for Halldén-completeness. ❑

The following general result holds (analogous theorems hold for the other functions shown in (94) – (97) with respect to transitive closure (for $X_{\mathbf{4}}$) and reflexive closure (for $X_{\mathbf{T}}$)).

THEOREM 102. *Let L be a complete logic whose class of frames is closed under symmetric closure. Then $L.\mathbf{B}$ is complete for symmetric L-frames. If L has the finite model property, so does $L.\mathbf{B}$. If L has interpolation, so does $L.\mathbf{B}$.*

Proof. Assume that $\Delta \vdash_{L.\mathbf{B}} \varphi$. Put $n := \mathrm{dp}(\Delta;\varphi)$. We show that

$$\Delta; \Box^{\leq n} X_{\mathbf{B}}(\Delta;\varphi) \vdash_L \varphi \tag{99}$$

(In other words, we show that $Y_{\mathbf{B}}(\Delta) := \Box^{\leq \mathrm{dp}(\Delta)} X_{\mathbf{B}}(\Delta)$ is a local reduction function from $L.\mathbf{B}$ to L.) Clearly, if (99) holds, we have $\Delta \vdash_{L.\mathbf{B}} \varphi$. Assume that it fails. Then there is an L-frame $\langle F, \lhd\rangle$ and a model

$$\langle F, \lhd, \beta, x\rangle \vDash \Delta; \Box^{\leq n} X_{\mathbf{B}}(\Delta;\varphi); \neg\varphi \tag{100}$$

Let $\blacktriangleleft$ denote the symmetric closure of $\lhd$. Then $\langle F, \blacktriangleleft\rangle$ is an $L.\mathbf{B}$-frame, by assumption. We claim that for every $\chi \in \mathrm{sf}(\Delta;\varphi)$ and every y accessible in at most $n - \mathrm{dp}(\chi)$ steps from x using $\lhd$ (or in fact $\blacktriangleleft$):

$$\langle F, \blacktriangleleft, \beta, y\rangle \vDash \chi \quad \Leftrightarrow \quad \langle F, \lhd, \beta, y\rangle \vDash \chi \tag{101}$$

The only critical step is $\chi = \Box\chi'$. ($\Rightarrow$) is clear. ($\Leftarrow$). Suppose that we have $\langle F, \blacktriangleleft, \beta, y\rangle \vDash \neg\Box\chi'$. Then there is a z such that $y \blacktriangleleft z$ and $\langle F, \blacktriangleleft, \beta, z\rangle \vDash \neg\chi'$. (1) $y \lhd z$. Then the induction hypothesis yields $\langle F, \lhd, \beta, z\rangle \vDash \neg\chi'$, and the claim follows. (2) $y \ntriangleleft z$. Then $z \lhd y$. Moreover, $\langle F, \lhd, \beta, z\rangle \vDash \neg\chi' \to \Box\neg\Box\chi'$, and so $\langle F, \lhd, \beta, y\rangle \vDash \neg\Box\chi'$.

Finite model property is easy; for interpolation just observe that the global reduction function is splitting. ❑

Notice that it follows that any combination of symmetry, transitivity and reflexivity is covered by these theorems. This can be generalized to polymodal logics. Finally, observe that all the reduction functions split.

THEOREM 103 (Kracht). *Let L be a polymodal logic characterized by any combination of reflexivity, symmetry and transitivity for any of the modal operators. Then L has the finite model property and interpolation.*

This covers among other **K4** and **S4** and fusions thereof. Similarly, passing from a monomodal logic to its minimal tense extension preserves interpolation if the logic is complete. For $\mathbf{alt_1}$ one needs to assume that L is a subframe logic.

Using similar techniques, one can show the following.

THEOREM 104. *Let $L \supseteq \mathbf{K4}$ be a subframe logic with interpolation. Then $L.\mathbf{G}$ and $L.\mathbf{Grz}$ are subframe logics which have interpolation.*

Finally, one can also prove the following observation.

PROPOSITION 105 (Rautenberg). *Let χ be a constant formula. Then if L has local (global) interpolation, so does $L \oplus \chi$.*

5.3 Beth Properties

As is known from predicate logic, interpolation is related to the Beth-property. However, in modal logic the relationship is somewhat more complex.

DEFINITION 106. L has the **local Beth-property** if the following holds. Suppose that $\varphi(p, \vec{q})$ is a formula and

$$\varphi(p,\vec{q}); \varphi(r,\vec{q}) \vdash_L p \leftrightarrow r \tag{102}$$

Then there exists a formula $\chi(\vec{q})$ such that

(103) $\varphi(p, \vec{q}) \vdash_L p \leftrightarrow \chi(\vec{q})$

If (102) is satisfied, $\varphi(p, \vec{q})$ is called a **local implicit definition** of p. If $\chi(\vec{q})$ satisfies (103), it is called the **corresponding explicit definition** of p.

There is a stronger property, the **local projective Beth property**. Here it is required that if

(104) $\varphi(p, \vec{q}, \vec{r}_1); \varphi(p', \vec{q}, \vec{r}_2) \vdash_L p \leftrightarrow p'$

there exists a formula $\chi(\vec{q})$ such that

(105) $\varphi(p, \vec{q}, \vec{r}_1) \vdash_L p \leftrightarrow \chi(\vec{q})$

The global notions are defined similarly. Notice that a local implicit definition is also a global implicit definition. Hence if L has the local Beth-property it also has the global Beth-property.

THEOREM 107 (Maksimova). *A classical modal logic has local interpolation iff it has the local Beth property.*

PROPOSITION 108 (Maksimova). *Let L be a classical modal logic. If L has interpolation then it has the global Beth-property.*

The logic **G.3** has the global Beth-property but fails to have global interpolation. The logic $\mathbf{S4.1.2} \cap \mathbf{S5}$ has the global projective Beth-property but fails to have interpolation ([44]).

5.4 Fixed Point Theorems

A rather different property is shown by logics above **G**. Say that a formula $\psi(\vec{q})$ is a **fixed point** of $\varphi(p, \vec{q})$ for p in L if

(106) $\vdash_L \psi(\vec{q}) \leftrightarrow \varphi(\psi(\vec{q}), \vec{q})$

If a logic has fixed points for all formulae $\varphi(p, \vec{q})$ where p only occurs inside the scope of a $\Box$ (or $\Diamond$) then the logic is said to have the **fixed point property**. It is clear that if $L \subseteq M$ then if $\psi(\vec{q})$ is a fixed point for $\varphi(p, \vec{q})$ for p in L it is one in M, too. The following is known as the **fixed point theorem**.

THEOREM 109 (Sambin, de Jongh). *Suppose that $\varphi(p, \vec{q})$ is a formula in which every occurrence of p is in the scope of a box. Then $\varphi(p, \vec{q})$ has a fixed point for p in* **G**.

Proof. The conditions on $\varphi(p, \vec{q})$ imply that on any finite **G**-frame, the valuation for p is fixed by that for $\vec{q}$. So, $\varphi(p, \vec{q})$ globally implicitly defines p. **G** has local interpolation and so the global Beth property, whence $\psi(\vec{q})$ exists. ❑
